Typical two-pipe radiator connections are shown in Figs. 54 and 55. While these show top inlet supply connections which are preferred, it is also possible to connect the supply to the bottom of the radiator. Short radiators may be connected with top supply and bottom return on the same end.

A typical method of connecting convectors is shown in Fig. 56. Sometimes the supply valve is omitted on convector connections, and a damper is supplied in the outlet grille for heat control.

A typical connection for finned pipe convectors is shown in Fig. 57.

Typical connections to blast heaters are shown in Figs. 58, 59, and 60. Fig. 61 shows a typical return and connection for blast heaters connected to high-pressure systems.

A typical two-pipe connection to a unit heater is indicated in Fig. 62.

CONTROL VALVES

Gate valves are recommended in all cases where service demands that the valve be either entirely open or entirely closed, but they should never be used for throttling. Angle globe valves and straight globe valves should be used for throttling in such cases as bypasses around pressure-reducing valves or on bypasses around traps.

CHAPTER 27

DISTRICT HEATING

Steam Requirements, Boiler Plants, Steam Distribution, Design Considerations, Distribution Pressures, Pipe Sizes, Conduits for Piping, Manholes and Tunnels, Accessory Equipment, Insulation, Return of Condensate, Building Piping and Equipment, Metering, Hot Water Distribution

THE term *district heating* refers to the supplying of heat from a central plant to a group of buildings in a city, institution, housing development, or industrial or commercial area. The heat may be used for any applicable purpose such as space heating, air conditioning, or processing. It is usually preferable that groups of commercial, industrial, or institutional buildings be supplied with heat from a central plant rather than from individual plants in order to permit design for better combustion efficiency with less expensive fuel, and reduction of labor per unit of output. The central plant justifies use of more competent personnel, and often decreases the investment required.

Those phases of district heating which frequently fall within the province of the heating engineer are treated here, and information is given for solving incidental problems. Some data are included with reference to special requirements for steam piping in buildings served with district steam. The data are confined principally to the use of steam as the heating medium, but the use of hot water has gained some recognition in recent years.[1]

In the design of a district heating system to provide public utility service in a city, it is advantageous to make a thorough study of the entire problem with competent men having experience in both design and operation of such systems.

STEAM REQUIREMENTS

The first step in the design of a district heating system is to determine the maximum hourly and the annual steam requirements of each of the buildings to be supplied. Methods of determining the maximum *hourly* requirements will be found for space heating in Chapter 12, for building service-water heating in Chapter 56, and for various process applications in Table 1.[2] Measured demands of several types of buildings are given in Table 9, Chapter 37.

Methods of estimating *annual* steam requirements for heating various types of buildings are also given in Chapter 37. Table 7 in Chapter 37 lists the average annual steam consumption per degree-day for buildings located in all sections of the United States. Annual steam requirements for building service-water heating are given in Table 2 of this chapter. Additional data on annual steam requirements, including those for process uses and air conditioning, of various types of buildings in a number of cities may be found in the *District Heating Handbook*, Third Edition.[3]

BOILER PLANTS

In the design of a plant for district heating, consideration should be given to the following factors:

1. *Annual load factor.* This factor is the ratio of the average hourly plant send-out (defined as rate of flow to the distribution system) to the maximum hourly send-out, which is a direct measure of the extent to which investment in facilities is used. It is often employed to determine savings by equipment offering higher efficiency. The load factor for space heating is usually between 15 and 30 percent. For space heating plus additional steam requirements such as water heating, cooking, or laundry, it is between 15 and 40 percent. Where process requirements predominate, as in factories, load factors are sometimes 50 percent or more. Load factors for various types of buildings are given in Table 9, Chapter 37.

2. *Duration of plant output.* The cumulative number of hours for the various plant send-outs and the predicted peak boiler demand on the coldest day are used in conjunction to determine the number and sizes of boilers, in order to effect most efficient loading of individual units and the plant as a whole. The cumulative number of hours a typical district heating plant will send out steam at various plant outputs, with outputs expressed in percentage of maximum hourly rate, is given in Table 3. It will be noted that the duration of plant output for the higher send-outs is very low.

3. *Feed-water treatment.* Good feed-water treatment is an absolute necessity in a plant in order to be able to operate the boilers at maximum outputs. Dirty tubes will limit boiler capacity. Proper feed-water treatment will prevent corrosion and scale formation and keep boiler outage to a minimum.

4. *Smoke abatement.* This is a modern requirement. The installation of suitable fuel-burning and dust-collecting equipment to limit the emission of smoke and fly ash is usually necessary.

5. *Plant location.* A boiler plant location is determined by an economic study of fuel handling, water supply, system piping, land costs, and other associated factors. Such a study usually reveals that the economical location of the plant will be near the distribution center, in order to simplify and shorten the distribution piping. Plant location and the local air pollution ordinances will have a direct bearing on the type of firing equipment selected and the dust collection apparatus required.

STEAM DISTRIBUTION

Distribution piping in district heating systems must be designed in accordance with the same basic principles applying to any other steam piping. The piping may be run through buildings, through the air on poles or other structures, or underground in conduits or tunnels. Local conditions and investment will be governing factors in establishing the route of the pipes.

Design Considerations

Important points in laying out distribution piping are:

1. Piping within buildings or basements is normally least expensive to install and to maintain.

2. Underground installations involve excavation which represents a substantial portion of the total cost. The depth of such excavations should be kept to a minimum after due consideration has been given to the possible damaging effect of the operating-line heat on lawns and shrubbery and the possible damage to the underground structure due to heavy traffic, etc.

3. Walking tunnels usually are not provided for steam mains

Table 1 .... Unit Steam Consumption of Process Equipment[a]

Kitchen Appliances (exclusive of water heating)	Consumption,[b] Lb per Hr	Pressure, psig
Stock and vegetable kettles (per 5 gal)	20.0	7–20
Vegetable steamers (per compartment)	40.0	7–20
Steam tables (per sq ft)	1.7	7–20
Bain-Maries (per sq ft)	3.4	7–20
Coffee urns (per gal)	3.4	7–20
Water urns (per gal)	5.0	7–20
Soup warmers (30 x 30 x 28 in.)	100.0	7–20
Egg boilers (3 compartments)	18.0	7–20
Clam, lobster, and potato steamers (per compartment)	40.0	7–20
Oyster pots	18.0	7–20
Plate and cup warmers (per 20 cu ft)	35.0	7–20
Food-warming ovens (per 20 cu ft)	35.0	7–20
Silver burnisher and washers	69.0	7–20
Dishwashers (per tray)	60.0	7–20
Laundry Equipment		
Tumblers		
40 x 94 in.	360	100
30 x 36 in.	225	100
Washers, (per gal water heated)	1	15–100
Flatwork ironers,		
100 to 120 in. chest type (per roll)	60	100
50 to 100 in. cylinder type (per machine)	60–120	100
Standard presses	105	100
Large shirt body presses	190	100
Cuff and neckband presses	15	100

[b] These values represent approximate requirements after warm-up period.

in the district heating industry because of their relatively high first cost as compared with smaller conduits unless they are required to accommodate miscellaneous other services or to provide underground passage between buildings.

4. Overhead piping on poles or structures is generally less expensive than underground lines, especially in some institutional and industrial areas and may be a means of eliminating buried conduit in areas where underground installations would be expensive or undesirable. Thin corrugated aluminum sheets or asphalt-saturated asbestos felt are available for covering the insulation on lines exposed to the weather. Such lines may introduce freeze-up problems, higher heat losses and, in many locations, would be considered unsightly.

5. High-pressure transmission feeders may be employed where the plant is remote from the distribution area, or where it is desirable to augment the capacity of an existing system Design of such feeders and of distribution systems for various load conditions is covered fully in *District Heating Handbook*, 3rd Edition.[3]

6. Piping routed in loops with suitable valves to provide alternate feeds for major loads, allows service to be maintained despite trouble in any one feeder.[4]

7. It is desirable to estimate as far as possible the probable growth and change in load centers. Since character of the district served is almost certain to change with time the distribution system must be planned so that it can be adapted to accommodate changes. It is helpful to provide a master distribution plan which can be revised from time to time to suit conditions as the system grows.

Steam Distribution Pressure

The pressure at which the steam is to be distributed will depend upon that available at the plant and pressure requirements of apparatus to be served.[4]

The advantages of low-pressure distribution (2 to 50 psig) compared with high pressure are: (1) lower heat loss per square foot of pipe surface; (2) lower losses from leakage, trap discharge, and venting; (3) less trouble with traps and valves; (4) less trouble from flash steam at drainage points; (5) simplified problems in pressure reduction at the buildings; (6) suitability of standard fittings; and (7) general reduction in maintenance costs.

Some heating companies find that the overall losses in relation to steam delivery are higher with high-pressure distribution. With distribution pressures not exceeding 50 psig, there is less danger if the full distribution pressure should build up in the radiators or heaters through the faulty operation of pressure-regulating valves. With pressures higher than 50 psig, or the safe working pressure of heating or process equipment, a second pressure-reducing valve or some form of emergency relief is required to prevent excessive pressures in the radiators or other equipment.[4]

Pressure reducing valves are more fully described in Chapter 26 (Steam Heating Systems). The installation of reducing valves on district steam installations, however, may present specific problems that are not normally encountered in building steam heating applications. Utility companies in some instances must assume greater responsibilities in their operation and maintenance and are often under regulations that are different for various cities.

The advantages of high-pressure distribution are: (1) smaller pipe sizes; (2) availability of the steam for various other operations requiring higher pressures than the building heating system; and (3) wider flexibility in allowance for maximum pressure drop. Where distribution pressures are not as high as desired, higher pressures can be obtained by use of a steam compressor.[4]

It is sometimes desirable to install a separate high-pressure line from the boiler plant for steam supply to laundries or other high-pressure equipment rather than to operate the entire distribution system at higher pressures.

Pipe Sizes

In district heating work it is common practice to design the piping system on the basis of pressure drop. The initial pressure and the minimum permissible terminal pressure are specified, and the pipe sizes are so chosen that the required amount of steam, with suitable allowances for future increases, will be transmitted without exceeding this pressure drop. The steam velocity is therefore almost disregarded and may be very high. Velocities of 35,000 fpm are not considered high for pipes in conduits. Where pipes pass through buildings, however, consideration should be given to the possibility of objectionable noise due to high velocity. By the use of permissible pressure drops with high velocities, after allowance has been made for future increase in load, the pipe sizes may be kept to a minimum with consequent savings in investment. Some lines in a loop system may need to be increased in size in order to handle reverse-direction flow in emergencies.[4]

The steam flowing through any section of the piping can be computed from a study of the hourly steam requirements of the several buildings served. In this connection, allowance should be made for the diversity of the load, that is, the ratio of the coincident maximum demand of all of the group of buildings served by the main, to the sum of the individual maximum demands of each of the buildings served. This ratio is known as the Coincidence Factor and varies from 0.50 in some institutional groups to 0.90 in areas where loads are principally for heating and heat is turned on at about the same time each morning. Consideration should also be given to the net total load on a line, based on a study of the loads in the various buildings, in order to determine the relative merits of providing one or more separate supply lines to serve all-year loads. Such lines will permit turning off the mains that supply strictly seasonal space-heating loads during the summer months.

When lengths of pipe, steam quantities, and initial and terminal pressures have been chosen, the pipe sizes can be calculated by means of Figs. 22 to 26 of Chapter 26. The district-heating industry, however, uses *Unwin's* formula for *determining pipe sizes because pressure drops* can be determined simply and directly from a chart. This formula has been checked by tests, and found correct within ranges of velocity used in district heating. A convenient chart developed from this formula is available from the National District Heating Association.[7]

Conduits for Piping

Conduits for underground steam pipes are used to protect the pipe and insulation from external damage and to provide a space in which the pipe is free to expand or contract while held in proper alignment. The conduit should be constructed of non-corrosive materials, or, if of metallic content, should be suitably protected against corrosion. It must be of adequate strength to withstand the earth and traffic forces to which it will be subjected. The conduit should be reasonably waterproof and in many cases provision should be made to drain seepage from its inside. With any form of conduit unless it is actually below water level, provision should be made to completely exclude water or to carry away ground water and prevent it from collecting around the conduit. This is often accomplished by placing a layer of coarse gravel or stone underneath and partly surrounding the conduit with one or two lines of tile having open joints which serve to carry the water to a sewer or other suitable

Table 2 .... Annual Steam Consumption for Water Heating for Various Types of Buildings, per Cu Ft of Volume[a,b]

Type of Building	Consumption, Lb/(Yr) (Cu Ft)	Consumption Lb/(Yr) (Cu Ft) (100 F deg Temp. Rise of Water)
Hotel	3.20	2.66
Residence club	2.56	2.11
Apartment house	2.41	1.99
Department store	0.95	0.79
Office	0.85	0.71
Theater	0.57	0.48
Parking garage	0.46	0.38

Table 3 .... Load Duration for Typical District-Heating System

(Cumulative Hours of Plant Send-out per Year at Various Loads Expressed in Percent of Peak Hourly Load[a])

Plant Output % of Peak	Hours per Year	Plant Output % of Peak	Hours per Year
100	5	55	1800
95	40	50	2200
90	90	40	3100
85	150	30	4100
80	300	20	5150
75	500	15	5700
70	750	10	6400
65	1050	6	8760
60	1400		

[a] Based on curve on page 89, *District Heating Handbook*, Third Edition, 1951.
Note: A plant having a peak send-out of 100,000 lb per hr will send out 80,000 (80 percent of 100,000) lb per hr *or more* for 300 hr per yr.

outlet. Proper foundations should be provided to prevent settlement and to insure proper pitch of piping at all times.

Manholes may be required at intervals to provide access to valves, traps, and expansion joints. They should be drained. Some safe means of disposing of condensate from piping should be provided.

There are many types of conduits. They fall into six following general classifications: Box-type, Solid-pour, Prefabricated, Tile, Monolithic, Granular Fused, and Waterproof. Cross-sections of a few of the typical types are shown in Fig. 1.

Box-type conduits are typical of those built with common materials and have many variations. Conduit A, Fig. 1, shows a commonly used type in which a corrugated metal form is placed as an inverted U over the insulated pipe line installed on a concrete slab. The concrete may be reinforced or not, depending upon the load on the conduit. Drainage is provided by the drainage pockets filled with crushed stone or gravel and may be installed on either or both sides of the conduit. They conduct water from the top of the conduit to the drain below which is connected to the sewer or some other disposal facility. Variations of the concrete-box type have side walls constructed of hollow vitrified tile, concrete blocks, or other suitable materials, and covered with a reinforced concrete slab. The top and sides are sometimes covered with a waterproofing membrane of asphalt or hot pitch and roofing paper.

The solid-pour construction, Conduit B, Fig. 1, is also usually made with common materials and consists of poured structural concrete which is vibrated and tamped around a conventionally insulated steam line. If the insulation has a high compressive strength it can support the pipe, otherwise, the pipe should be supported independently. Reinforcing is sometimes used to prevent settlement. An eccentric space may be left around the pipe by using insulation larger than the outside diameter of the pipe to permit upward movement of the pipe during the warm-up periods. During construction, pipe is suspended by wires. Precautions should be taken to prevent the pipe from floating. The top of the conduit should be coated with asphalt emulsion or tar to help seal shrinkage cracks. Anchor stresses are higher with this type of construction. Variations of this type include enclosure of the pipe and insulation in tile, concrete, steel, or asbestos pipe and then pouring of concrete around outer pipe. This method provides space for pipe supports, if needed. External drainage can be provided by methods similar to the concrete box type construction.

Conduits constructed of common materials are often preferred by the district heating industry because of the conditions imposed in congested street beds, heavy traffic loads, and drainage conditions or because of the ease of opening and closing the conduit, for branch pipe connections.

Prefabricated conduits, C and D, Fig. 1, are commonly constructed in standard lengths. In some, as in C, the insulated pipe or pipes are placed within a corrosion-resistant helically-corrugated metal jacket which is protected with a heavy asphaltic coating. Similar casings are made of steel protected with an anti-corrosive compound. Both are of welded construction and can be tested under air pressure. In conduit D the insulated pipe is placed concentrically within the corrosion-resistant metal jacket and the intervening space between jacket and insulation poured full of high melting-point asphalt or left as an air space. In these conduits, the pipes are supported by precast rings or guides

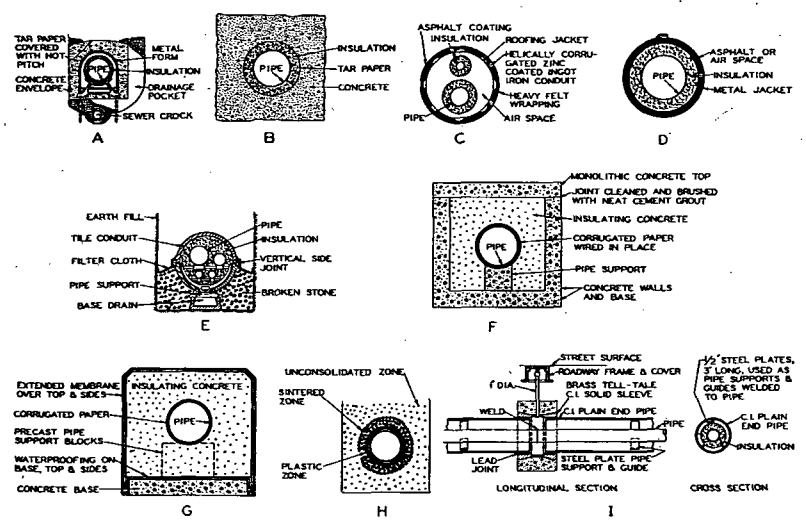

Fig. 1 . . . . A Few Typical Conduits for District Heating Use

to maintain alignment and to prevent pressure on insulation. Fittings are available for joints, bends, etc. Some of these conduits are also available with cast-iron casings.

Tile conduit E, Fig. 1, is constructed of specially-shaped glazed vitrified bell-and-spigot tile. In the conduit shown, the base drain is made in separate units and is designed to support the main conduit and pipe lines, and to drain the conduit. All joints are cemented. There are several types of tile conduits.

Monolithic conduits F and G, Fig. 1, are similar to the solid-pour type except that the insulation, referred to as insulating concrete, serves also as a conduit and is poured directly around the steam main. The insulation consists of expanded-mica, shredded-rubber or other cellular materials mixed with Portland cement or asphalt; or of a special foaming material mixed with Portland cement. The latter process creates a multitude of minute air cells in the concrete to obtain its insulating qualities. The poured structure is often protected by a water-proofing membrane and strengthened by a concrete duct.

Granular-fused type conduits such as H, Fig. 1, consist of a specially sized and selected granular bitumen which is poured in the trench around the pipes. The manufacturers advise that the conduit is formed when heat passing through the pipes forms three distinct concentric zones, all resistant to water penetration. A plastic area surrounds the pipe, outside of which is a sintered zone providing thermal insulation, and finally, an outer layer of unconsolidated particles providing further insulation value. This unconsolidated zone is also the load-bearing portion of the structure.

Waterproof conduits are intended for use where permanency and thoroughly tight joints are required. Some of the prefabricated conduits, C and D, Fig. 1, can be supplied with water-tight cast-iron casings and fittings. The casing shown in I, Fig. 1, consists of cast-iron pipe with lead-caulked joints enclosing the insulated steam main. It is water tight and intended for special applications, where, for instance the duct may be submerged, subject to flooding, or laid in extremely wet soil.

All of the preceding conduits have their application and the choice depends upon local conditions. Any underground conduit is only as good as, among other things, its foundations to prevent settlement, its external and internal drainage, its ability to stand up under the corrosive action of certain ground conditions (see Buried Pipe Lines, Chapter 55), its strength to carry the load imposed on it, its field installation, and its insulating properties.

Manholes

When conduits are used for underground piping, manholes may be required to house valves and other accessory equipment. They are built of a variety of materials such as reinforced concrete block. They should have adequate volume to permit men to work on equipment. They should be as nearly waterproof as possible and precaution should be taken to prevent entrance of surface water around the covers. Provision should be made for lifting necessary equipment from the pipe line, for drainage, for ventilation, and for automatic water-removal equipment if a sewer is not accessible.

Details of typical manhole construction housing a single expansion joint are shown in the *NDHA District Heating Handbook*, Third Edition, p. 164. If more equipment is installed, the size should be increased accordingly.

Where water removal equipment is required, sumps are installed under the manholes. Water can be removed periodically with portable pumps, or, where water conditions are bad or periodic inspection is not feasible, by installed sump pumps or water ejectors.

The motors for electric pumps should be enclosed in a separate compartment which is ventilated to protect it from heat and vapors. Precautions should be taken against corrosion as mentioned in the Section Piping and Accessory Equipment.

Piping Tunnels

Because of their relatively high first cost as compared with conduits, *walking tunnels* are usually not provided for steam mains unless, as in some institutions, they are required to accommodate miscellaneous other utility services or to provide underground passage between buildings.

Tunnels are usually built of reinforced concrete, brick, concrete blocks or other suitable structural materials, and are waterproofed on the outside. Provision for drainage and ventilation is essential.

Since tunnels and conduits are apt to be hot and humid, special precautions should be taken to reduce temperatures and protect equipment. Heat loss from pipes and supports can be reduced by insulating return mains and using more than normal insulation on steam mains. A metal jacket over the pipe covering can permit insulation to carry the weight of the pipe.[8]

The precautions on sizing, design, installation, and protection against corrosion, for accessory equipment, as discussed in the sections Piping and Accessory Equipment, and Conduits for Piping, should be taken for tunnels. Special precautions should be taken to prevent rapid deterioration of enclosed electrical conduit. All electrical boxes, junctions and outlets should be vapor proof. Ventilation of the tunnel can be obtained by installation of suitable fans or by natural means.

Piping and Accessory Equipment

A district heating distribution system is usually buried in the ground where it is not readily accessible for repairs or replacement. This makes it imperative that the system be carefully designed and installed. The *American Standard Code for Pressure Piping* ASA B-31.1—1955[9] has sections, covering district heating piping systems and fabrication details, from which general specifications and minimum requirements for piping and accessory equipment can be obtained.

Suggestions for selection and installation of materials based on long operating experience of the district heating industry are given in following paragraphs. More detailed information is available in the *District Heating Handbook*, Third Edition.[10]

Pipe. Either steel or wrought-iron pipe is satisfactory. Welded construction is most desirable.

Valves. Flanged cast-iron valves for pressures under 125 psig are satisfactory. For pressures from 125 to 300 psig flanged-steel and welded-end valves are used. Outside screw and yoke valves are preferred.

Fittings. Forged or rolled steel is used for pressures in excess of 125 psig. Where pipe-line apparatus is to be removable, flanged fittings are preferred.

Expansion Joints. Pipe bends to absorb expansion are preferable wherever feasible in order to eliminate the inspections, maintenance, and housing required by slip joints. Slip joints should be guided either externally or internally, or both. Corrugated-type joints should have stainless steel

or copper corrugations depending upon operating conditions. Spare expansion capacity should be allowed for contingencies such as higher pressures, superheat, and installation tolerances.

Anchors. Anchors can be of structural steel, special fittings, or U-shaped steel straps which partially encircle the pipes. Anchors should be firmly bolted or welded to a short length of cast or stainless steel set in concrete. Anchors are often fabricated by welding structural steel to pipe and embedding the ends in manhole walls or concrete poured in connection with conduit. Anchors are subject to humid conditions in conduits and manholes, and can deteriorate rapidly. They should be designed for adequate strength, intended life, and the steam pressure to which they can be subjected, with liberal factors of safety and protection from corrosion. Anchors should be attached to both sides of the pipe. Lugs should be welded to pipe on both sides of loop-type anchors to prevent slippage. The cantilever type of anchor should be avoided. Cast steel is preferred to cast iron for anchor material.

Alignment Guides. To assure pipe alignment and proper operation of expansion joints, pipes should be adequately guided. Special precautions should be taken if the pipe deviates from a straight line.

Pressure Reducing Valves. Suitable single-seated valves are preferable. The valves should be selected from the manufacturer's rating regardless of pipe size. Pressure gages are necessary at valve and control points. Valves require some auxiliary source of power for valve positioning, if they are to be controlled from a remote point to regulate terminal pressure. (See Chapter 26 for detailed recommendations regarding pressure reducing valves.)

Traps. To assure adequate drainage of piping, extra trap capacity and large drip pockets should be provided. Extra heavy or corrosion-resistant trap discharge piping is desirable. On steep grades or in high-velocity steam mains, special deflector scoops or baffles should be placed in the line to direct condensate into traps.[11]

Supports. Due to humid conditions in conduit and manholes, it is desirable to use stainless steel supports.

Instruments. The instruments required will be the same as for other steam systems as described in Chapter 43, Automatic Controls, or Chapter 44, Instruments and Measurements, with modifications depending on the records desired with regard to pressures and temperatures maintained or the records of response of the system to varying load demand.[12]

Branch Connections. Branch connections should be made at or near anchor points; if not, ample clearance must be provided around the branch to take care of pipe movement.

Insulation

Insulating materials constitute a primary element of district steam distribution structures and must be suitable for underground service. Insulation should be noncombustible, vermin-proof, moisture-resistant, durable, non-corrosive to steel pipe especially when wet, and able to retain its position in relation to the pipe line. It should be of a type which, if flooded, will dry out and regain its original physical, chemical and insulating properties. It should be relatively unaffected by such chemicals as are usually found in ground or other contaminated waters. It should have the lowest practical heat conductivity consistent with the given requirements.

Insulating properties vary with soil conditions, weather variations, types of conduits used, and, if in tunnels, the amount of ventilation. The selection of insulation to provide for the various conditions is covered in *District Heating Handbook*—Third Edition. Where underground insulation is applied directly to the pipe, copper wire is normally used to band the covering. Insulation may be poured as a monolithic structure in a suitable duct. Where insulation in an existing conduit has deteriorated the line may be reinsulated with a minimum amount of excavating by use of some of the materials used in monolithic conduits.[13] Insulation is discussed further in Chapter 32, and studies of heat loss from bare and insulated buried pipe are given in *District Heating Handbook*[14] and in *Piping Handbook*.[15]

RETURN OF CONDENSATE

If the condensate can be returned to the plant to be used for boiler feed water at an overall cost less than that required to process raw water, the installation of return lines parallel to the steam supply lines should be given consideration. A typical analysis of comparative costs of returning condensate and processing feed water is given in *District Heating Handbook*.[16]

Return of condensate by gravity is desirable, but usually because of terrain conditions or user's return facilities, the condensate is pumped back under pressure.

Pipes carrying condensate are more subject to corrosion than other parts of the system. Care must be taken to give proper pitch to the pipes and to provide proper venting of non-condensable gases. (See Chapter 55, Corrosion.)

BUILDING PIPING AND EQUIPMENT

There are certain fundamental principles that should be followed in the design of a building heating system which is to be supplied from district steam mains. Some of these are unique to district heating and some, although they may apply to any building have been demonstrated to be particularly important when district steam is used. District heating companies have certain regulations regarding the consumer's installation to safeguard the mutual interest of supplier and consumer and to insure satisfactory and economical service. When an installation is designed, local regulations and code requirements[17] should be observed.

Zoning. Where the hours of occupancy or heating loads differ in various sections of the building, it is good practice to install separate supply lines to the different sections. For example, in an office building with first floor stores or restaurants open in the evening, a separate main supplying the first floor will permit the steam to be shut off from the remainder of the building in the late afternoon. The division of the building into zones, each with a separately-controlled heat supply, is sometimes desirable, as it permits the heat to be adjusted according to variations in sunshine and wind. It is desirable, also, to provide separate lines for water heating and for various cooking or process appliances. In order that zones may operate at the optimum pressure, it is often advisable to install a separate pressure-regulating valve for each. See Fig. 29 of Chapter 26 for typical service installation with separate lines to heating zones and process equipment.

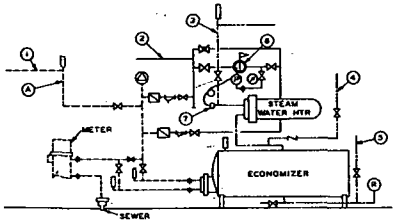
The heat supply should be graduated according to variations in the outdoor temperature. Because of the continuous availability and constant pressure of district steam, the most economical operation and satisfactory heating can only be obtained by the use of automatic temperature control which, except in unusual cases, is well justified. The application of control equipment in various types of build-

Table 4 .... Suggested Capacity of Traps

Type of Control	Trap Capacity, Lb/(Hr) (Sq Ft of Pipe and Radiation[a])
Continuous or modulating operation, intermittent with *on* periods over 3 hr in duration	⅓
Intermittent operation with *on* periods of ½ to 3 hr in duration	⅓
Intermittent operation with *on* periods of ½ hr or less	⅓[b]

[a] Square Feet EDR.
[b] Except for drip traps on mains which should be 1 lb per sq ft EDR.

ings is fully discussed in the book, *Principles of Economical Heating*.[18] Various types of control equipment are discussed in Chapter 43.



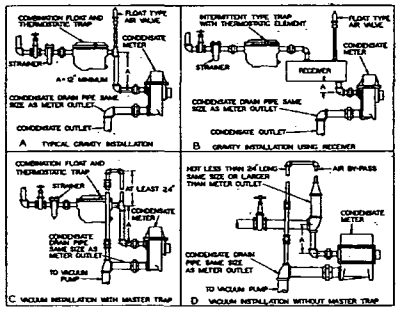
Rapid draining and venting of the heating system should be obtained by means of suitable traps and air vents in order to obtain rapid circulation and quick heating. This is particularly important with intermittent-type temperature-control equipment. The selection of traps is discussed in Chapter 26. Suggested trap capacities are given in Table 4 of this Chapter. To obtain efficient and economical operation of any system it is imperative that all traps be properly maintained. In a system supplied with district steam any leakage through traps may prevent air removal from the system and otherwise impair its operation. Furthermore, such steam must be condensed and its condensate cooled before being discharged to sewer. This represents a direct waste of steam.

Provision should be made for conveniently shutting off the steam supply at night and at other times when heat is not needed. A considerable amount of heat can be saved by shutting off steam at night and other times when optimum building temperatures are not required.[19] Equipment is available which will automatically shut heat off at night for varying lengths of time, depending upon outdoor temperature.[20]

Residual heat in the condensate should be salvaged. This heat may be salvaged by means of an air-cooling coil, or as is more frequently done, by a water-heating economizer, shown in Fig. 2, which preheats the hot water supply to the building.[21]

The condensate from the heating system, after leaving the traps, passes through the economizer. The water supply to the heater passes through the economizer, absorbing heat from the condensate. If the hot-water system in the building is of the recirculating type, the recirculating line should be connected *between* the economizer and the water heater proper, not at the economizer inlet, because the recirculated hot water is itself at a high temperature.

Since the heating-system load and the hot-water demand are not coincident a greater amount of heat can be extracted from the condensate if storage capacity is provided for the preheated water. Frequently, therefore, the economizer coils are submerged in a storage tank. Where condensate is pumped, the pump should discharge into a receiving tank equipped with a thermostatic air vent and the condensate should be permitted to flow by gravity through the economizer and meter.



1. Main Return Line from gravity heating system with all returns properly trapped or pump discharge from vacuum system. With vacuum system a receiving tank with thermostatic vent should be provided at Point A.

Fig. 2 .... Method of Installing a Water Heater and Economizer in a Gravity Heating System

METERING

The *Condensate Meter* was developed for the district heating industry and is an approved method of measuring condensate where all of it can be brought to a common point for metering purposes. Its simplicity of design, ease in testing, accuracy at all loads, low cost, and adaptability to either high- or low-pressure distribution have made it standard equipment with most heating companies.

Condensate meters must not be operated under pressure;

Meter Capacity Lb Per Hr	250	500	750	1500	3000	6500	12000

Diagram D.....	12	12	15	15	15	18	18

Fig. 3 .... Condensate Meter Installation Details

they are made for either gravity or vacuum installations. Typical meter installations are shown in Fig. 3. In diagram A a continuous-flow type trap is shown installed ahead of the meter, while in diagram B an intermittent type trap is used. In the latter case, a receiving tank must be placed between the trap and meter to prevent intermittent overloading of the meter. When measuring the discharge from a vacuum pump, a vented receiver should always be installed ahead of the meter.

Installations of meters in a vacuum return line are shown in diagrams C and D. In diagram C a master, continuous-flow trap is installed immediately ahead of the meter to prevent steam from entering it in case of leaking radiator or fixture traps. Where individual traps are reliable, connections may be made as shown in diagram D.

Flow meters are generally used for measuring sendout from plants, high-pressure requirements in buildings, and in installations where all of the condensate cannot be returned to a central point. Further information on flow meters is available from publications of the Fluid Meter committee of the American Society of Mechanical Engineers and from the *District Heating Handbook*,[28] and are described in Chapter 4.

HOT WATER DISTRIBUTION

District heating in the United States is confined almost entirely to the use of steam as the heating medium. Hot water has been used and is being used today, where economic conditions are favorable and good engineering practice dictates.

The use of low-pressure hot water distribution below 200 F has been practically discontinued for district heating in the United States because of practical and economic difficulties. The use of high-pressure, high-temperature water distribution at 275 to 400 F has found favor in Europe, where fuel is scarce and is finding some application in the United States.[29]

High-pressure water distribution has some practical and economic advantages over steam (see Chapter 29 High Temperature Water Systems). Higher thermal efficiencies, better daily and annual system load factors, lower water treatment costs, smaller pipe sizes, fewer piping accessories, and feasibility of installing pipe to follow contour of ground are given as a few. On the other hand hot water requires a two-pipe distribution system which increases the capital investment in some cases. System maintenance is complicated by the necessity to drain at least a portion of the system when connections are made or leaks repaired.

The advantages of hot water have exceeded the disadvantages in some industrial applications and in Air Force bases in this country. As the cost of fuel increases, additional applications will probably become practicable, especially in new installations serving buildings designed for hot water heating.[1]

CHAPTER 28

HOT WATER HEATING SYSTEMS

Features and Design of Low Temperature Hot Water Systems; Two-Pipe, One-Pipe, and Series-Loop Systems; Piping Principles; Circulating Pumps; Expansion Tanks; Boiler Room Piping; Use of Steam; Temperature Control; System Adjustment; Cleaning Systems

A HOT WATER heating system is one in which water is used to convey heat by flowing through pipes connecting a boiler or water heater with radiators, convectors, or other suitable heat distributing means. The systems discussed in this chapter have supply water temperatures less than 250 F and are classified as *Low Temperature Systems*. Systems having supply water temperatures above 250 F are classified as *High Temperature Systems* and are discussed in Chapter 29. Classified according to the means of generating flow, hot water heating systems are of two types: the *Gravity System* in which circulation of the water is due to the difference in weight between the supply and return water columns of any circuit or system, and the *Forced System* in which a pump, usually driven by an electric motor, maintains the necessary flow.

Since the available head or force producing circulation in a gravity system is limited, the piping must be of such size that the friction loss at the desired flow is not in excess of the available head.

Gravity circulation heads which can be obtained with various supply and return temperatures are shown in Fig. 1. The basic principles which determine design in gravity and forced systems are the same but since the former has less total head available to produce flow, greater precautions are necessary in design to secure even distribution of heat with gravity systems. Gravity systems are no longer of commercial importance. Complete details on the design of gravity type systems are contained in editions of THE GUIDE issued before 1957. Fig. 1 is also useful in determining effects due to temperature difference in forced systems when large elevation or temperature differentials occur.

This chapter is devoted to the design of forced hot water systems using supply water temperatures below 250 F.

The selection of type of distribution system for heating a particular building should be based upon an objective analysis of the characteristics of the building, the comfort and temperature conditions required, the system operating and maintenance characteristics, the space available for piping and equipment, and the economics involved.

FEATURES OF HOT WATER SYSTEMS

Advantageous features of forced low temperature hot water systems are:

1. The piping need not be run at a definite level or pitch but may change up and down as required by architectural and structural elements of the building. High points should be vented and low points be provided with drain connections.
2. Heat distribution when warming up is uniform.
3. Hot water systems are readily adaptable to simple approximate control of capacity and indoor temperature by instruments sensitive to outdoor temperature changes.
4. The system may generally be designed with a minimum of mechanical specialties thereby favoring economical maintenance.
5. Due to practical elimination of air, corrosion within the system is minimized.
6. Where extended glass exposures occur, the heating elements, which are relatively large because they operate at low temperature, may be well distributed under such exposures to counteract downdrafts.
7. Quiet operation may be expected in a properly designed and installed system.

In the design and operation of forced circulation systems, it is necessary to take precautions against any condition that would permit the water temperature to fall below freezing, particularly where coils are used to heat incoming outdoor air or where the heating plant may be shut down for more than 24 hours in cold weather.

If the static pressure in the system is high, it may be necessary to use boilers built for operating pressures above 30 psig unless a steam boiler with heat exchanger is used to heat the water. See discussion in this chapter in section Expansion Tanks and System Pressure Control.

DESIGN OF LOW TEMPERATURE HEATING SYSTEMS

The significant factors affecting the design of low temperature hot water heating systems are discussed in the sections that follow.

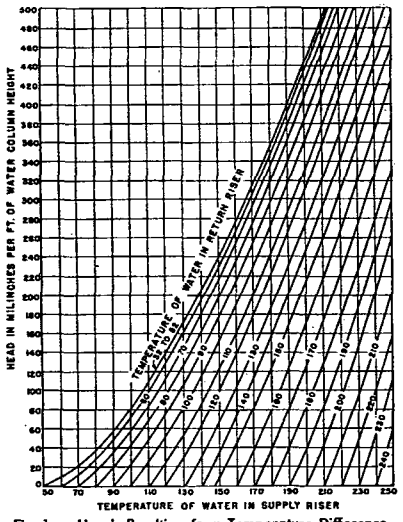
Heat Loss Calculations

The adequacy as well as the proper distribution of the heat in a building served by a hot water system depends primarily on the proper calculation of the heat loss for the individual spaces and the accurate sizing of the heating units to offset those heat losses. Heat loss should be determined in accordance with the principles discussed in Chapter 12, Heating Load.

Selection and Location of Heating Units

Information on the types of room heating units available for hot water systems will be found in: Chapter 14, Radiators and Convectors; Chapter 30, Panel Heating; and Chapter 15, Unit Ventilators and Unit Heaters. While the style or type of unit selected for a given space may depend on personal preferences of the purchaser, the designer should make certain that the heat output at the water temperature available is equivalent to the calculated heat loss from the space.

The heating units within each separately controlled circuit should be of similar types, for example: either all cast-iron or all fin-tube convector-type units. Fan units should not be included in a controlled direct radiation zone. The



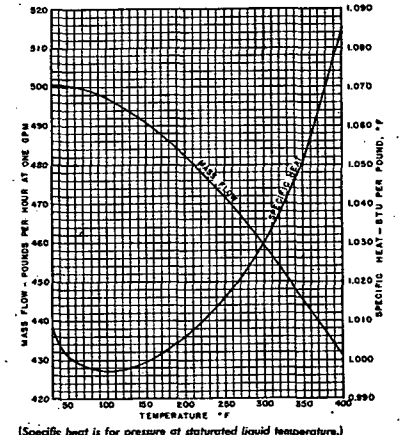


Fig. 1.... *Heads Resulting from Temperature Difference (Gravity Systems)*

(Specific heat is for pressure at saturated liquid temperature.)
(Basic data for calculation and construction of curves from Keenan and Keyes.)[1]

Fig. 2.... Mass Flow and Specific Heat of Water

radiation should be located at points of maximum heat loss or along outside walls, unless this is impracticable.

Determination of Water Flow Rate

The rate of water flow in a system is determined by the heat carrying capacity of the water. This capacity is the product of the rate of flow, the specific heat, and the temperature drop of the water as it passes through the heating units. The equation generally used to describe this relationship is:

$$H = Wc(t_1 - t_2) \qquad (1)$$

where

H = heat carrying capacity, Btu per hour.
W = mass flow or weight of water, pounds per hour.
c = specific heat of water.
t_1 = temperature of water entering heating unit, Fahrenheit.
t_2 = temperature of water leaving heating unit, Fahrenheit.

The equation may be rewritten as follows for convenient use with Fig. 2.

$$H = Gwc(t_1 - t_2) \qquad (2)$$

where

G = rate of water flow, gallons per minute.
w = rate of water flow per gallon per minute, pounds per hour.

The value of w should be obtained from Fig. 2 for the temperature at which the rate of flow is determined, and the value of c should be determined at the average temperature. For example: If water enters a heating unit at 210 F and leaves at 190 F, and a water flow of 1 gpm is measured at 190 F, the heat carrying capacity, found by substituting values from Fig. 2 in Equation 2, is

$H = (1)(484)(1.005)(210\text{-}190) = 9728.4$ Btu per hr or 9.73 MBh

At 60 F the mass flow rate is 500 lb per hr at 1 gpm and the specific heat is very close to 1 Btu per (lb) (F deg). Accordingly, at a 20-deg temperature drop, 1 gpm will release 10 MBh.

This value, 10 MBh per gpm of water at a 20-deg temperature drop, is extensively used throughout the hot water heating industry in the calculation of data for low temperature systems. It is considered well within the limits of accuracy of heating system design. If 1 gpm will release 10 MBh at a 20-deg drop, it will release 15 MBh at a 30-deg drop, and 20 MBh at a 40-deg drop.

Most low temperature systems installed today are designed on the basis of a 20-deg temperature drop. The temperature drop selected in the design of a system is used to determine the water flow necessary to supply the heat required under conditions of maximum heat loss with supply water temperature at a maximum value. If the supply water temperature is increased at any time, the capacity of a heating unit and the temperature drop of water through the unit is increased accordingly. When the supply water temperature is modulated according to outdoor temperature, the temperature drop of the water in the system is considerably less than the design value during the greater part of the heating season.

The use of a design temperature drop greater than 20 deg should be considered where large quantities of required ventilation air are heated by extended-surface coils, where the required pumping capacity is high, where pumping costs are a critical item, and where extended systems make a saving by the reduction in pipe size possible.

Factors considered in selection of a proper temperature drop for a system are (1) the effect of the design average water temperature and water velocity on the capacity and cost of the heating units, (2) the size and cost of the piping, and (3) the initial and operating cost of the pump.

Design Water Temperature

The *design supply water temperature* is the maximum temperature of the water supplied to the system for the purpose of developing the selected rated capacity of the heating units.

The *design average water temperature* of a hot water heating system is the design supply water temperature less ½ the design temperature drop. Capacities of heating units are generally determined on the basis of the design *average* water temperature for cast-iron radiation and for baseboard or finned pipe radiation. Where a greater degree of precision is required to establish the capacity of heating units, for example, for contract and competitive bidding work, it may be desirable to determine heating unit capacities on the basis of design supply water temperature and temperature drop through the unit. This is particularly true where the secondary heating surface in the heating element of the unit is a large percentage of the total heating surface, as in convectors. Design supply water temperatures for radiation systems vary from 180 to 250 F, a common temperature being 210 F.

Factors considered in the selection of a design supply water temperature are (1) the effect on the capacity of the heating unit, (2) the effect on occupants who may be near the unit, and (3) the greater possibility of boiling as the pressure varies.

Pipe Sizing Methods

The theoretical basis of calculations of head loss due to friction of fluids in pipe is the Darcy or Fanning equation, discussed in some detail in Chapter 4, Fluid Flow.

Pipe sizes for hot water heating systems are determined most conveniently from charts such as Figs. 3 to 6 and Table 1 showing pressure loss in relation to rate of flow and size of pipe. Allowance for fittings is generally expressed in elbow equivalents which is the number of 90-deg elbows that would have equivalent friction loss at the same rate of flow. Fig. 7 and Table 2 are useful in determining the number of elbow equivalents which then may be converted to equivalent length of pipe by means of Table 3. Figs. 3 to 7 and Tables 1 to 3 are based chiefly on empirical equations developed by F. E. Giesecke in cooperative research with the Society at the University of Texas and the Engineering Experiment Station of the Agricultural and Mechanical College of Texas.[8-12]

The friction loss selected for sizing pipe for a system depends upon the type of pump used and the economics of small pipe size and high pump head versus large pipe and low pump head. Noise is also an important factor. Velocities are usually limited to a maximum of 4 fps for pipe sizes less than 2-in. to reduce the possibility of noise. Velocities up to 10 fps are frequently used in piping larger than 6-in. Average friction drops of 1.0 to 4.0 ft of water per 100 ft of pipe (120 to 480 milinches per ft of pipe) are commonly used in sizing piping systems. The actual friction loss for a

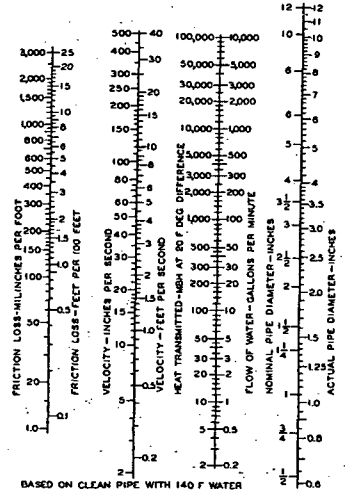

Fig. 3.... Friction Loss Due to Flow of Water in Iron Pipe[2,3]

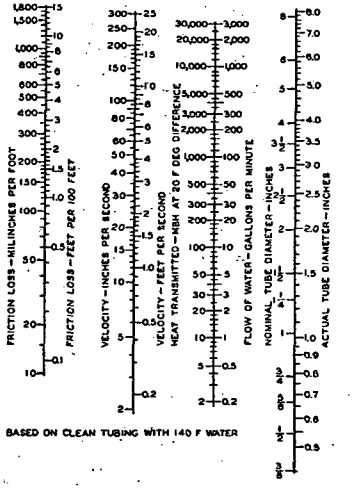

Fig. 4.... Friction Loss Due to Flow of Water in Type L Copper Tube[4]

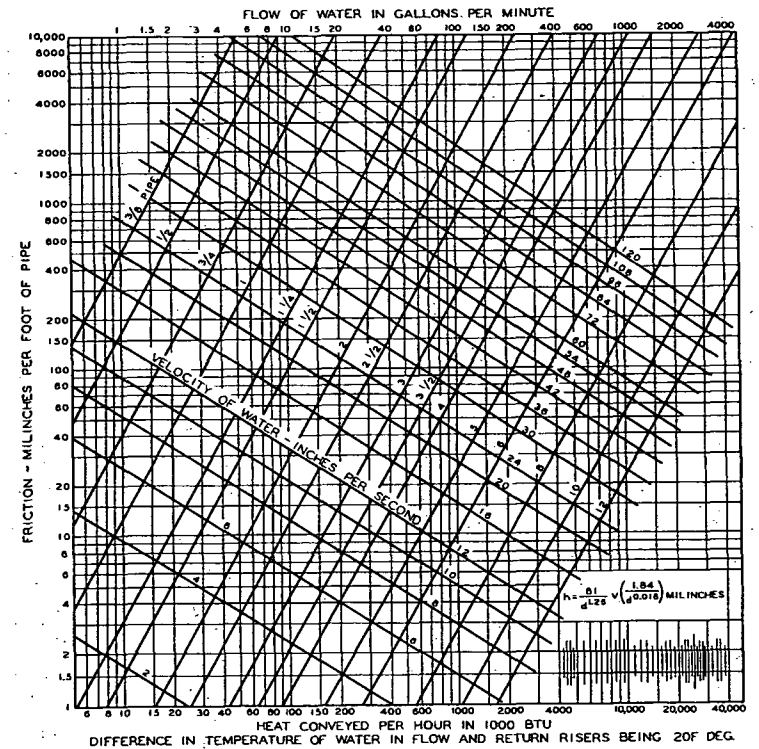

particular section of pipe may vary considerably from the average loss for the system due to the limitations of commercial pipe sizes. For example, if the average friction loss is 2.0 ft of water per 100 ft of pipe (240 milinches per ft), the actual friction loss in particular sections of pipe may vary from 1.0 to 3.0 ft per 100 ft (120 to 360 milinches per ft).

One method of sizing pipe is based on preliminary selection of a pump. The head which the pump can produce is divided by the equivalent length of the longest circuit to obtain an average design friction loss.

The equivalent length of a system or circuit is the length of pipe in series flow in the circuit, plus the length of pipe equivalent in resistance to the fittings and also the equipment in series flow in the circuit. For preliminary calculation the equivalent length is sometimes assumed to be 1.5 times the measured length.

Table 1 can be used for pipe sizing by this method. It provides the designer with a means for quickly assessing the relative effects, economic and otherwise, of various pumps on the system in terms of pipe size.

After sizing the piping on the basis of a preliminary design friction loss the actual friction loss at design rate of flow

Lower scale of chart is based on 20-deg temperature difference between flow and return risers. To find friction when temperature drop is other than 20 deg, multiply the actual heat conveyed by (20 ÷ actual temp. drop) and read the corresponding friction.

[a] See Table 3 for equivalent length of one elbow.

should be calculated. The friction loss at design flow for all individual sections of pipe and for all fittings in the longest piping circuit should then be summarized.

Table 2 shows the number of elbow equivalents for various fittings. These equivalents can be converted to equivalent feet of pipe by use of Table 3. Fig. 7 shows the elbow equivalents for determining friction loss in tees. If the pipe size calculation indicates a required pump head different from that of a standard pump, pipe sizes in the system may be changed to establish a closer relationship between the two. The relationship between systems and pump heads is discussed in the section Circulating Pumps.

If there are more circuits than one in a system, the friction loss for the longest circuit should be used to determine

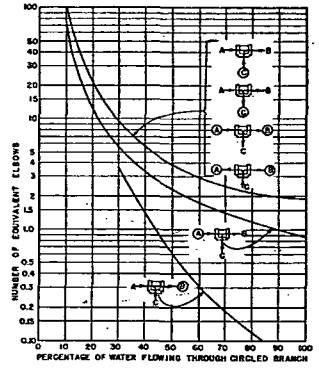
the pump head requirement. Piping in the other circuits should be sized to obtain the same total friction loss.

Effects of Antifreeze Fluids. Antifreeze solutions are sometimes used in heating systems when the danger of freezing exists. They should not be used in direct-fired boiler application. Corrections must be made in flow rates, pipe size, and pump capacity relative to water when antifreeze solutions are used. See Chapter 49, Snow Melting.



SELECTION OF PIPING ARRANGEMENT

The type of distribution system selected for any particular building will depend primarily on the structural and architectural characteristics of the building, the need for separate control of different zones, the pressure head due to the height of the building, the space available for piping, and the relative cost of different arrangements of piping. Consequently, mains may be run in basement, separate floors, or in space above highest heating units.

There are four distinct arrangements of main piping: (1) the two-pipe reversed-return system, (2) the one-pipe system, (3) the series-loop system, and (4) the two-pipe direct return system. The last is not recommended unless elaborate pipe sizing technique and provision for adjustment are employed.

Two-Pipe Reversed-Return System—Description and Design

The two-pipe reversed-return main system, Fig. 8, has two mains, one supplying water to the heating units or to risers

Notes: 1. The chart is based on straight tees, that is, branches A, B, and C are the same size.

2. Head loss in desired circuit is obtained by selecting proper curve according to illustrations, determining the flow at the circled branch, and multiplying the head loss for the same size elbow at the flow rate in the circled branch by the equivalent elbows indicated.

3. When the size of an outlet is reduced the equivalent bellows shown in the chart do not apply. The maximum loss for any circuit for any flow will not exceed 2 elbow equivalents at the maximum flow (gpm) occurring in any branch of the tee.

4. The top curve of the chart is the average of 4 curves, one for each of the tee circuits illustrated.

Fig. 7. . . . Elbow Equivalents of Tees at Various Flow Conditions[9, 11]

to heating units, and one collecting water returned from these units. The piping is arranged in such a manner that the sum of the equivalent length of supply and return piping to any unit is approximately equal to that of any other unit.

Compared with a one-pipe system, the two-pipe system may:

1. Have a smaller average pipe size. While two mains are required, the sizes of the mains vary as water passes from one main through the heating unit to the other. The maximum size of either main is no larger than the size of a one-pipe main.
2. Be more flexible in its application because larger friction loss may be used in the heat-transfer unit circuits.
3. Require a minimum pumping head because the heating unit resistances are in parallel.
4. Permit adjustment of flow through individual units of radiation over wider limits.

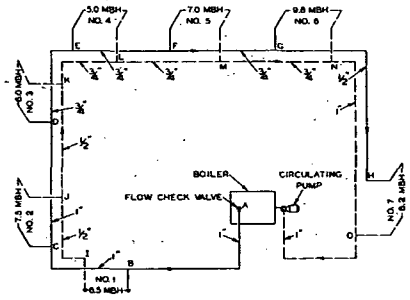


Fig. 8. . . . A Two-Pipe Reversed-Return System

Continuing the comparison, some disadvantages are:

1. Two mains may require more pipe fitting labor than a single main.
2. Some additional pipe may be required to achieve a reversed return.
3. A two-pipe system will be slightly more expensive for small systems.
4. The piping for two mains may be unsightly in occupied spaces.

Important considerations in the design of a two-pipe reversed-return distribution system are:

1. The head which the pump must generate is equivalent to the friction drop through the circuit having the highest resistance. At design flow, the resistance through the distribution system to any one heating unit should be the same as that through any other unit. Where the length of pipe required to obtain distribution to a particular section must be shorter than to other sections, it is desirable to design that section with a higher friction loss.
2. A reversed return, as indicated in the section Adjustment of Flow and Capacity, will reduce the need for adjustments necessary to obtain equal total head through each heating unit circuit.
3. Fan-type air-heating units with extended-surface coils can be used with a higher water temperature drop than that recommended for direct radiation. It is necessary to avoid a difference in air temperature across the face of the coil in such units. One method of minimizing this difference is to install a minimum of two serpentine coils in each unit, one in front of the other. Coil

connections are made so that water travels from top to bottom in one coil and from bottom to top in the other.

The design of a two-pipe reversed-return system will be illustrated by *Example 1*.

Example 1: Design a two-pipe reversed-return hot water heating system for a 37 x 29 ft one-story residence with basement having a heat loss of 50 MBh (50,000 Btu per hr). The heating units are to be convectors operating with a supply water temperature of 210 F and a 20-deg temperature drop. The piping layout and location of convectors are shown in Fig. 8.

Solution: A 50 MBh load with a 20-deg drop requires a water circulation of 5 gpm. The length of the reversed-return circuit is determined as 138 ft of pipe, by following the supply from the boiler to point *G* Fig. 8 and the return from point *N* back to the boiler. The estimated total equivalent length is 138 × 1.5 = 207 ft. This, plus an allowance of the equivalent of 25 ft of pipe for one convector circuit results in a total equivalent length of pipe of 232 ft. Fig. 9 shows that a 1-in. pump has a capacity of 5 gpm at 4.7 ft available head. The preliminary average design friction loss is then 4.7 × 100/232 or 2 ft per 100 ft of pipe (240 milinches per ft). This value can also be determined by reference to Table 1, where, using the vertical column under 5 ft, the next larger equivalent length to 232 ft is 250 ft. To the right in this line read the average design friction loss as 2 ft per 100 ft or 240 milinches per foot.

The piping may be sized initially from Table 1 as follows: In the friction loss column find the value 2 ft per 100 ft. Proceed to right in the same line to the nearest gpm value and then read the pipe size at the top of the column.

The pipe sizes found by this method for the various sections of Fig. 8 are shown in the following table:

Section	MBh	Gpm	Pipe Size inches
Supply			
A–B	50	5.0	1
B–C	43.5	4.35	1
C–D	36	3.6	¾
D–E	30	3.0	¾
E–F	25	2.5	¾
F–G	18	1.8	¾
G–H	8.2	0.82	½
Return			
I–J	6.5	0.65	½
J–K	14	1.4	½
K–L	20	2.0	¾
L–M	25	2.5	¾
M–N	32	3.2	¾
N–O	41.8	4.18	1
O–A	50	5.0	1

The risers to the convectors may also be sized for the same average friction loss, 2 ft/100 ft or 240 milinches per foot, as follows:

Convector No.	1	2	3	4	5	6	7
Load MBh	6.5	7.5	6.0	5.0	7.0	9.8	8.2
Gpm	0.65	0.75	0.60	0.5	0.7	0.98	0.82
Pipe size	½	½	½	½	½	½	½

After the initial pipe sizes have been selected the friction loss in the system should be recalculated as indicated in the following table. The highest pressure drop circuit should be marked off into sections; each of a different flow rate. The total equivalent length of each section should then be determined by adding its elbow equivalent length (see Tables 2 and 3 and Fig. 7) to its actual measured length. Total friction loss is established from

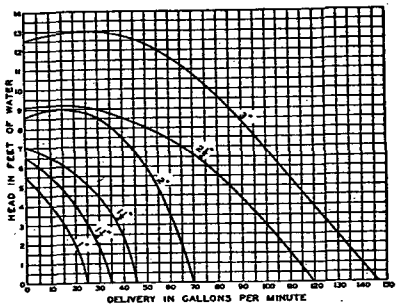

Fig. 9.... Performance Chart for Circulating Pump

charts or tables for each section by multiplying its total equivalent length by the actual friction loss per foot at design flow. The circuit friction pressure drop is the summation of individual section pressure drops as shown in Table 4.

If the total friction loss as determined does not agree with the pump head, some pipe size changes will be necessary to obtain closer agreement. The slight difference in head calculated by milinches and by feet of head is due to use of only 2 significant figures for the latter. This is well within the accuracy required.

As would be expected the calculated head of 4.02 ft is different from the 4.7 ft estimated. This is due to two factors: (1) the difference between the actual and estimated number of fittings and (2) the differences between actual and estimated losses in the different sections as the friction losses were generally below the average friction loss assumed.

The 1-in. pump initially selected would be entirely satisfactory for the installation and would produce a flow slightly in excess of 5 gpm. A procedure to determine the actual flow and head capacity of the pump and system is discussed under Circulating Pumps.

One-Pipe System, Description and Design

The one-pipe system, Fig. 10, has a single main for both supply and return. Special fittings installed at the connections to radiation risers or runouts generate the head necessary to produce flow through the heating unit. In this system the main or circuit loop does not change size from the first to the last radiation unit. The amount of water flowing in the main is constant, except at points where some of it is bypassed through radiation. Since the water temperature in the main drops progressively, some designers consider it necessary to increase the size of heat-transmitting surface accordingly by using a progressively lower design water temperature in sizing the heating units. Most one-pipe heating systems are designed, however, on the basis of a single design water temperature. Generally, the theoretical increase in heat-transmitting surface is needed only when the system is operating at full design output. A water temperature drop in the main of 20 deg or less minimizes the capacity reduction effect.

In comparison with a two-pipe system, the one-pipe system:

1. Permits simpler piping due to the use of one main of uniform size.
2. May be more acceptable when pipe is exposed in occupied spaces.
3. Is very adaptable to small systems or to individual loops

in large systems, either horisontal or vertical, as a part of a two-pipe system, or to obtain zone control in large combination systems.

4. May be lower in installation cost.
5. Has a simpler problem in regard to water-flow adjustment.

Continuing the comparison with two-pipe systems some disadvantages of one-pipe systems are:

1. The amount of water which can be bypassed by a one-pipe fitting or fittings is limited by the economics of design and the head applied. The fittings are not generally used to provide the water flow necessary for large air-handling units having a high pressure drop.
2. The pump head required is slightly higher than that required for a two-pipe reversed-return system of similar flow requirements.
3. If the progressive increase of radiation size as temperature drops is taken into account, a design complication and additional cost factor are encountered.
4. The main flow design temperature drop should not exceed 20 deg.

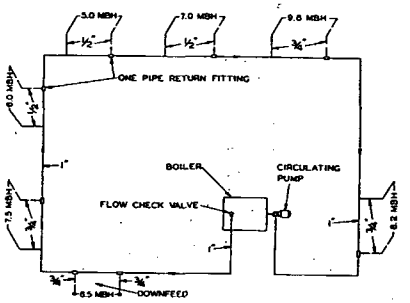

Fig. 10.... A One-Pipe System

Design of a One-Pipe System

The basic design premise of a one-pipe system is that the pressure drop of the one-pipe fitting, or fittings, at the required main flow, be equal to or greater than the radiation circuit pressure drop at its required flow. The system may be divided into two or more loops for smaller main pipe sizes and pumps. Main and radiation circuit temperature drops may be different. For example, a 10-deg temperature drop may be used in the main with a 20-deg drop through the radiation.

Example 2: A one-pipe system is to be designed for the residence discussed in *Example 1*. Fig. 10 shows the piping arrangement for the one-pipe system. The size of the convectors is determined on the basis of a 210 F design supply water temperature and a 20-deg design temperature drop as in *Example 1*.

Solution: For initial selection of pump use a 1-in. pump having a capacity of 5 gpm at 4.7-ft head. The measured pipe length is 140 ft which establishes an equivalent length of 140 × 1.5 =

210 ft. The preliminary design friction loss is then found in Table 1, as in *Example 1*, to be 2¼ ft per 100 ft or 270 mi per ft. At this average design friction loss (see Table 1) a 1-in. main will be used for the required flow of 5 gpm.

From manufacturers' data at 5 gpm flow, the pressure drop from a 1-in. fitting is established at 3000 mi or 0.25 ft. If any heating units are located below the main the gravity head due to temperature difference should be subtracted from available fitting pressure drop. In this example, the riser and convector friction pressure drop should not exceed 3000 mi or 0.25 ft.

The friction loss through the ½-in. risers to the 9.8 MBh convector was calculated to be 0.28 ft or 3450 mi in *Example 1*. This loss plus the 0.1-ft (1200-mi) loss in the convector, equals 0.38 ft (4650 mi) which exceeds the capacity of the fitting. If ¾-in. risers are used, however, the riser pressure drop is considerably reduced. For 9.8 MBh flow the pipe friction drop is 0.34 ft for 100 ft (40 mi per ft). The equivalent length changes from 22 to 26 ft. The riser pressure drop is then 26 × 0.34 or 0.09 ft (26 × 40 or 1040 mi). The head loss through the convector circuit is then 0.09 + 0.1 or 0.19 ft (2240 mi). Since this is below the available fitting pressure drop, the riser size is satisfactory.

Other upfeed risers are sized in a similar manner.

The piping to the 6.5 MBh convector below the main is sized as follows:

The water in this circuit will cool to room temperature during off periods. The center line of the convector is 6½ ft below the main. The thermal head opposing circulation in the convector circuit when one riser is filled with 210 F water and the other has 70 F water is found to be 465 mi per ft or 465 × 5.5 = 2560 mi total. Subtracting 2560 from the 3000 mi pressure drop in the fittings leaves 440 mi available to *start* circulation. The combined convector and riser pressure drop equals 1380 mi even when a 1-in. riser is used. Since the convector and riser pressure drops are greater than the available fitting pressure loss, a change must be made. The total fitting pressure drop could be increased by adding a supply one-pipe fitting, or by increasing fitting pressure drop through use of a larger pump. In this case, the riser is sized on the basis of an added fitting. In accordance with the sizing procedure followed in this example, a ¾-in. riser is adequate.

The pipe sizes selected should be recalculated at the design flow rates either in milinches as shown in the upper part of the following table or in feet per hundred feet as shown in the lower part of the table.

Section	Pipe Size In.	Load MBh	Loss per Foot of Pipe Mi	Length—Ft			Total Friction Loss Mi[a]
				Linear Pipe	Elbow Equiv.	Total Equiv.	
Main	1	50	240	140	87[b]	227	54,500
8 one-pipe fittings at 3000 mi[c]							24,000
Total							78,500
							= 6.55 ft

Section	Pipe Size In.	Load MBh	Loss per 100 Ft of Pipe Ft	Length—Ft			Total Friction Loss Ft
				Linear Pipe	Elbow Equiv.	Total Equiv.	
Main	1	50	2.0	140	87[b]	227	4.54
8 one-pipe fittings at 0.25 ft head[c]							2.0
Total							6.54

[a] Mi = milinches.

[b] The elbow equivalent length is based on: 8 elbows, 2 tees, 2 gate valves, 1 flow check valve and 1 boiler.

[c] The actual value for resistance of the one-pipe fittings should be obtained from the fitting manufacturers. They are frequently lower than the value assumed in this example.

The pump capacity required is 5.0 gpm at 6.54 ft head. The 1½ in. pump as shown in Fig. 9 would meet the requirements of the system based on the assumptions stated for the problem.

Series-Loop System—Description and Design

This system, illustrated in Fig. 11, consists of one or more loops or circuits. In each circuit, as the same water is circulated through the heating units in succession, the size of pipe should not vary materially in any portion of a circuit. The system circuit length thus becomes very important because it influences directly the water flow rate, pressure drop, and temperature drop. Since the water temperature in each

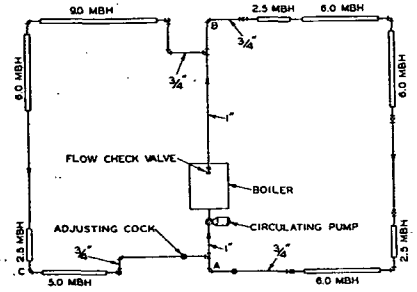

Fig. 11.... A Series-Loop System

successive heating unit decreases progressively, some designers consider it necessary to increase progressively the size of heating units sufficiently to compensate for the drop in temperature. If a small design temperature drop, such as 20 deg or less is used, it may not be necessary to increase the heating units in size toward the end of the circuit.

Various considerations affecting the design of a series-loop system are given in the following paragraphs:

1. It may be possible to eliminate all or large sections of the distribution main and thereby reduce cost. In large buildings it may be necessary to use a partial two-pipe main in combination with the series-loop system for certain sections or divisions of the building.

2. The practicability of the system will depend upon the quantity of water to be circulated through the heating units and the friction loss. Baseboard or finned-type pipe elements for series-loop systems are usually manufactured from standard steel pipe or copper tubing. The friction loss can be determined from Figs. 3 and 4.

3. If a series-loop system serves more than a single space, and if the design temperature drop for the system is in excess of 20 deg, the size of the heating unit should be determined on the basis of the temperature of the water entering the particular heating unit and the temperature drop across the unit. The temperature drop through a particular heating unit is equal to the capacity of that unit divided by the capacity of the total radiation circuit multiplied by the total temperature drop of the circuit.

4. Since the temperature of the water supplied to heating units in the series-loop system cannot be regulated, it is advisable to provide dampers in the cabinets containing finned pipe or baseboard radiation to permit adjustment of the heat delivery by each unit. Valves or adjusting fittings, if used in the water circuit, would affect the performance of the entire loop and would not be a satisfactory means of controlling the heat output of the units.

Certain disadvantages of the series-loop system are:

1. The difficulty of making suitable provision for adjustment and balancing of the system.

2. The total circulating head required may be excessive.

3. The design of the system may be more difficult than for one-pipe or two-pipe main systems.

Example 3: A series-loop system is to be designed for the residence used in *Examples 1* and *2* for two-pipe and one-pipe design. No heat will be supplied to the basement. The total heat loss equals 45,500 Btu. Baseboard-type radiation having a rating of 0.5 MBh per linear foot at an average temperature of 190 F, is selected as the radiation used. The heating units are of baseboard type having a rated output of 0.5 MBh per linear foot at an average temperature of 190 F. They are connected by ¾-in. pipe. A 20-deg design temperature drop will be used.

Solution: For a 45.5 MBh load 4.55 gpm must be circulated for a 20-deg temperature drop. For a single looped main the measured length equals 140 ft. The approximate equivalent length equals 140 × 1.5 or 210 ft. If the 1¼-in. pump, Fig. 9, were initially selected, it would develop a 6-ft head at 4.55 gpm delivery. For an available head of 6 ft and an equivalent length of 218 ft (nearest to 210 ft) Table 1 shows that only 3 gpm will circulate through the ¾-in. main. A larger, and more costly pump may be tried. The 3-in. pump, Fig. 9, has 12.7 ft available head at 4.55 gpm delivery. If 12-ft available head and 250-ft equivalent length are used as the nearest available values, Table 1 indicates that a flow of 4.3 gpm at a velocity of 2.5 fps will be established through the ¾-in. main. However, because of cost, appearance, and temperature drop considerations, this may not be desirable.

If the system is divided into two loops, as shown in Fig. 11, a smaller pump may be used and the system temperature drop decreased.

The 1¼-in. pump at 6-ft head for 4.55 gpm is again selected for preliminary sizing of piping.

The measured supply main length plus the length of the longest loop circuit is 106 ft. The equivalent length equals 106 × 1.5 or 159 ft. For 6-ft available head and 160 ft equivalent length, Table 1 indicates that the friction loss would be 3¾ ft per 100 ft or 450 mi per ft. At this friction loss the supply main would be of 1-in. size for a flow of 7 gpm (which is more than the required 4.5) and the ¾-in. looped main would deliver 3.7 gpm (more than the required 2.25 gpm). Because the flows are more than required, the system temperature drop would be less than 20 deg. A smaller pump could therefore be used if desired.

The pipe sizes should be recalculated at the design flow rates as follows:

Section	Heat Load MBh	Design Flow Gpm	Friction Loss Ft/100 Ft	Pipe Size In.	Equiv. Ft	Total Equiv. Ft	Press Drop Ft
AB	45.5	4.55	1¾	1	36.0[a]		
	2 elbows				5.0		
	2 gate valves				2.5		
	1 flow valve				50.0		
	1 boiler				7.5	101	1.77
BCA	22.5	2.25	1½	¾	70[a]		
	8 elbows				13.6		
	1 cock				1.7		
	2 tees @ 50%				13.6	99	1.5
Total							3.27

[a] Actual pipe length.

Since the total system head loss equals 3.27 ft at a flow of 4.55 gpm and the 1¼-in. pump is a satisfactory selection.

If desired, the actual design temperature drop can be determined. Because the pump head at 4.55 gpm is greater than 3.27 ft, the flow in the system will increase until pump head and flow equal system pressure drop and flow. Construction of a system curve, as described under centrifugal pumps, shows that for the system with the pipe size selected and with the 1¼-in. pump, equilibrium will be reached at 6-ft head and 6.2 gpm flow. The actual temperature drop for design conditions would then be (4.5/6.2) × 20 or 14.5 deg, approximately.

Combination Systems

Three types of systems have been illustrated, namely: one-pipe, two-pipe reversed-return, and series-loop. Actually the design for a particular building may be a composite of two or even all three of these types of systems. For example, a two-pipe reversed-return system of distribution may be used with a number of one-pipe loops in a single building such as an apartment house, or a two-pipe reversed-return system may be used with a main riser at each end of a building with a series-loop system used to serve the space on each floor of the building. In any case, it is well to bear in mind the principles of design involved in each particular type of system for that portion of the installation where it is used.

Adjustment of Flow and Capacity

Where the heating elements and piping are properly sized and arranged, a hot water system is, to a large extent, self-adjusting. This is so because the mean temperature of the water flowing inside the heating unit is the most important factor in determining its output. If the flow of water is within 5 to 15 percent of the correct value for a given heating unit, the difference in mean temperature will not exceed 1 or 2 deg and, consequently, the effect on heat output will be negligible. However, the limitations of commercial pipe sizes and pipe arrangement sometimes result in flow rates considerably different than those required to develop the proper output of the heating units. A means of adjusting the heat output of heating elements and branch circuits must be provided in the system to correct these effects.

Adjusting means may be necessary due to the type of system, for example, the two-pipe system using direct-return mains. In this system the water flow circuits are hydraulically unbalanced, because the water for the first heating load taken off the main is the first to be returned. As a result, the first heating unit will receive a much greater flow than is required to develop its rated output. The flow through the last heating unit can be so low that practically no heat is delivered. The poor distribution of flow in the direct-return system can be corrected by the installation of orifices or of adjusting fittings or valves, by means of which the system is balanced after it is placed in operation. In some cases, proper flow distribution can also be established by careful pipe size selection. That is, the piping can be sized so that the pressure drop through each piping circuit is the same at the design flow rate.

These troubles are minimized by the reversed-return system, Fig. 8. In this system the water for the first heating load taken off the main is the last to be returned, and all circuits are of approximately equal length. Proper hydraulic balance is therefore easily obtained and the system is inherently self-adjusting. While the reversed-return piping circuit is much preferred, in some large installations a saving in pipe can be effected by use of a direct-return system.

When selecting the type of piping arrangement such as one-pipe, two-pipe, series-loop, upfeed, and downfeed, the

adaptability of each arrangement for proper hydraulic balance should be considered.

Air Elimination

If air and various other gases which occur in hot water heating systems are not eliminated from the flow circuit, they may collect in the heating units or piping and reduce the flow of water and the heat output. These gases, designated *air* in this text, are in the piping before it is filled with water, are introduced with the water used to fill and replenish the system, and also are formed to a limited degree from chemical action inside the system and from the movement of low temperature air-saturated water from the

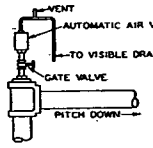

Fig. 12.... Typical Automatic Air Vent Valve Installation

expansion tank to the system.[13] Loss of air by absorption in the water may be prevented by a flexible diaphragm preventing contact of water and air in the expansion tank and having adequate movement to permit the expansion of the water in the system.

The air is eliminated from the flow circuits by trapping it into the expansion tank as explained in connection with discussion of *dip tubes* in the section Boiler Room Piping and

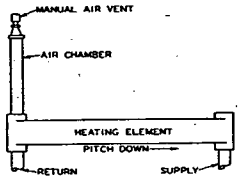

Fig. 13.... Typical Air Vent Valve Installation on Heating Element

by the installation of manual or automatic air vent valves at all high points in the system.

Automatic air-vent valves may be used to eliminate air from the mains and major equipment. Like other mechanical devices, they are subject to malfunction. Small pieces of dirt or scale can lodge on the valve seat, causing it to leak. Corrosion, scale, or sludge in the valve can prevent the valve from opening to eliminate air. All systems should be designed to have a minimum number of automatic air-vent valves, but where a valve is required there should be no hesitancy about using it. In large systems where large numbers of automatic air-vent valves are necessary, provision should be made for service of each valve without draining the system (Fig. 12). The drip from each air vent valve should be piped to a drain to prevent building damage and facilitate inspection for leakage. Automatic air-vent valves should not be installed in piping where temperatures in excess of 215 F can occur without careful analysis of possible temperature-pressure effects.

Each unit of radiation which can act as an air trap should be provided with an air chamber and air-vent valve (Fig. 13). The use of manual air-vent valves or porous plug- or disc-type manual-automatic valves is recommended for radiation.

Piping Principles

Piping should be pitched up in the direction of flow in all cases when pump operation is constant, and wherever possible when pump operation is intermittent to assure consistent air elimination during conditions of either flow or no-flow. Piping is pitched ¼ in. per 10 ft as standard practice.

When changing the size of pipe in horizontal runs, eccentric reducers should be used to keep the top of the pipes in line.

A means of manual capacity adjustment should be provided for each heating unit. Manual valves or adjusting cocks are frequently provided for this purpose. Dampers at the heating element or at the outlet of convection-type units may be used. The heating unit located in the area of a zone thermostat should be equipped with a key-operated adjusting device to discourage tampering by unauthorized personnel.

The piping should be installed to provide for thermal expansion of the pipe without imposing undue stress on connections or equipment. Spring pieces of sufficient length, as required by the diameter of the runout and the amount of expansion to be absorbed, should be installed at connections to radiators and risers. Expansion joints or loops and properly located anchors should be used where required. See Chapter 31, Pipe, Fittings, Welding.

All mains and risers located in exterior walls should be covered with sufficient insulation to prevent freezing. Trunk mains running between buildings must be protected by conduit or installed in trenches below the frost line and properly insulated. When heating mains are run in locations where they could possibly be immersed in water, the conduit should be watertight.

Circulating Pumps

Circulating pumps used in hot water heating systems can vary from small ⅙-hp booster-type pumps with a capacity of 5 gpm at 6- or 7-ft head to pumps handling hundreds, even thousands, of gallons per minute at heads limited only by the pressure characteristics of the system. The selection of a pump for a system is based on an analysis of operational characteristics of the pump and system. Both first cost and operating cost are involved. See discussion under Pipe Sizing Methods, Expansion Tanks and System Pressure Control. Pumps with mechanical seals have found wide acceptance in hot water heating. Pump characteristics, as affected by system characteristics, should be given consideration to insure non-overloading conditions in pump motor operation.

Any given pump, when operated with a given fixed-head system, will operate at only one point on its curve, the intersection of the pump curve with the system curve. Pump curves may be obtained from manufacturers. System curves can be constructed by plotting head versus gpm for different flow rates. The head for various flow rates can be estimated by use of the equation:

$$\frac{H_2}{H_1} = \left[\frac{G_2}{G_1}\right]^2 \quad \text{or} \quad H_2 = H_1\left[\frac{G_2}{G_1}\right]^2 \qquad (3)$$

where

H_1 = calculated system head.
H_2 = head at new flow rate.
G_1 = calculated flow rate.
G_2 = assumed new flow rate.

For economic or for operational reasons two similar pumps are sometimes used in parallel on a single circuit. When so used the combined pump curve showing the relationship of flow to head due to operation of both pumps is established by adding the flow capacity of one pump to the flow capacity of the other at identical heads. If two pumps are placed in series, the relationship of flow to head due to operation of both pumps is established by adding the pump heads at identical flows. When using pumps in series, they must be identical or similar since the maximum flow will be limited by the smaller pump. Gate valves should be provided to enable isolation of either pump when only one is in operation.

The Heat Source or Boiler

The most frequently used source of heat is the 30 psi hot water heating boiler, constructed of cast iron or steel in accordance with the *ASME Boiler and Pressure Vessel Code*, Section IV for Low Pressure Heating Boilers. See Chapter 35, Heating Boilers, Furnaces, Space Heaters. Boilers, classed as low-pressure heating boilers, may be used for hot water with pressures as high as 160 psig if the temperature of the water does not exceed 250 F and if they are constructed according to the ASME code for the pressure at which they are operated.[14]

The ASME code requires installation of a relief valve on each hot water heating boiler to limit the pressure exerted on that boiler to the value for which it was designed and tested.[14] Similar requirements exist for converters and electric water heaters. This operating pressure limit for the boiler is an important factor in the design of the hot water heating system. Together with the size and characteristics of the expansion tank, it determines the permissible height from the boiler to the top element or pipe of the distribution system, as discussed under Expansion Tanks. In addition to the pressure relief valve required by the ASME code, a hot water heating boiler should be equipped with a thermometer, located at or near the top of the boiler, and a reliable pressure or altitude gage with a range at least twice that of the maximum operating pressure or altitude allowable for the boiler.

EXPANSION TANKS AND SYSTEM PRESSURE CONTROL

The objectives of system pressure control are to limit the pressure at all equipment in the system to the allowable working pressure of the equipment; maintain minimum pressure for all normal operating temperatures in order that air can be vented and cavitation at the pump suction and boiling of system water prevented; and accomplish these objectives with as little addition of new water to the system as possible.

An expansion tank is the primary device used to accomplish system pressure control. The excess water volume in the system resulting from increased temperature is stored in the expansion tank during periods of high operating temperatures and returned to the system when the system water temperature is lower. The expansion tank must be designed to store the required volume of water during maximum design operating temperatures without exceeding the maximum operating pressure allowable, and to maintain required minimum pressure when the system is cold. Some designers provide an automatic fill valve to maintain the minimum

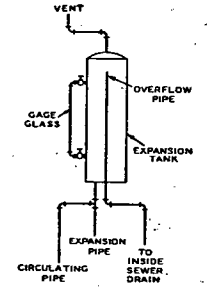

Fig. 14.... An Open Expansion Tank

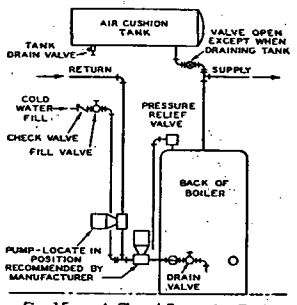

Fig. 15.... A Closed Expansion Tank

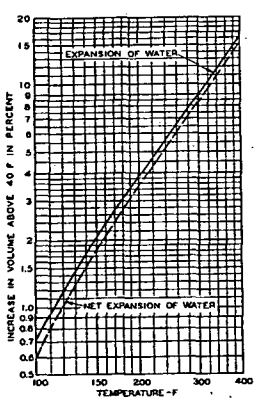
pressure in the system by supplying water to make up for losses due to leakage. Others prefer that water added to the system be supplied by a manually operated valve.

The relief valve installed on a hot water boiler in accordance with the ASME code performs the function of limiting the maximum pressure at the boiler. Since it is a safety device, it should not be considered an operating control.

Systems are designated as open (Fig. 14) or closed (Fig. 15).



The *open tank* system is vented to the atmosphere and is generally limited to installations having operating tempera-

tures of 180 F or less because of system boiling and tank water evaporation problems. The tank should be at least 3 ft above the high point of the system and should be connected to the suction side of the pump to prevent subatmospheric system pressures caused by pump operation.[15] The system should have an internal overflow drain. Provision must be made to prevent water from freezing in the tank, the tank vent, and the pipe leading to the tank. These provisions are also required by the ASME code. The minimum tank volume should be equal to 6 percent of the total system water volume.

The *closed system* utilizes an airtight tank which provides a means of pressurizing the system for operation over a wide range of conditions. As the excess water due to thermal expansion moves into the expansion tank, it compresses the air trapped therein and increases the pressure on the system. If the tank, or the amount of air in it, is too small, the pressure on the system will exceed the maximum allowable, and cause the relief valve to waste water from the system. When the system cools, the pressure will drop to a value less than minimum, making the venting of air impossible or drawing air into the system if automatic air vent valves are located at a high point of the piping. If the tank is too large, it will cost more and require more space.

Determining Tank Size

The size of a closed expansion tank is determined by: volume of the water in the system; range of water temperatures normal to operation of the system; pressure of the air in the expansion tank when the fill water first enters the tank; relationship of the height of the boiler which usually, but not always, is the item in the system with the lowest working pressure; the expansion tank, and the high point of the system; head of the circulating pump; location of the circulating pump with respect to the expansion tank connection, and the boiler. The expansion tank size for a closed

Note: Net expansion of water equals actual expansion of water less volumetric expansion of metal system.[17]

12	30	12.090	5.96	11.565	5.46

system may be determined from the following ASME formula. This formula should be used only for operating temperatures between 160 F and 280 F.

$$V_t = \frac{(0.00041t - 0.0466)V_s}{\frac{P_s}{P_f} - \frac{P_s}{P_s}} \qquad (4)$$

where

V_t = *minimum* volume of the expansion tank, gallons.
V_s = system volume, gallons.
t = maximum average operating temperature, Fahrenheit.
P_s = pressure in the expansion tank when the water first enters, usually atmospheric pressure, feet of water, absolute.
P_f = initial fill or minimum pressure at tank, feet of water, absolute.
P_s = maximum operating pressure at tank, feet of water, absolute.

A widely used formula recommended for temperatures below 160 F is:

$$V_t = \frac{E}{\frac{P_s}{P_f} - \frac{P_s}{P_s}} \qquad (5)$$

where

E = net expansion of the water[16] in the system when heated from minimum temperatures to maximum temperature, gallons (See Fig. 16).

The volume of the water in a system should be determined from water capacities of heating units as given by manufacturers and the volume of pipe or tube from tables such as Table 5.

Effect of Pump Location

The required minimum pressure, P_f, and the maximum pressure in the expansion tank, P_s, may change for specific systems, depending on the effect of relative pump and tank location on system pressure changes caused by pump operation. Refer to diagrams *A*, *B*, *C*, and *D* of Fig. 17 and following discussion.

The degree of system pressure change caused by pump operation is established by the pump head. Whether the pump head will be added to, or subtracted from the system static pressure at the time of pump operation is determined by the relative pump and tank location. This is so because *the junction of the tank with the system* is a point of *no pressure change* regardless of whether or not the pump operates. Consequently, when the tank is located close to the pump suction, the pump suction pressure is unchanged when the pump starts and the pump head appears as an increase of pressure on the system. Conversely, when the tank is located close to the pump discharge, the pump discharge pressure is unchanged when the pump starts and the pump head appears as a decrease in pressure at the pump suction and on the system.

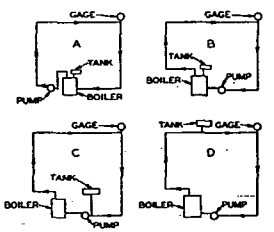

Fig. 17. . . . Effect of Pump Location and Expansion Tank Connection

When the pump discharges away from the boiler and expansion tank (*A*, Fig. 17) all pressure changes created by pump operation are additive. A gage located at any point in the system will show an increase in the pressure on starting the pump equal to the friction pressure drop between the gage and the boiler inlet (tank). Since the tank is located on the boiler, boiler pressures are unaffected by pump operation. The minimum pressure, P_f, required, is equal to height of the system above the expansion tank, plus any pressure required to assure positive air venting and *prevent boiling; if the maximum water temperature exceeds* 212 F. The maximum pressure, P_s, depends upon the pressure rating of that item of equipment having the lowest rated working pressure, usually the boiler or boiler relief valve, and the vertical distance between it and the expansion tank. This arrangement is recommended where high head pumps are used.

When the pump discharges into the boiler and expansion tank (*B*, Fig. 17), all pressure changes induced by pump operation are subtractive. A gage, located at any point in the system, will show a decrease in pressure on starting the pump equal to the pipe friction pressure drop between the gage and boiler outlet (tank). Assuming no friction loss between the discharge of the pump and the expansion tank, the minimum pressure, P_f, must be increased above that discussed for *A*, Fig. 17, by the head of the pump. The maximum pressure, P_s, is determined as described for *A*, Fig. 17. Arrangement *B* results in the largest size expansion tank, but is commonly used in residential and other small installations where water volumes, system heights, and pump heads are all low.

When the pump discharges into a boiler and the tank is connected to the pump suction line as in *C*, Fig. 17, the boiler is subjected to an increase in pressure equal to the pump head when the pump operates. The required minimum pressure, P_f, is as described for *A*, Fig. 17. The tank final operating pressure, P_s, equals the boiler working pressure, as discussed under *A*, Fig. 17, minus the pump head. With arrangement *C* the size of the expansion tank will be smaller than for arrangement *B*, but larger than for arrangement *A*.

Attic tanks are used for the purpose of tank size reduction. When used, as shown in *D*, Fig. 17, a gage located at any point between the tank and the discharge of the pump will show an increase in pressure when the pump operates, while any point between the tank and the suction line of the pump will show a decrease in pressure. This decrease in pressure on the suction side of the tank connection requires that a pressure equal to friction loss between the tank connection and the suction of the pump should be added to the vertical distance the tank is located below the high point of the system to obtain the minimum tank pressure, P_f. Since the pump is located between the expansion tank connection and the boiler, the maximum tank pressure, P_s, would be obtained as described under *C*, Fig. 17, except that pump effect on the boiler pressure *is reduced by the friction* loss between the tank connection and the boiler. If the pump were discharging from the boiler instead of into it, the pump operation would not affect P_s.

The following *Examples 4, 5,* and *6* illustrate the principles applying to sizing of closed expansion tanks.

The system used in the examples has: (1) a water volume of 1000 gal, (2) a high point of the system at the top of a return riser 25 ft from the top of the boiler directly above the boiler room, (3) a circulating pump having a 20-ft head, and a 30 psi boiler with an ASME rated relief valve as the item of equipment having the lowest pressure rating. The P_s is atmospheric pressure, 34 ft of water, absolute, in all examples. The design average water temperature is 200 F. Friction losses between the high point of the system and the boiler are assumed to be negligible.

Example 4: Determine the size of expansion tank required when connected as shown in *A*, Fig. 17.

Solution: Installation is as shown in *A*, Fig. 17, with the expansion tank at the same level as the relief valve. The net expansion of the water in the system is represented by the term $(0.00041\ t - 0.0466)V_s$ of Equation 4 and, hence, is

$$[(0.00041)(200) - 0.0466]\ (1000) = 35.4 \text{ gal.}$$

As stated, P_s is 34 ft of water, absolute. Referring to the discussion for *A*, Fig. 17, P_f, the minimum pressure, is equal to the height of the system above the expansion tank, 25 ft, plus 4 ft for positive venting, a total of 29 ft of water, gage, or 63 ft of water, absolute. P_s is equal to the relief valve setting, 30 psi × 2.31 ft of water, 69.3 ft of water, gage, or 103.3 ft of water, absolute.

Substituting in Equation 4:

$$V_t = \frac{35.4}{\frac{34}{63} - \frac{34}{103.3}} = 170 \text{ gal.}$$

Example 5: Determine the size of expansion tank required when connected as shown in *B*, Fig. 17.

Solution: All conditions remain the same, except that the expansion tank connection is at the discharge of the pump rather than at the suction. When the pump operates, the pressure at the top of the return riser is reduced by an amount equal to the head of the pump. Therefore, to maintain a positive pressure at the top of the system, the minimum pressure must be in-

creased an amount equal to the head of the pump, 20 ft of water. P_f, the minimum pressure, equals 29 plus 20, or 49 ft of water, gage, or 83 ft of water, absolute. The required volume by Equation 4 is

$$V_t = \frac{35.4}{\frac{34}{83} - \frac{34}{103.3}} = 440 \text{ gal.}$$

Example 6: Determine the size of expansion tank required when it is connected as shown in *D*, Fig. 17.

Solution: The expansion tank is located at the top of the system with the result that the height of the system has no effect on the required minimum pressure, P_f. However, the tank is located far enough from the pump so that friction loss in the piping between the pump and the tank must be considered in determining the pressure effect of pump operation on system pressures. Assume that the tank is located at a point such that the friction loss between the tank connection to the system and the suction of the pump is 8 ft, with the resistance in the return riser to the boiler still considered negligible.

The pressure in the expansion tank remains the same whether the pump runs or not. Therefore, since 8 ft of friction loss exists between the expansion tank and the pump suction at the top of the return riser, the pressure in the expansion tank must be increased by that amount to maintain a positive air venting pressure at that point.

P_f, the minimum pressure in the tank should be the sum of 4 ft for positive venting pressure and 8 ft for pump effect, or 12 ft water, gage, which is 46 ft of water, absolute. Since the pump is located between the expansion tank connection and the boiler, P_s, the maximum pressure *in the tank*, must be less than the operating pressure of the relief valve by an amount equal to the effect of pump operation on the boiler pressure. In this case, the effect of the pump is reduced by the friction loss between the expansion tank and the boiler. The head of the pump, 20 ft, less friction as discussed, 8 ft, *is* equal to 12 ft.

P_s, then, is 69.3 less 12, which is 57.3 ft of water, gage, or 91.3 ft of water, absolute. Other factors remain as discussed in the other examples. Substituting in Equation 4 the required expansion tank size is:

$$V_t = \frac{35.4}{\frac{34}{46} - \frac{34}{91.3}} = 96 \text{ gal.}$$

In *Examples 4, 5,* and *6*, the calculated size of the expansion tank has been indicated. It is customary practice to select a standard tank size not less than that calculated.

The two following important factors in tank sizing have not been illustrated in the *Examples 4 to 6*:

1. *Use of compressed air to increase the amount of air in the tank.* This factor affects the value of P_s by increasing it above atmospheric pressure. The use of compressed air to *charge* the expansion tank reduces the required tank volume.

2. *Effect of a design maximum temperature higher than 212 F.* The effect of design temperatures above 212 as used by some designers is given in the discussion of *A*, Fig. 17. It is possible to obtain proper operation of the expansion tank without adding the pressure required to maintain liquid water at temperatures in excess of 212 F. Two things are necessary on this basis of design: (*a*) the pressure increase in the system as the temperature increases from 40 F to 212 F and to the final design temperature must be sufficient to keep the pressure above that corresponding to the temperature of the water in order to prevent boiling and (*b*) the operating personnel for the system must be instructed regarding the proper pressure for various system temperatures in order that proper pressure control of the system may be maintained. An automatic fill valve cannot be used to maintain the minimum pressure for such a system.

In small systems where the volume of water is small and where the pressures due to pump and static heads are low, expansion tanks are small and no critical problems are encountered. However, for large systems the size of the expansion tank and the problems of pressure control can become critical. The following means of reducing expansion tank size and establishing satisfactory pressure control may be investigated in addition to the methods discussed under *A* to *D*, Fig. 17:

1. Compressed air, if available, can be admitted to the expansion tank to obtain the desired pressure.

2. The head of the pump may be reduced by the use of larger pipe sizes, or greater design temperature drop.

3. The boiler may be constructed for pressures higher than 30 psig.

4. The steam boiler may be used with a steam-to-water heat exchanger to heat the water circulated.

The point of connection of the expansion tank to the system should be studied carefully to guard against the possibility of isolating the tank from a hot boiler or any part of the system by normal operation of automatic, check, or manual valves.

BOILER ROOM PIPING

The arrangement of equipment, its capacity, and the piping arrangement for its connection will vary, depending upon the size and characteristics of the systems which it serves. Most of the principles involved in these arrangements have been discussed. Fig. 18 shows the piping and specialties considered necessary for the most basic system. The *ASME Low Pressure Heating Boiler Code* requires that provision must be made for draining a closed expansion tank without emptying the system. A valve is commonly included in the expansion piping to the tank but it must not close a connection to the safety relief valve. Fig. 19 shows a more elaborate multizone system. Most systems will fall between these extremes as the engineer fits the design to the requirements of the installation.

One device in boiler piping which facilitates elimination of air before it can enter the mains is the dip tube. Air will separate from the water in a heating system at a point where the velocity and pressure are the lowest and where the temperature is the highest. Although the pressure at the boiler is generally high, it is a logical place to perform the separation. Fig. 18 shows the use of a dip tube. This extension of the outlet pipe forms a dead space at the highest and hottest part of the boiler. The air will tend to separate from the

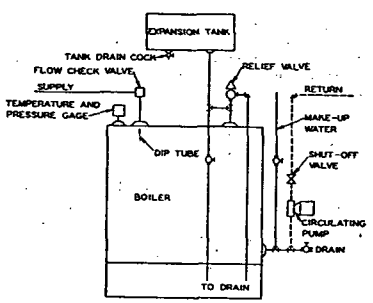

Fig. 18. . . . Basic Boiler Connections for a Hot Water System

water in this space. The air can be conducted to the expansion tank by a connection from the tank to the highest point of the boiler (see Fig. 18). The connecting pipe should be as direct as possible and be pitched upward continuously to the tank. If the expansion tank is not connected directly to the boiler, an automatic air vent valve should be installed at the high point of the boiler, instead.

In general, the manufacturer's recommendation on the number of outlets to be used for a particular boiler for a given application should be followed. This applies also to return connections.

The prevention of thermal shock through proper use of return connections should be considered in piping arrangement. Where more than one pump are used for circulation, the discharge of the pumps should be joined before being discharged into the boiler. A check valve should be installed in the discharge of each pump, unless another method of preventing backflow through the pump circuit is provided. Where temperatures higher than normal are maintained in the boiler, the connection of the return to the boiler should follow the manufacturer's recommendations for such service.

Where a multiple boiler installation is used, provisions should be made to prevent the bypassing of water through a boiler which is not being maintained at control temperature. In some cases this provision takes the form of automatic control valves interlocked with the boiler temperature control to be open only when the temperature in the particular boiler is being maintained at operating conditions. In other cases, manual valves are installed in the boiler returns and opened only when the burner switch which places the firing device at the command of the boiler temperature control is in the *ON* position.

Weighted check valves, or flow check valves, should be installed in the supply piping from the boiler to prevent gravity circulation during periods when the circulating pumps are not operating. If the piping is arranged with separate supplies to individual zones, a weighted check valve should be installed in the supply piping to each zone.

THE USE OF STEAM WITH HOT WATER HEATING SYSTEMS

The use of a steam boiler or district steam with a converter (heat exchanger) has many advantages for tall buildings. The piping for the steam used in this type of a system should follow the principles outlined in Chapter 26, Steam Heating Systems. In tall buildings the system can be zoned vertically as shown in Fig. 20, that is, with a given number of floors per zone and a converter for each zone. This type of design makes the limitation of maximum pressure in the system possible. With a converter-type system, the volume of water in the boiler is not a part of the volume of water causing thermal expansion in the system. Since the boiler in a hot water system may hold 30 to 50 percent of the total water volume of the system, the reduction in the size of the expansion tank and the problems involved therewith are of major importance.

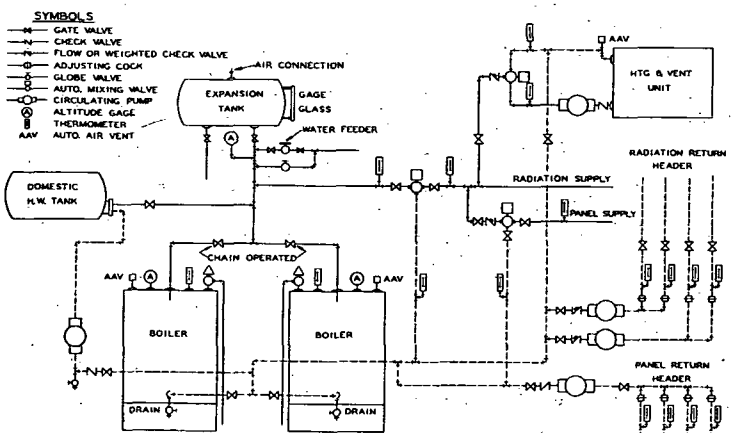
The use of steam in extended-surface coils for heating air will often be more desirable in a system where steam is available. This type of installation will result in less expensive coils, and simplified coil controls.

TEMPERATURE CONTROL

Methods of temperature control for hot water heating systems, including zone controls, are covered in Chapter 43, Automatic Control.

SYSTEM ADJUSTMENT

Two common methods of determining the effects of capacity adjustment are: the measurement of space tempera-



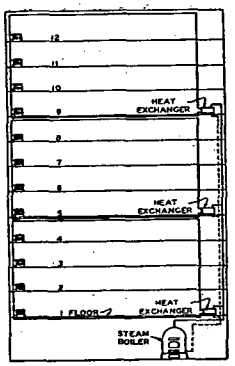


Fig. 19. . . . Boiler Piping for Multiple-Zone Multiple-Purpose Heating System

tures by room thermometers, and the determination of the temperature drop of water flowing through a heating unit or zone by means of surface contact thermometers or thermometers installed in the piping. When adjustment is made by means of water temperature drop, the capacity of the units after adjustment must equal the heat delivery actually required. Control is then accomplished by making the temperature drop through all units equal.

(Provision should be made for expansion in each closed circuit)

Fig. 20. . . . Vertical Zoning of Hot Water Heating System in a 12-Story Building

The procedure for making a permanent adjustment of heat distribution in a larger system should be as follows:

1. Select a time or day when conditions of heat gain are minimum; i.e., nighttime or an overcast day. Outdoor temperatures should be such as to require at least 50 percent of the system capacity to maintain the design indoor temperature.

2. Place the system in operation and make certain that all valves, adjusting fittings, and dampers are in the open position. Automatic control which might reduce the flow or capacity of any unit should be rendered inoperative. Doors and openings between rooms should be closed.

3. Prepare a form for recording data on temperatures in spaces or at the supply and return of heating elements or of zones.

4. After the system has reached equilibrium a complete record should be made of temperatures throughout the system.

5. An initial adjustment of flow regulating devices in the system should be made on the basis of the record of the original readings. A new set of temperature readings should be recorded after sufficient time has been allowed to establish a new equilibrium throughout the building.

6. Continue adjustments of flow control devices until a satisfactory condition is obtained.

7. When a satisfactory adjustment has been accomplished, it is advisable to *mark the position of each of the adjusting fittings or valves.* This facilitates return to proper control settings if the flow controls are disturbed by accidental or emergency changes at any time.

CARE AND MAINTENANCE OF SYSTEMS

A hot water heating system should last during the life of the building if it is designed, installed, and maintained properly. Maintenance instructions for individual elements of the system such as burners, motors, pumps, and accessories may be obtained from the manufacturers who supply this equipment. Two factors contribute in a most important way to the satisfactory operation and life of the hot water heating system: (1) the proper cleaning of the system when installed; and (2) a minimum change of water in the system, except as required by periodic maintenance of the boiler or draining of the expansion tank.

INITIAL CLEANING OF SYSTEM

Rules that should be followed for the initial cleaning of the system are:

1. All equipment and piping should be thoroughly cleaned of iron cuttings and other refuse during assembly and installation.

2. When installation is complete, the system should be filled with a solution of 1 lb of trisodium phosphate per 50 gal of water and should be operated for 24 hr at maximum temperature with all pumps operating. The system should then be drained and thoroughly flushed with water before refilling.

In order to minimize the addition of water to the heating system, the operation of air-vent valves, relief valves, and the tightness of the system generally should be subject to continuous inspection. Drips from automatic air-vent valves should discharge in places where leakage is readily detected. Continual operation of the pressure relief valve should be a signal for the inspection, repair, or replacement of the relief valve, or a check on the operation of the expansion tank or the automatic water feeder, if one is provided.

CHAPTER 29

HIGH-TEMPERATURE WATER SYSTEMS

Features; Basic System; Design Considerations: Boilers, Boiler Piping and Controls, Direct-Contact Heaters and Auxiliary Heat Exchangers, Boiler Feed Pumps, Circulating Pumps; Distribution Piping Design: District Distribution, Pipe, Valves and Fittings, Thermometers and Pressure Gages; Space Heating Equipment; Temperature Control; Water Treatment; Storage

HIGH-TEMPERATURE water systems discussed in this chapter are those operating with supply water at temperatures exceeding 250 F. Operating temperatures range from 250 to 430 F, with pressures from 55 to 350 psig. High-temperature water systems used in the United States are predominantly closed-type systems.

This chapter is intended to give a broad general idea of principles and practices that apply to high-temperature systems and distinguish these systems from the systems operating below 250 F.

FEATURES OF SYSTEMS

The following are among the outstanding features of high temperature as compared to low temperature systems:

1. It is common practice to use greater temperature drops.

2. Supply and return piping may be given the same pitch or grade, or may be run level. Grading is desirable but a definite minimum pitch is not required.

3. Piping may slope up or down or run at a variety of elevations to suit the terrain and the architectural and structural requirements without provision for drainage at each low point except for emptying sections of piping for shutdown. This feature may reduce the excavations required.

4. The pressure in any part of the system must always be above the pressure corresponding to the temperature at saturation in the system in order to prevent flashing of the water into steam.

5. Processes requiring different temperatures of water may be served at their required temperatures by use of heat exchangers, by regulating the flow to certain processes, by placing some processes in series with others, etc.

6. Heat may be stored in the mains and boiler by build-up of temperature in the return main during periods of light load.

THE BASIC SYSTEM

High-temperature water systems are basically similar to the conventional forced hot water heating systems since they require boilers or direct contact heaters for heating the water, expansion or pressurizing tanks or both, circulating pumps, distribution piping, and heat transfer or emission equipment, as shown in Fig. 1. The principal differences from the low temperature system are the higher pressure used, the consequently heavier equipment, and the manner in which pressure is maintained on the water. When cushioned by steam in the boiler, the system in effect is a hot water system using a boiler producing steam to heat the water. The supply piping draws water from the boiler below its water level so that water flow may occur even though steam is kept above the surface of the water. For an equivalent heat load the rate of water flow through the boiler is 6 to 10 times that for steam systems.

Water is circulated in a closed circuit from the central station to areas where heat is required and back to the boiler.

The size of installation, the extent of the load, and the operating temperature will govern central boiler-plant design and construction. Some determining considerations are:

1. Type of load: heating, process, or both.

2. Distance from heating plant to space or process requiring heat.

3. Terrain of land on which buildings are located.

4. Zoning requirements based on occupancy and load distribution.

5. Quantity of steam used for power equipment, if required.

Variations in elevation may make it desirable to locate the boiler house on the highest ground in order to obtain maximum static pressure head on the system. Boiler auxiliaries such as boiler feed pumps, pressure tanks, economizers, and system circulating pumps are usually located in the boiler house, as indicated in Fig. 2.

DESIGN CONSIDERATIONS

Factors to be considered in selecting the type of boiler are (1) the maximum operating pressure of the system, (2) the water temperature requirements during a 24-hr operating period, and (3) the size of the load. Process loads may require water at a given minimum supply temperature continuously, while space heating and other loads may permit a lower water temperature at night or an off period during each 24-hr operating period.

Water temperature requirements also influence the manner of pressurizing the system. Simplicity of operation is an important consideration in selecting a method of pressurizing when boilers are not operated during the night. Variations in supply water temperature and temperature drop also should be taken into account in selecting a pressurizing method.

Theoretically, water temperatures up to about 350 F may be provided using boilers and piping suitable for 125 psig, but practically, maximum water temperatures will be limited

by the system design and elevation characteristics to values between 300 F to 325 F. Most systems are being designed with the system circulating pump in the supply line and with a steam drum for pressurization, expansion, and temperature control. In this type of system, the temperature of the water from the steam drum cannot exceed the temperature of the steam in the drum which corresponds to its pressure at saturation. The point of maximum pressure is at the discharge of the circulating pump. If this pressure is to be maintained below 125 psig, the pressure in the drum, corresponding to the water temperature, cannot exceed 125 psig minus the sum of the pump head and the pressure head due to the difference in elevation between the drum and the circulating pump.

Elevation effects and the pressures required to prevent the flashing of water to steam in the supply system can also limit the maximum water temperature that may be used and must, therefore, be studied in evaluating the temperature-pressure relationships of the system.

The properties of water which govern the features of the design are:

1. Temperature vs pressure at saturation (see Fig. 3).
2. Density or specific volume (v_s) vs temperature.
3. Enthalpy or sensible heat (h_f) vs temperature.
4. Viscosity vs temperature.

The relation of temperature and pressure, specific volume, and enthalpy are all discussed in Chapter 3. Data for the normal temperature-pressure ranges are given in Table 3 of Chapter 3. The properties of water for the range 212 F to 400 F are shown in Table 1.

Water temperatures of 350 to 400 F requiring 250 psig working pressure will largely be limited to district and institutional installations. In such applications the heat quantities and distances to be covered usually justify the added cost of the heavier pipe, fittings and special valves.

Boilers

The boiler plants of the larger high-temperature water systems are comparable to boiler plants of power generating stations operating within the same pressure range. The boilers should be selected for size and type in keeping with the load and design pressures. Both steam for power or processing and high-temperature water for heating may be supplied from the same boiler plant. The load is determined by the heat required for:

1. Space heating and winter air conditioning.
2. Generated steam required for power.
3. Water heating or heat processes.

The boilers may be water-tube, horizontal return-tube or Scotch marine type, and may be equipped with any conventional fuel-firing apparatus. Water-tube boilers are favored for higher pressure ranges—200 psig and upward. Boilers may be of either forced circulation or gravity circulation type. The circulating pump of forced circulation boilers must operate continuously during operation of the boiler. Water-tube boilers frequently require separate vessels for the pressure cushions, depending on the volume of the steam drum relative to system requirements. When systems using fire-tube boilers are cushioned by steam, expansion space may be available within the boiler itself.[1] A separate vessel usually is used when the system is cushioned by air or other gas.

Proper distribution of return water and of water flow is essential in all types of boilers to prevent tube failures due to overheating or unequal expansion in boiler tubes.

Expansion Pressure Cushion

Four methods are used to produce and maintain the necessary pressures on the system:

1. A steam cushion in the steam space of the boiler or a steam drum.
2. A separate expansion tank for steam pressurizing.
3. Compression tank with compressed air or an inert gas.
4. An automatic pressure pump.[2, 3, 4]

A steam cushion or a pneumatic cushion is generally favored because it may also accommodate the expansion. The *steam cushion* method for maintaining pressure above the water level in the boiler requires space to accommodate the expansion of the water volume within the system when heated to the system operating temperature. Systems which do not use steam for maintaining the required pressure, or in which the boiler steam space is inadequate to accommodate the change in water volume, will require additional tanks or steam drums for expansion.

The arrangement of the tanks for pneumatic cushioning is similar to the closed expansion tanks when air pressures are used for cushioning or pressurizing. A suitable means of balancing or a connection from the bottom of the tank should be made to the main system return header. (See Fig. 4.)

A major problem when pressurizing by steam is to maintain a proper boiler water level while providing for the change in water volume due to expansion and contraction. Boiler water level and flow connections should be designed to utilize the steam drum in adjusting to changes in water

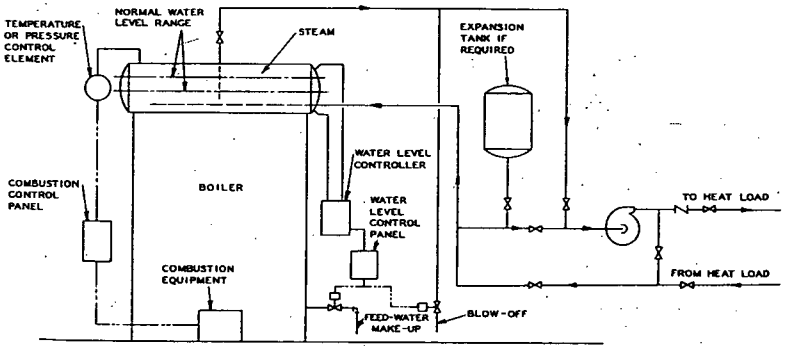

Fig. 4 .... Schematic Arrangement of Combustion and Feed-Water Controls

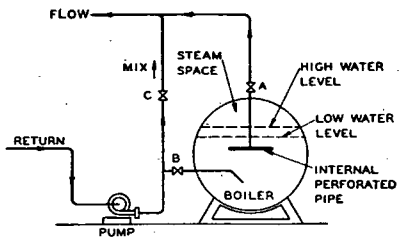

Fig. 5 .... Arrangement of Boiler Piping

volume. The problem of change in water expansion and contraction is minimized by rarely closing down a large system after it is in operation.

When pressurizing with a boiler feed pump automatically operated by pressure control, a relief valve for the maximum system pressure is provided. The pressure control is set to operate the boiler feed pump and feed water from the make-up tank to the boiler whenever the pressure falls to the regulator *cut-in point* setting, and stop when the *cut-out point* is reached. If the pressure increases beyond the safe limit of relief valve setting, excess water will flow through the relief valve to the make-up water tank. Pressurizing may also be done by a continuously operating boiler feed pump.

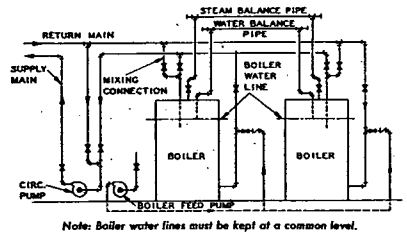

Fig. 6 .... Piping Connections for Two or More Boilers in High-Temperature Water Systems Pressurized by Steam

Boiler Piping

When the circulation pumps discharge to the system supply piping, the flow main should not rise above the boiler water line high enough to reduce the total pressure sufficiently to permit flashing in the piping. Whether the pump is connected so as to deliver water to the system supply piping or to the boiler inlet line, the arrangement is a complete circuit and the water is returned to the boiler for reheating. The returned water is brought into the boiler below the water line as shown in Fig. 5.[8]

When two or more boilers are used to supply a common load, means must be provided to equalize the flow of water to each boiler (see Fig. 6). Automatic water control is desirable. Balance pipes to maintain equal pressures must be liberal in size as shown in the following table.

Boiler Rating Millions Btuh	Balance Pipe Dia, Inches
2.5	3
5	3½
10	4
15	5
20	6
30	8

Valves should be used in connections to individual boilers when more than one boiler is required as in power plant practice.

Natural or forced circulation may be used to produce internal boiler flow. Internal baffles or distribution pipes are arranged to prevent stratification and promote circulation in the boilers. Arrangements for this purpose vary with the

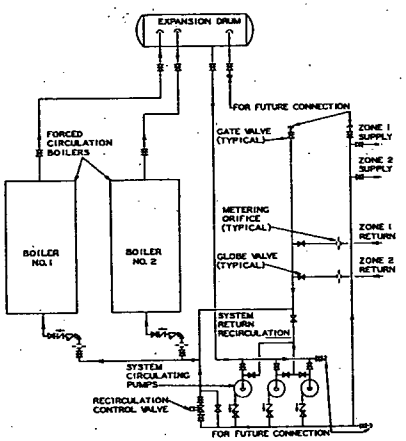

Fig. 7 .... High-Temperature Water Piping for Combined Pump System

various designs. In natural circulation, convection currents and the system circulating pump circulate the water through the boiler. Fig. 7 shows the piping arrangement for the system which is also known as the combined pump system. This method should be used only with boilers having a comparatively low pumping head loss.[8]

In forced circulation boilers a circulating pump takes the water from the steam drum and discharges it back into the boiler, the proper water path being obtained by suitable boiler design. This is referred to as the separate pump system because the boiler circulating pump is separate from the distribution system pumps. One pump is normally used for each boiler to draw water from the expansion drum, circulate it through the boiler and return it to the expansion drum (Fig. 8). The system circulating pumps draw water from the expansion drum and circulate it through the distribution system only. The system return is connected to the suction side of boiler circulating pumps or to the expansion drum. This method permits the use of boilers with either high or low head loss.

With steam pressurizing, the water line must be held within proper limits to always provide a water seal at the entrance to the supply flow pipe. Otherwise, flashing or steam bubbling could occur in the supply pipe as the water level rises and falls.

Boiler Controls

Some of the automatic controls indicated in Fig. 4 and extensively used for operating boiler plants are:

1. Automatic combustion and safety control: control of fuel and combustion with flow changes.
2. Water level control: control of make-up and shutdown on low water.
3. Safety valve (steam), automatic relief valve (hot water): on large water systems small additional relief valves should be provided to relieve minor excess pressures.

On installations large enough for high-temperature water heating to be economic, automatic control is usually a worthwhile investment. When package type boilers are used, automatic combustion control and water level control are usually components of the boiler package.

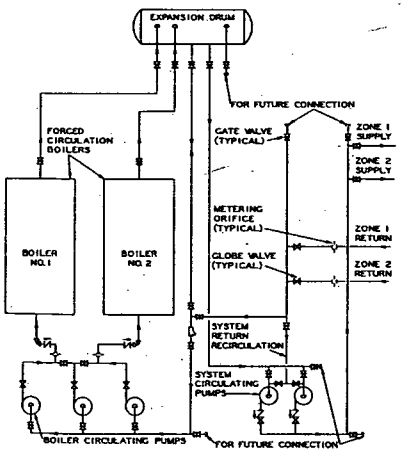

Fig. 8 .... High-Temperature Water Piping for Separate Pump System

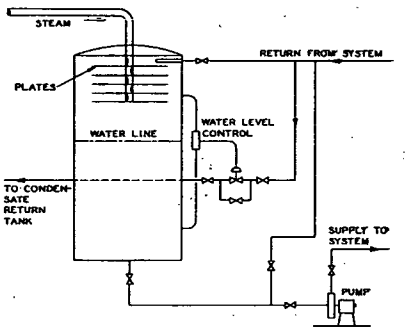

Fig. 9 .... Direct Contact Heater for Generating High-Temperature Water

Direct-Contact Heaters and Auxiliary Heat Exchangers

High-temperature water may be obtained from direct-contact heaters in which steam from turbine exhaust, extractors, or steam boilers is mixed with return water from the system (see Fig. 9). The mixture takes place in the upper part of the heater where the water cascading from horizontal baffles comes in direct contact with steam.

The steam in the upper part of the heater serves as the steam cushion for pressurizing the system. The lower part of the heater serves as the expansion tank for the system.

Where the water heater and the boiler operate under the same pressure, the surplus water is usually returned to the boiler through a pipeline connecting the outlet of the high-temperature water circulating pump to the boiler. This

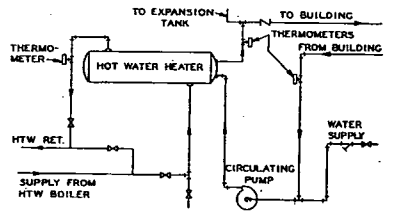

Fig. 10 .... High-Temperature Heat Exchanger Heating Water for Low-Temperature Heating System

system is also applicable where mixed steam and high-temperature water services are required.[1]

Fig. 10 shows a method by which high-temperature water in a heat exchanger heats water for a comfort heating system which uses supply water temperatures of 180 F to 240 F. With high-temperature water at 300 to 350 F a temperature differential between entering and leaving water of approximately 100 deg may be used. Automatic control of such generators or converters is preferable and is discussed in a later section, Temperature Control.

Fig. 11 shows a tubular heat exchanger in which low- or medium-pressure steam is produced by heat transferred from high-temperature water circulated through the tubes. In order to produce the required quantity of steam the mean water temperature in the tubes may need to be within 20 to 30 deg of the original temperature of water in the high temperature system.

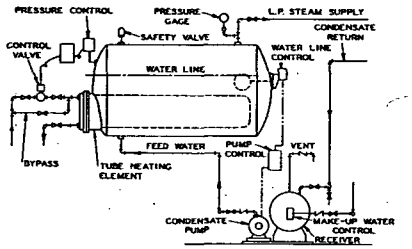

Fig. 11 .... Heat Exchanger Used as Steam Generator

Boiler Feed Pumps

Boiler feed pumps should be provided for supplying make-up water to the boilers where local pressures are, or may be, below the boiler pressure. If the boiler plant supplies steam for heating only, the pump sizes will be small. Boiler feed pumps should, however, have reserve capacity and should have a hot well or receiver whose water level is controlled by automatic means. When steam is used for power purposes, boiler feed pumps must not only return condensate but also supply make-up water to replace wasted condensate.

Circulating Pumps

Circulating pumps for temperatures above 240 F should be built for continuous operation at high temperature. The preferable types have bearings and stuffing boxes that are water cooled. The bed plate and mountings should be designed to permit expansion and contraction without causing misalignment. Since continuity of service depends upon the circulating pumps, they should be installed in duplicate to provide standby service.

It is good practice to locate the circulating pump in the supply line in order to maintain all parts of the distributing system at pressures exceeding boiler pressure. This location is also preferred since water in the system would flash into steam if the pressure in the piping decreased below the pressure corresponding to the temperature of the water at saturation. Connections which permit some return water to bypass the boiler and enter the supply line as a means of preventing flash steam in the flow main are very important.

Sufficient net positive suction head (NPSH) should be available at the pump suction flange. Proper design of the pump piping in this respect will avoid *cavitation*.[2] In selecting a pump its pumping head and water circulation rate must be carefully evaluated in order to permit selection of the proper driving motor. The effect of density variation between the high and low temperature must be considered. Pump characteristics as affected by system characteristics, should be given consideration to insure nonoverloading conditions in pump motor operation.

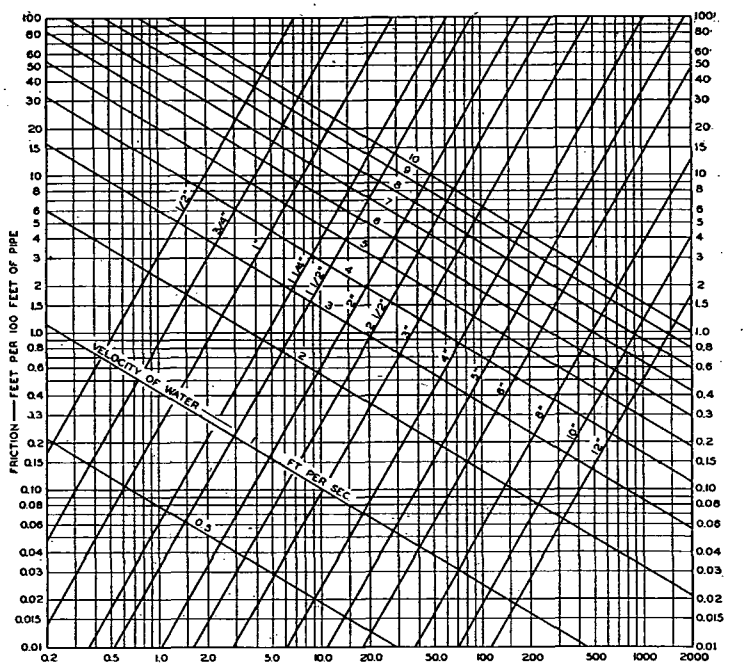
DISTRIBUTION PIPING DESIGN

The arrangement of piping and necessity for zoning will be determined by such factors as the hours of operation, the nature of the space occupancy, and the required water temperature. These factors, together with the heat requirements of the equipment served, will establish the temperature drop which, in common practice, may range from 80 to 150 deg.

Economic considerations require that the savings due to use of small pipe and high velocity circulation be balanced against the cost of valves, pumps, etc., that are suitable for operation at the high friction loss and pressure. The best overall investment will be secured when there is a proper relation between first cost, operating cost (including that of the operating personnel), and the fixed charges.

Fig. 12 shows the relation (based on the Fanning formula in Equation 8 of Chapter 4) of the water flow in thousands of pounds per hour to the friction loss in feet of 62 F water at a mean temperature of 300 F in Schedule 40 commercial steel pipe in sizes ½ to 12 in. The temperature 300 F is a normal mean between flow and return temperatures in the system. Correction of friction loss for other temperatures may be obtained from Fig. 13. Allowance for friction loss in fittings may be obtained from Table 2.

District Distribution



The conventional conduit or tunnel distribution systems are employed with similar techniques used for installation. Although the mains may be run at different elevations at will, it is important that high points be vented and the low points drained by the air collection and venting arrangement described earlier. Grading is not critical. See Chapter 27, District Heating.

The piping serving each building or process load should have a valved bypass connection between the supply and the return pipe in addition to the usual stop valves as indicated in Fig. 1.

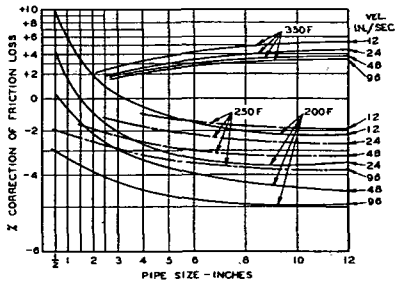
Pipe, Valves, and Fittings

All pipe, valves, and fittings used in high-temperature systems should comply with the requirements of the *American Standard Code for Pressure Piping*, ASA B 31.1—1955. This code states that hot water systems shall be designed for the highest pressure and temperature actually existing in the piping under normal operation. This pressure is the cushion pressure plus pump head plus static pressure.

Individual heating equipment units should preferably be installed with a lock-shield valve for balancing the flow and a separate valve for shut-off. These may be placed in the most convenient position for accessibility. If the unit is to be isolated for service, valves will be needed in both the supply and return piping to the unit. Valve trim should be of stainless steel or other alloy that will prevent corrosion.

(Friction given in feet of 62 F water per 100 ft of pipe.)

Fig. 12 .... Friction Loss for 300 F Water in Commercial Steel Pipe (Schedule 40)



Thermostatically operated valves in the control equipment should be of the electric-motor-operated or pneumatic type. Their selection is discussed in a later section, Temperature Control. (See also Chapter 43, Automatic Control.)

High points in piping should be provided with chambers and air vents for collecting and removing air and low points should have provision for sludge removal, as illustrated in Fig. 14.

Loop-type expansion joints, in which the expansion is absorbed by deflection of the pipe loop, are preferable to the packed-metal type. If mechanical expansion joints are used, they should be of the guided type.

As high-temperature water is more penetrating than low-temperature water, leakage due partly to capillary action should not be ignored because even a small amount of leakage vaporizes immediately. This slight leakage becomes noticeable only on the outside of the gland and stem of the valve where thin deposits of salt are left after evaporation.

The insulation of high-temperature water lines is similar to that of steam lines.[3] The selection of the economical thickness of pipe insulation is discussed in Chapter 32.

Fig. 13 .... Correction of 300 F Friction Loss for Other Water Temperatures

Thermometers and Pressure Gages

Pressure gages should be installed in the pump discharge and suction and at locations where pressure readings will assist operation and maintenance. Thermometers (preferably dial type) or thermometer wells should be installed in the flow and return pipes, the pump suction and discharge, and at any other points of major temperature change or where temperatures are of importance in operating the system. Thermometers and gages are desirable in the piping at the entrance to each building, hot water converter, or steam converter. (See Chapter 44.)

SPACE HEATING EQUIPMENT

In industrial areas, space heating equipment may often be operated with high-temperature water due to its availability. Convectors and radiators may require water temperatures in the low and medium temperature range (120 to 180 F or 200 to 250 F) depending upon how close they are to the occupants and upon the pressure for which they are designed. The water velocity through the heating equipment affects its capacity. This must be taken into account in selecting the equipment because, if a large water-temperature drop is used, the rate of circulation is reduced and consequently the velocity of flow may be reduced sufficiently to lower appreciably the rate of heat transfer. (See Chapter 5.)

TEMPERATURE CONTROL

The principles discussed under Control of Flow in Chapter 43 apply to high-temperature water systems, but added consideration should be given to the selection and location of control components.

Valve Selection

Valve selection and sizing are very important because of the relatively high temperature drops and smaller flows encountered in high-temperature water systems. To obtain good control, the valve must be sized so that it is effective over its full range of stem travel. It is recommended that the valve size be selected on the basis of a pressure drop at full flow equal to approximately 50 percent of the pressure difference between supply and return mains at the location of the equipment served. The pressure drop across the valve must not be sufficient to result in a downstream pressure below the saturation pressure at the temperature existing at any point or flashing into steam will result. A valve with equal percentage flow characteristics is desirable. Sometimes two small valves are used rather than one large valve to improve the controllability of the system. Stainless steel trim is recommended, and all valve body materials and packing should be suitable for the high temperatures and pressures encountered. The valve should have a close-off rating at least equal to the maximum head produced by the circulating pump. Generally, two-way valves are more desirable than the three-way type because of the equal percentage flow characteristics and the smaller capacities available in two-way valves. Single-seated valves are recommended in preference to double-seated valves since the latter do not provide tight closing.

Valve Location

Control valves preferably should be located in the return lines from heat transfer units in order to reduce the valve operating temperature and to prevent the high-temperature water from flashing to steam at the lower discharge pressure. Sometimes valves are located as low as practicable to increase the static head at the valve and further minimize the possibility of flashing.

Typical Applications

A typical application is the control of the temperature of water leaving a heat exchanger in which high-temperature water is used as the heating medium. The temperature measuring element should be located where it can best detect changes and thus prevent overheating of the outlet water and possible flashing. When the measuring element is located in the leaving water, there must be a continuous flow through the exchanger and past the element. If the water leaving the exchanger is used for space heating, the set point of the thermostat in this water (which controls the temperature of the leaving water by controlling the inlet temperature to the exchanger) can be readjusted in accordance with outdoor temperature.

Another typical application is the control of a low- or medium-pressure steam generator, usually less than 50 psig, using high-temperature water as the source of heat. In this application a proportional pressure controller in the steam generator supply positions a high-temperature water valve located in the return line to maintain the desired steam pressure.

High-temperature water is sometimes used to supply coils in air handling units where heating surfaces are so placed that possibility of personal contact is avoided. Careful sizing of coil and valve is required to obtain stable control. In some cases face and bypass damper control is used,

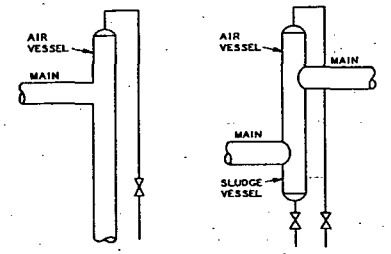

Fig. 14.... Methods of Venting High-Temperature Water Mains

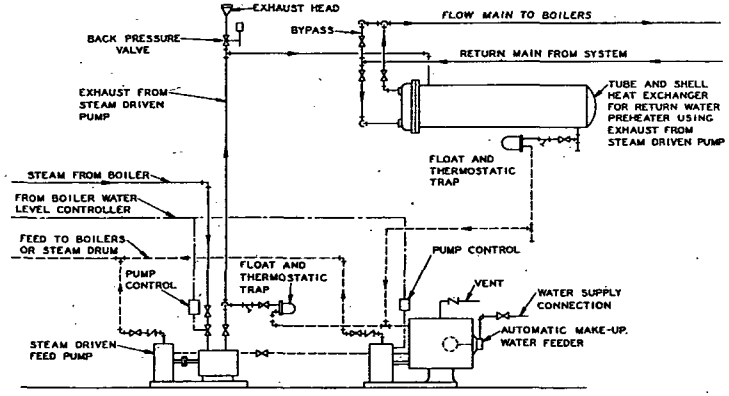

Fig. 15.... Arrangement of Boiler Feed Where Exhaust Steam Is Available

because then the control of water flow through the coil is not as critical.

In some cases face and bypass damper control is used in conjunction with valve control. The coil valve, operating in sequence with the damper, must be closed when the face damper is closed. The coil arrangement should be such as to minimize air temperature pick-up when the bypass damper is at or near the open position.

WATER TREATMENT

Water treatment is seldom required where there is continual re-use of the water. Where none of the water is lost, except such minor amounts as may accompany venting or be due to occasional leakage at stuffing boxes, it is usually sufficient to make the water slightly alkaline when the system is first filled. Where the make-up water is appreciable, treatment appropriate to the mineral content and quantity is indicated. See Closed Recirculation Systems in Chapter 55.

It is desirable that systems with steam driven auxiliaries be arranged to conserve the heat in the exhaust. Steam driven auxiliaries can rarely be justified unless the exhaust steam can be used. Usually this is accomplished with a minor addition in capital expenditure. Fig. 15 shows an arrangement for boiler feed where exhaust steam is available.

STORAGE

High-temperature water systems may be operated to even out the peak loads and low loads within 24-hr cycles by storage. Storage is usually accomplished by the bypassing of water from the flow to the return mains and thereby storing heat in the return main for future use, or storing heat in accumulators. Systems which experience normal peaks may obtain as much as 15 percent added capacity through such heat storage.

CHAPTER 30

PANEL HEATING

Application Methods: Embedded Piping for Ceilings, Walls, or Floors; Warm Air and Electrically Heated Ceilings, Walls, or Floors; Output from Panel Surfaces: Radiation, Convection and Combined Heat Transfer, Panel Heat Losses; Design of Panel Heating Systems: Warm Water Panels for Plaster, Metal, and Concrete Ceilings; Wall Panels and Concrete Floor Panels, Installation Details and Accessories, Controls; Warm Air and Electric Panels

IN this chapter the term, Panel Heating, is used to describe a method of space heating in which heat is supplied by large heated areas of interior room surfaces operating at relatively low surface temperatures (80 to 125 F). The heating elements usually consist of warm water piping, warm air ducts, or low temperature electrical resistance elements embedded in, or located behind, ceiling, wall, or floor surfaces.

Panel heating may be considered as another method of convenient and effective space heating. The heat loss requirements may be calculated in the conventional manner except that the heat loss through the area occupied by the heated panel need not be included. An assumed or computed reverse heat loss from the panel, however, should be included in determining heating main size and the boiler load. The heat release from the panel is expressed in terms of hourly heat output per square foot of surface. The room air temperatures to be maintained are approximately the same as those maintained by heating systems employing cast-iron radiators, convectors, or warm air ducts.

This chapter does not include a separate discussion of such topics as the influence of radiation on human comfort, the mechanisms by which human beings release heat, and other similar topics that apply to all methods of heating interior spaces for human comfort. The reader is referred to Chapter 6 for a detailed discussion of these subjects.

APPLICATION METHODS

The great majority of panel installations of the past 50 years (which is the period of the modern utilization of this method of heating) have used warm water as the heating medium which is circulated in embedded piping. More recently, the use of warm air ducts, and embedded electrical heating elements, has come into favor, especially where specific local factors have influenced such use. Steam has been used only occasionally because of the problems which result from its higher temperature.

When the heating medium is warm water, both ferrous (steel or wrought iron) or non-ferrous (generally copper or aluminum) pipe or tube are used widely in ceiling, wall, or floor panel construction. Tube sizes used are ⅜, ½, ⅝, and ¾ in. OD, while piping is generally ½, ¾, or 1 in. IPS. Where coils are embedded in concrete or plaster, no threaded joints should be used for either pipe coils or mains. The construction should be of all-welded type. Changes in direction should be made by bending the pipe itself, rather than by use of fittings. Solder-joint fittings are used for non-ferrous heating coils and piping. It is recommended that a medium temperature solder of 95 percent tin—5 percent antimony, or capillary brazing alloys, be used. All piping should be subjected to a hydrostatic test of at least three times the working pressure, but not less than 150 psig.

The most common forms of panels applied in panel heating are: (1) embedded piping for ceilings; (2) embedded piping for walls; (3) embedded piping for floors; (4) air heated ceilings, walls, or floors; (5) electrically heated ceilings, walls, or floors.

Embedded Piping for Ceilings

When piping is embedded in ceilings, the construction used is generally one of the following:

a. Pipe or tube is embedded in the lower portion of a concrete slab, generally very close to its lower surface. If plaster is to be applied to the concrete, the piping may be placed directly on the wood forms. If the slab is to be used without plaster finish, then the piping should be installed not less than ¾ in. above the undersurface of the slab. Fig. 1 shows this method of construction. The minimum coverage must be in compliance with the local building code requirements.

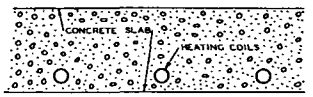

Fig. 1 . . . . Coils in Structural Concrete Slab

b. Pipe or tube is embedded in a metal lath and plaster ceiling. If the lath is suspended to form a hung ceiling, both the lath and the heating coils are securely wired to the supporting members in such a way that the lath is below, but in good contact with the coils, as shown in Fig. 2. Plaster is then applied to the metal lath, care being taken to embed the coil, as shown in Fig. 2.

c. Copper tube of the smaller diameters is attached to the underside of wire lath or gypsum lath. Plaster is then applied to the lath to embed the tube, as shown in Fig. 3.

d. Other forms of ceiling construction are prefabricated panels of metal, composition board, wood paneling, etc., having warm water piping, tube, or channels built into the panel sections.

Coils are usually of the sinuous type, although some header or grid type coils have been used in ceilings. Coils may be of either ferrous or non-ferrous pipe or tube, with coil pipes spaced from 4½ to 9 in. on centers, depending on the required output, pipe or tube size, and other factors.

Where plastering is applied to pipe coils, a standard three-coat gypsum plastering specification[1] is followed, with a minimum of ⅜ in. of cover below the tubes when the tubes

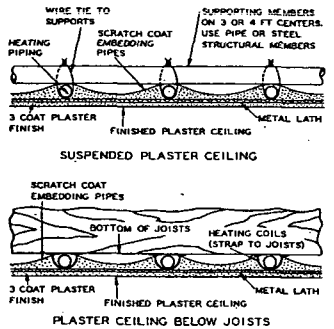

Fig. 2 .... Coils in Plaster Above Lath

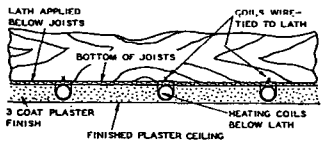

Fig. 3 .... Coils in Plaster Below Lath

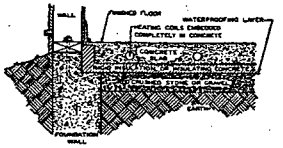

Fig. 4 .... Coils in Floor Slab on Grade

are installed below the lath. Generally, the surface temperature of plaster panels should not exceed 120 F, and this is usually met by limiting the water temperature in the pipes or tubes in contact with the plaster to a maximum temperature of 140 F. Insulation should be placed above the coils to reduce the *reverse loss* which is the difference between the heat supplied to the coil and the net useful output to the heated room.

In order to protect the plaster installation and to assure proper air drying of the plaster, it is recommended that no heat be applied to the panels for two weeks after all plastering work has been completed. When the system is started for the first time, the water supplied to the panels should be at a temperature not more than 20 deg above the prevailing room temperature at that time (but not in excess of 90 F). Water should be circulated at this temperature for about two days. Then the water temperature should be increased at a rate of approximately 5 deg increase per day to 140 F.

During the air-drying and preliminary warming-up periods, adequate ventilation should be provided to carry off moisture from the panels. No paint or paper should be applied to the panels until these periods have been completed. No paint or paper should be applied while the panels are being operated. After paint and paper have been applied, a further shorter warm-up period, similar to that for the first time starting, is also recommended.

Embedded Piping for Walls

Although not so universally used as ceiling panels, wall panels may be constructed by any of the methods outlined for ceilings.

Embedded Piping for Floors

The construction for piping embedded in floors will depend upon whether (*a*) the floor is laid on grade, or (*b*) the floor is above grade.

a. Both ferrous and non-ferrous pipe and tube are used in floor slabs which rest on grade. The coils are constructed as either sinuous-continuous pipe coils, or arranged as header coils with the pipes spaced from 6 to 18 in. on centers. The coils are generally installed with 1½ to 4 in. of cover above the coils. It is recommended that insulation be used to reduce the perimeter and reverse losses. Fig. 4 shows the application of pipe coils in slabs resting on grade. Coils should be embedded completely and should not rest on an interface. Any supports used for positioning the heating coils should be non-absorbent and inorganic. It is suggested that reinforcing steel, angle iron, pieces of pipe, or stone concrete mounds be used. No wood, brick, concrete block, or similar materials should be used for support of coils. Generally, a waterproofing layer is desirable to protect insulation and piping.

b. Where the coils are embedded in structural load supporting slabs above grade, construction codes may affect their position. Otherwise, the coil piping is installed in the same manner as described for slabs resting on grade.

c. A warm-up and start-up period for concrete panels should be similar to that outlined for plaster panels.

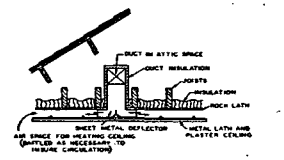

Fig. 5 .... Warm Air Plaster Ceiling Construction

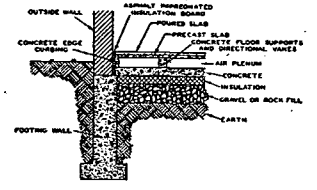

Fig. 6 .... Warm Air Floor Panel Construction

Air-Heated Ceilings, Walls, and Floors

Several methods have been devised to warm the interior room surfaces by circulating heated air through passages behind these surfaces. In some cases, the heated air is recirculated in a closed system. In others, all or a part of the air is passed through the room on its way back to the furnace to provide supplementary heating and ventilation.[2] Figs. 5 and 6 indicate two common types of construction. Care must be exercised to assure compliance with any building codes that might apply. (See also section on Warm Air Ceiling Panel Systems in Chapter 18.)

Electrically Heated Ceilings, Walls, or Floors

Several different forms of electric resistance units are available for heating the interior room surfaces. These include: (1) resistance cables that may be embedded in a manner similar to hot water piping in concrete or plaster; (2) prefabricated electric heating panels to be attached to room surfaces; and (3) electrically heated fabrics or other materials for application to, or incorporation into, finished room surfaces. Figs. 7 and 8 indicate two methods of installation. The constructions of electric panels for ceilings, walls, and floors are described in greater detail in Chapter 17, Electric Heating.

HEAT OUTPUT FROM PANEL SURFACES

A heated panel transfers heat to a room by convection and radiation. In the following paragraphs, the two transfer mechanisms are first considered separately and then combined to facilitate design calculations.

Radiation Transfer

The radiation transfer can be evaluated by means of the Stefan and Boltzmann equation:

$$q_r = 0.173 F_e F_r \left[\left(\frac{T_p}{100} \right)^4 - \left(\frac{T_r}{100} \right)^4 \right] \qquad (1)$$

where

q_r = heat transfer by radiation, Btu per (hour) (square foot).
T_p = temperature of panel heated surface, Fahrenheit, absolute.

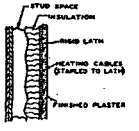

Fig. 7 .... Electric Heating Cables in Plaster

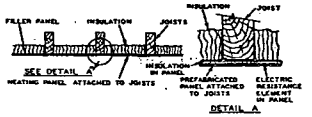

Fig. 8 .... Prefabricated Electric Panel

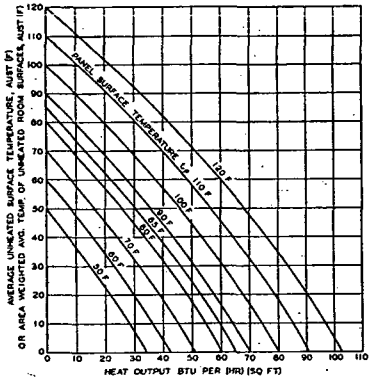

Fig. 9 .... Heat Output by Radiation

T_r = mean radiant temperature of all unheated surfaces, Fahrenheit, absolute.
F_e = the configuration factor (dimensionless).
F_r = the emissivity factor (dimensionless).

A combined configuration and emissivity factor for a simple, box-like room in which there is a *uniformly* heated ceiling, floor, or wall, all other surfaces are at another temperature, and all surfaces are perfectly diffusing is given by Hottel[3] as:

$$F_e = F_e F_r = \frac{1}{\frac{1}{F_{1-2}} + \left(\frac{1}{e_1} - 1 \right) + \frac{A_1}{A_2} \left(\frac{1}{e_2} - 1 \right)} \qquad (2)$$

where

F_e = combined configuration and emissivity factor.
F_{1-2} = view factor = 1.0.
e_1 and e_2 = emissivities of the surfaces.
A_1 and A_2 = areas of the surfaces.

In practice the emissivity of conventional, non-metallic, non-reflecting surfaces will be found to be about 0.9. When this emissivity is used in Equation 2, the combined factor will be found to be about 0.87 for most rooms. Substituting this value in Equation 1, the constant becomes about 0.15 and the equation can be rewritten:

$$q_r = 0.15 \left[\left(\frac{t_p + 460}{100} \right)^4 - \left(\frac{\text{AUST} + 460}{100} \right)^4 \right] \qquad (3)$$

where

t_p = temperature of panel surface, Fahrenheit.
AUST = area-weighted average temperature of unheated surfaces in room, Fahrenheit.

The actual radiation transfer in a room may be somewhat different from that given by Equation 3 because of non-uniform temperatures, irregular room surfaces, variations in

emissivity of materials, etc. It is generally agreed, however, that the equation is accurate to within 10 percent when used in conventional heating and cooling calculations. Tests[4] conducted in the ASHAE Environment Laboratory[5] showed that the value of the constant of Equation 3 was 0.152 in the test room. The design information in this chapter is based on that value of the constant.

Radiation exchange calculated from Equation 3 is given in Fig. 9. The values apply to either ceiling, floor, or wall panel radiation output.

Convection Transfer

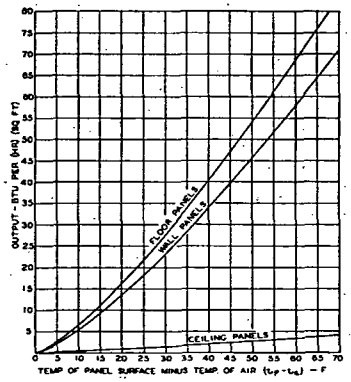
Convection values of heat transfer are not easily established. Convection in a panel heated space is usually considered to be of the *natural* type, that is, air motion is generated by the warming (by conduction) of the boundary layer of air which starts moving as soon as its temperature exceeds that of the surrounding air. In practice, however, there are many factors which interfere with or affect *natural* convection. The configuration of the room and the space connected to it and the variation in temperature throughout the two spaces determine the *natural* convection. Infiltration, ventilation, and the movement of persons may serve to introduce some *forced* convection which can disturb the natural process.

The laboratory approach has been to measure the *natural* convection in a bare, box-like room which is sealed against infiltration and in which all surfaces, except the heated panel, are at one uniform temperature. Convection was also measured with varying amounts of infiltration and a correction determined for use in practical problems.[6, 7]

Tests[4] conducted in the ASHAE Environment Laboratory indicated that the natural convection from floors and ceilings can be calculated from Equations 4 to 9 which follow.

Natural convection from heated ceiling

$$q_c = 0.041 \frac{(t_p - t_a)^{1.25}}{D_e^{0.25}} \qquad (4)$$



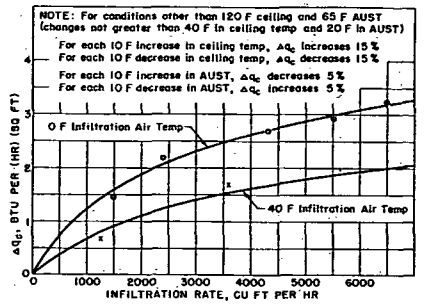


Fig. 10 . . . . Heat Output by Convection from Floor and Ceiling Panels

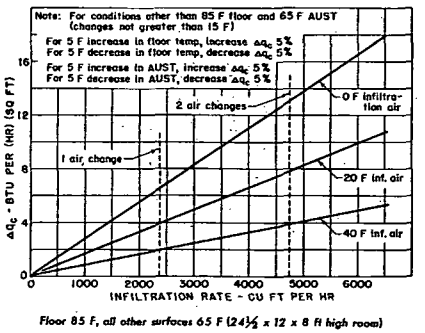
Ceiling at 120 F, all other surfaces at 65 F (24½ x 12 x 8 ft high room)

Fig. 11 . . . . Additional Heat Flow from Ceiling due to Infiltration Air[6]

Natural convection from heated floor



$$q_c = 0.39 \frac{(t_p - t_a)^{1.25}}{D_e^{0.50}} \qquad (5)$$

Natural convection from heated wall

$$q_c = 0.29 \frac{(t_p - t_a)^{1.25}}{H^{0.05}} \qquad (6)$$

where

q_c = heat transfer by convection, Btu per (hour) (square foot).
t_p = temperature of panel surface, Fahrenheit.
t_a = temperature of the air, Fahrenheit.
D_e = equivalent diameter of panel (area × 4 ÷ perimeter), feet.
H = height of wall panel, feet.

Floor 85 F, all other surfaces 65 F (24½ x 12 x 8 ft high room)

Fig. 12 . . . . Additional Heat Output from Floor due to Infiltration Air

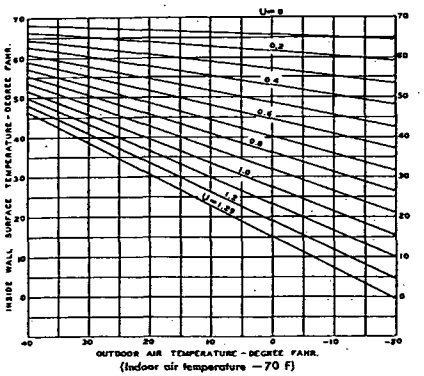


Fig. 13 . . . . Relation of Inside Surface Temperature to Overall Coefficient of Heat Transfer

Measurements of panel performance in furnished test rooms which did not have uniform temperature surfaces showed variations that are not large enough to be significant in heating practice.[6] Other tests[8] established that the effect of room size was also usually insignificant. The convection equations can therefore be simplified to:

Natural convection from heated ceiling

$$q_c = 0.021 (t_p - t_a)^{1.25} \qquad (7)$$

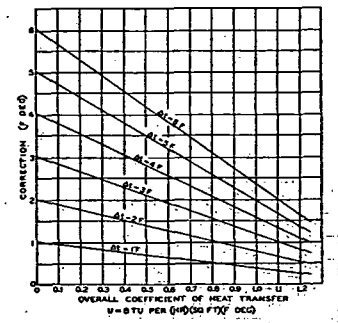
Natural convection from heated floor

$$q_c = 0.32 (t_p - t_a)^{1.25} \qquad (8)$$

Natural convection from heated wall

$$q_c = 0.26 (t_p - t_a)^{1.25} \qquad (9)$$

Fig. 10 shows panel convection outputs calculated from these equations.



Infiltration and ventilation increase the convection from panels. Figs. 11 and 12 show the amount of increase Δq_c observed in the ASHAE Environment Laboratory.[6, 7] Equations 7 and 8 and Figs. 11 and 12 were used in the development of the design data for this chapter.

Combined Heat Transfer

The heat transfer from a panel to a room can be determined by adding the radiant heat transfer from Fig. 9 to the convective heat transfer from Fig. 10.

Use of Fig. 9 requires the calculation of the AUST, the area-weighted average surface temperature of the unheated surfaces in the room. In calculating AUST, the surface temperature of *inside* walls is assumed to be the same as the room air temperature. The surface temperatures of *outside* walls and exposed floors or ceilings can be obtained from Fig. 13 for a 70 F room air temperature. Corrections for other temperatures may be obtained from Fig. 14.

The combined heat transfer for ceiling panels and floor panels in rooms in which the air temperature is 70 to 76 F can be read directly from Figs. 15 and 16, respectively. These two diagrams apply to rooms in which the AUST

$\Delta t = t_a - 70$
If Δt is positive: $t_{ai}' = t_{ai} +$ correction
If Δt is negative: $t_{ai}' = t_{ai} -$ correction
t_a = indoor air temperature
t_{ai} = inside wall surface temperature based on t_a = 70 F
t_{ai}' = actual inside wall surface temperature

Fig. 14 . . . . Inside Wall Surface Temperature Correction for Air Temperatures Other Than 70 F

does not differ greatly from room air temperatures. Tests[6, 7] showed that the two temperatures are normally nearly equal.

Effect of Floor Coverings

Floor coverings may have a pronounced effect upon the performance of a floor panel system. The added thermal resistance of the floor covering causes a reduction in upward heat flow, and increases the heat flow to the underside of the

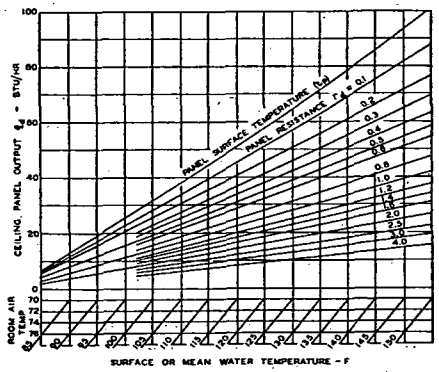


Fig. 15 . . . . Ceiling Panel Design Graph Showing Panel Surface Temperature and Mean Water Temperature vs Output Downward

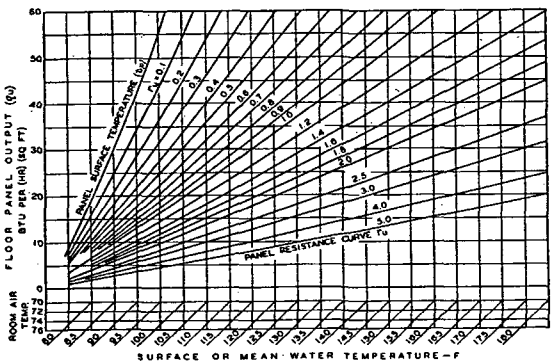

Fig. 16 . . . . Floor Panel Design Graph Showing Panel Surface Temperature and Mean Water Temperature vs Output Upward

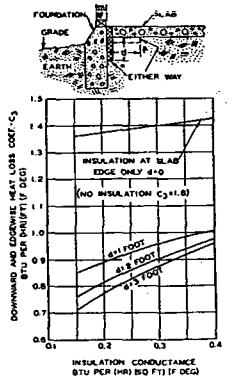

Fig. 17 . . . . Downward and Edgewise Heat Loss Coefficient for Concrete Floor Slabs on Grade

slab. To maintain a given upward heat flow after a floor covering has been added, the temperature of the heating medium must be increased. Data on the thermal resistance of common floor coverings are given in Table 4, and the application of the data is illustrated in *Example 2*.

Where covered and bare floor panels exist on the same system, it is necessary to maintain the water temperature high enough to satisfy the covered panels, and balance the system by throttling the flow to the bare slabs. When possible, it is desirable to divide the covered and bare panels into *separate zones*.

Panel Heat Losses

Heat transferred from the upper surface of ceiling panels, the back surface of wall panels, the underside of floor panels, or the edges of any panel is considered a panel heat loss. Panel heat losses are part of the building heat loss if the heat is transferred outside of the building. If the heat is transferred to another heated space, the panel loss is a source of heat for the space and is not a part of the building heat loss. In either case, the magnitude of the panel loss should be determined.

Panel heat loss to the space outside the room should be kept to a reasonable amount by insulation. Panel heat loss to heated spaces may require reduction by insulation if the amount of heat transferred is excessive or if objectionable temperatures will be developed. For example, a floor panel may overheat the basement below and a ceiling panel may cause the temperature of a floor surface above it to be too high for comfort.

The heat loss from most panels can be calculated by using the coefficients given in Chapter 9, Heat Transmission Coefficients of Building Materials. These coefficients should not be used to determine the downward heat loss from panels built on grade because the heat flow from them is not uniform.[10, 11, 12] The heat loss from panels built on grade can be estimated from Fig. 17.

DESIGN OF PANEL HEATING SYSTEMS

Design Steps

Panel design requires specification of the following: panel area, size and location of the heating elements in the panel, insulation on the reverse side and edge of the panel, required input to panel, and temperature of the heating elements. The procedure is summarized as follows:

1. Calculate the hourly rate of heat loss for each room.
2. Determine the available area for panels in each room.
3. Calculate the required unit panel output.
4. Determine the required panel surface temperature.
5. Select the means of heating the panel and the size and location of the heating elements.
6. Select the insulation for the reverse side and edge of the panel.
7. Determine the panel heat loss and the required input to the panel.
8. Determine the other temperatures which are required or developed.
9. Design the system for heating the panels in accordance with conventional practice.

In the steps outlined for design, the effect of each assumption or choice on comfort should be considered carefully. Tests are now being made at the ASHAE Research Laboratory to identify and measure the factors which contribute to comfort and to establish comfort design principles. Until the results are available the following general rules may be followed:

1. Place panels near the cold areas where the heat losses occur.
2. Do not use high temperature ceiling panels in very low ceilings.
3. Keep floor temperatures at or below recommended limits.

Warm Water Panels

This section contains a simplified procedure for the thermal design of water-heated panels for use in residences and commercial buildings. The procedures are based primarily on the experimental data obtained at the ASHAE Research Laboratory. This work has been reported in a series of research papers which are listed in the references and bibliography at the end of this chapter.

A panel designed by these procedures will maintain the desired room air temperature for the selected outdoor conditions. Room air temperature is the selected criterion of comfort. The design procedure is restricted to situations in which the area-weighted average temperature of unheated surfaces of walls, glass, and floor or ceiling does not differ greatly from room air temperature. Room-scale tests, which simulated various conditions of construction and outdoor temperature, have shown that this near-equality of the two temperatures normally prevails.

The procedures are applicable within the following range:

Outdoor design conditions: Temperatures as low as −30 F.

Room air temperature: 70 to 76 F.

Air changes: No more than two air changes per hour.

Room dimensions: Rooms having normal proportions; ceiling height between 7 and 12 ft.

Room construction: Any type of wall construction and any amount of glass area. (Both, however, have an effect upon comfort.) Conventional interior finishes and furnishings.

Design Examples

In the design examples which follow use is made of the letter symbols shown in the table Letter Symbols for Examples of Design Methods.

Letter Symbols for Examples of Design Methods

A_p = panel area, square feet.

C_1 = coefficient of heat transfer from the *upper* surface of the concrete slab which forms the ceiling panel to air above panel at point t_b, Btu per (hour) (square foot) (Fahrenheit degree temperature difference between panel surface and air).

C_2 = coefficient of heat transfer from *lower* surface of concrete slab to air below the panel at point t_b, Btu per (hour) (square foot) (Fahrenheit degree temperature difference between panel surface and air).

C_3 = coefficient of downward and edgewise heat loss of exposed slab, Btu per (hour) (linear foot of exposed slab perimeter) (Fahrenheit degree difference between concrete surface and outdoor air).

P = length of exposed edge of slab, feet.

q_d = downward heat flow from panel, Btu per (hour) (square foot).

q_{de} = apportioned downward and edgewise heat flow from panel, Btu per (hour) (square foot).

q_u = upward heat flow from panel, Btu per (hour) (square foot).

r_d = total thermal resistance of panel to downward heat flow, (Fahrenheit degree) (hour) (square foot) per Btu.

r_{dc} = thermal resistance of material between the underside of the concrete slab and the ceiling surface below, (Fahrenheit degree) (hour) (square foot) per Btu.

r_{dc} = thermal resistance of bare concrete panel to downward heat flow, (Fahrenheit) (hour) (square foot) per Btu.

r_u = total thermal resistance of panel to upward heat flow (Fahrenheit degree) (hour) (square foot) per Btu.

r_{uc} = thermal resistance of floor covering, (Fahrenheit degree) (hour) (square foot) per Btu.

r_{uc} = thermal resistance of bare concrete slab to upward heat flow, (Fahrenheit degree) (hour) (square foot) per Btu.

t_a = design room air temperature, Fahrenheit.

t_{ao} = outdoor design air temperature, Fahrenheit.

t_b = air temperature above or below panel at point to which U, C_1, or C_2 is taken, Fahrenheit.

t_i = inlet water temperature, Fahrenheit.

t_o = outlet water temperature, Fahrenheit.

t_{mw} = mean water temperature, Fahrenheit.

t_{max} = maximum water temperature permissible for a given construction, Fahrenheit.

t_{mwo} = design mean water temperature (selected for each zone), Fahrenheit.

t_p = panel surface temperature, (exposed surface) Fahrenheit.

t_s = surface temperature of top of concrete slab, Fahrenheit.

U = overall coefficient of heat transfer for the given construction between room air and the point t_b, Btu per (hour) (square foot) (Fahrenheit degree temperature difference).

Procedure for Plaster Ceiling Panels[13]

The procedure for designing a plaster ceiling panel will be illustrated by *Example 1*.

Example 1: Three rooms, A, B, and C, are to have a common water supply temperature; that is, they represent a single zone. They are to be maintained at 72 F air temperature when the outdoor air temperature is zero F. The ceilings of rooms A and B have floors above them with the space heated to 72 F and an air-to-air U value of 0.25 Btu per (hr) (sq ft) (F deg). The ceiling of room C has insulation in the joist spaces and an uninsulated attic space with a combined U value of 0.05 from room C to outdoor air.

Step 1. Heat Loss

Calculate the heat loss of each room by methods outlined in *Chapter 12, Heating Load*, but *do not include* any heat loss through the area covered by the panel.

Room dimensions and calculated heat losses are as follows:

Room	Dimensions Feet	Heat Loss Btu per hour
Room A	11 x 12 x 8	6300
Room B	11 x 12 x 8	2500
Room C	15 x 21 x 8	8000

Step 2. Required Panel Output

Divide the heat loss of each room by the maximum ceiling area in the room which can be used as a heating panel. The result is the minimum heat output per square foot of panel that will satisfy the requirements of the room. The panel that requires the highest output per square foot will generally control the design, because the temperature of the fluid in the system must be high enough to produce the required out-

put from that panel. The required panel output is given in the following table.

Available Panel Area Sq Ft	Required Panel Output, q_d Btu/(hr) (sq ft)
Room A 132 sq ft	$\frac{6300}{132} = 47.7$
Room B 127 sq ft	$\frac{2500}{127} = 19.7$
Room C 306 sq ft	$\frac{8000}{306} = 26.1$

Step 3. Panel Surface Temperature

From Fig. 15 find the panel surface temperature needed to yield the required heat output to each room, using the output determined in Step 2 and the design room air temperature. This use of Fig. 15 for Room A is illustrated in Fig. 15A.

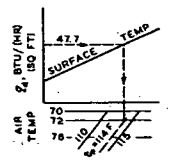

Fig. 15A . . . . Determination of Panel Surface Temperature for Room A from Fig. 15

The values of t_p determined for Rooms A, B, and C are as follows:

Room A t_p = 114 F
Room B t_p = 92 F
Room C t_p = 97 F

Step 4. Upward Heat Flow

Determine the upward heat flow from each panel using Fig. 18. The upward heat flow must be determined in order to obtain the downward panel resistance and to select the proper size of boiler. The use of Fig. 18 is illustrated for Room A in Fig. 18A. Note that the U values shown on Fig. 18 are those

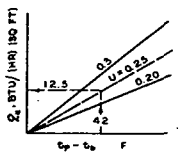

Fig. 18A . . . . Determination of Upward Heat Flow for Room A from Fig. 18

for the entire structure of which the panel is a part and are taken from room air (temperature, t_a) to air above the panel (temperature, t_b) and for that reason $q_u \neq U(t_p - t_a)$. U values may be obtained from Chapter 9, Heat Transmission Coefficients of Building Materials.

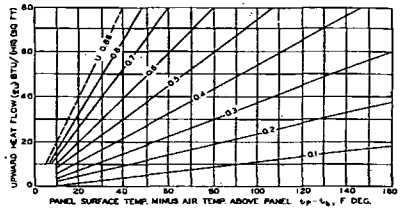

Fig. 18 . . . . Upward Heat Flow from Plaster Ceiling Panel

The values of q_u for Rooms A, B, and C as determined from Fig. 18 are as follows:

Room	U	$t_p - t_a$ F Deg	q_u Btu/(hr)(sq ft)
A	0.25	42	12.5
B	0.25	20	6.0
C	0.05	97	5.0

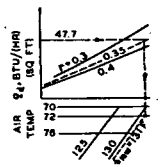
Step 5. Downward Panel Resistance

Assume tentative pipe or tube spacings for the panel construction to be used from those listed in Table 1, choosing the closer spacings when higher outputs are required. Also in Table 1 find the resistance of each panel (r_d), using heat flow ratios calculated from the flow rates determined in Steps 2 and 4, interpolating as required.

Room	Spacing (Inches)	Heat Flow Ratio Resistance (r_d)	
A	4½	$\frac{12.5}{47.7} = 0.26$	0.35
B	9	$\frac{6}{19.7} = 0.30$	0.90
C	9	$\frac{5}{26.1} = 0.19$	0.85

Step 6. Mean Water Temperature

For the required panel output (q_d) found in Step 2, the panel resistance (r_d) found in Step 5, and the room air temperature (t_a), find the mean water temperature (t_{mw}) from Fig. 15. This use of Fig. 15 is illustrated in Fig. 15B.



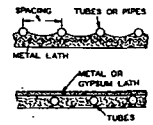


Fig. 15B . . . . Determination of Mean Water Temperature for Room A from Fig. 15

Table 1 . . . . Thermal Resistance of Plaster and Metal Ceiling Panels

	Spacing in.	Thermal Resistance to Downward Heat Flow (r_d) (F deg) (hr) (sq ft) per Btu					
		Heat Flow Ratio, q_u/q_d					
		0	0.2	0.4	0.6	0.8	1.0[a]
Plaster Panels[b] Standard Gypsum Plaster, Three Coats	4½	0.30	0.34	0.38	0.42	0.46	0.50
							
⅜ in. (nom.) non-ferrous tube or ½ in. (nom.) ferrous pipe *above* metal lath tied at 8-inch intervals with good tube embedment, or ⅜ in. (nom.) nonferrous tube *below* metal or gypsum lath.	6	0.45	0.51	0.57	0.63	0.69	0.75
	9	0.75	0.85	0.95	1.05	1.15	1.25
	12	1.15	1.29	1.43	1.57	1.71	1.85
Aluminum Panel[c] 1/16 in. Minimum Thickness 							
pipe or tube installed so that excellent heat conduction to ceiling surface is obtained.	3	0.07	0.07	0.07	0.07	0.07	0.07

[a] Any ceiling panel also acts as a floor panel to the extent of its upward heat flow. If the upward heat flow is high and the space above is occupied, check floor surface temperature for possible foot discomfort (see Reference 7). Also check effect on heating requirements of the space above. It is not good practice to have the major portion of the upper room's heating requirements supplied by the upward heat flow of a ceiling panel below.

[b] Recommended maximum inlet water temperature (t_{mwa}) 140 F.

[c] Recommended maximum inlet water temperature (t_{mwa}) 220 F.

Values of t_{mw} for Rooms A, B, and C as determined from Fig. 15 are as follows.

Room A t_{mw} = 131 F, Room B t_{mw} = 110.5 F, Room C t_{mw} = 119 F

Step 7. Design Mean Water Temperature

Select a single design mean water temperature (t_{mwa}) for each group of rooms which is to comprise a zone, choosing the highest mean water temperature (t_{mw}) of the group subject to the following:

a. If $t_{mw} + \frac{(t_i - t_a)}{2}$ is equal to or less than t_{max} (see Nomenclature and Table 1, this mean water temperature (t_{mw}) is an acceptable design mean water temperature (t_{mwa}). Proceed to Step 8.

b. If $t_{mw} + \frac{(t_i - t_a)}{2}$ is greater than t_{max}, go back to Step 5 and select a panel construction which has a lower panel resistance (r_d). This can be accomplished by either or both of the following:

1. Reducing the tube spacing,

2. Decreasing the upward heat flow (q_u) by providing additional insulation above the panel.

If the required mean water temperature is still too high apply either or both of the following:

1. Reduce the heat loss of the room,

2. Provide supplementary heating.

In Example 1, assume $t_i - t_a$ = 15 F deg and t_{max} = 140 F. Then since t_{mw} = 131 F, $t_{mw} + \frac{1}{2}(t_i - t_a)$ = 138.5 F and is less than t_{max}. Thus 131 F can be used as the design mean water temperature t_{mwa}.

Step 8. Design Panel Output

From Fig. 15, find the panel output (q_d) for design mean water temperature (t_{mwa}), room air temperature (t_a), and panel resistance (r_d). Fig. 15C shows how Fig. 15 is used to find q_d for Room B in this step.

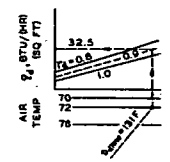

Fig. 15C . . . . Determination of Design Panel Output for Room B from Fig. 15

The mean water temperature (t_{mwa}) found for Room A in Step 6 was used as the design mean water temperature (t_{mwa}). The panel output for Room A which was determined in Step 2 is therefore the design panel output for this room. Design panel outputs for Rooms B and C can be found from Fig. 15 using the design mean water temperature (t_{mwa}).

Room	Design Panel Output (q_d) Btu per (hr) (sq ft)
A	47.7
B	32.5
C	33.0

Step 9. Design Panel Area

Divide the room heat loss found in Step 1 by the design panel output found in Step 8.

Room	Design Panel Area (A_p) Sq ft
A	132 (Unchanged from Step 2)
B	77
C	242

Step 10. Total Panel Output

Add the heat flow upward (q_u) to the design panel output (q_d) and multiply by the design panel area to obtain the total panel output. If the design panel output is different from the panel output (q_d) used in Steps 3 and 4, the heat flow upward (q_u) should be redetermined.

Room	q_u	q_d	$q_u + q_d$	A_p	Total Panel Output $A_p(q_u + q_d)$ Btu/hr
A	12.5	47.7	60.2	132	7946
B	9.5†	32.5	42.0	77	3234
C	5.5†	33.0	38.5	242	9317

† redetermined

Step 11. Fluid Circuit

Design the fluid circuit (panel piping and mains) for a temperature drop of 10 to 20 F deg between the water inlet and outlet of the panel (see Chapter 28, Hot Water Heating Systems).

Step 12. Boiler Size

Size the boiler according to method contained in Chapter 35, Heating Boilers, Furnaces, and Space Heaters. The net Btu rating of the boiler should equal or exceed the total output of all panels plus any other loads on the boiler.

Procedure for Metal Ceiling Panels[12]

Follow the procedure for Hot Water Plaster Ceiling Panels.

Procedure for Concrete Ceiling Panels[13]

Concrete ceiling panels are distinguished from concrete floor panels in intermediate floors by the position of the tubes in the concrete slabs (see Tables 2 and 3). Both types of panels have heat outputs in both directions in amounts determined by the thermal resistances and the temperature differences in the two directions. The effect of both outputs on heating requirements of the spaces and the comfort of the occupants should always be considered. (See section on Procedure for Concrete Floor Panels—Intermediate Slab.)

The procedure for hot water plaster ceiling panels cannot be applied in ite entirety to concrete ceiling panels because some of the simplifying assumptions regarding the upward heat flow from plaster panels are not valid for concrete panels. The necessary modification of the plaster ceiling panel procedure is as follows:

Step 1. Heat Loss

Follow the procedure for Plaster Ceiling Panels, Step 1.

Step 2. Required Panel Output

Follow the procedure for Plaster Ceiling Panels, Step 2.

Table 2 .... Thermal Resistance of Concrete Ceiling Panels

Panel Construction	Spacing in.	Thermal Resistance (F deg)(sq ft)(hr) per Btu					
		Heat Flow Ratio q_u/q_d					
		0		0.5[a]		1.0[a]

	15	3.7	0.30	1.0	0.40	0.9	0.45

[a] Any ceiling panel also acts as a floor panel to the extent of its upward heat flow. If the upward heat flow is high and the space above is occupied, check floor surface temperature for possible foot discomfort (see Reference 7). Also check effect on heating requirements of the space above. It is not good practice to have the major portion of the upper room's heating requirements supplied by the upward heat flow of a ceiling panel below.

Step 3. Panel Surface Temperature

Follow the procedure for Plaster Ceiling Panels, Step 3.

Step 4. Upward Heat Flow Estimate

a. If the upper surface of the slab is exposed to form a floor, find the heat flow upward from Fig. 16, using the panel surface temperature (t_p) found in Step 3, and the air temperature of the space above.

b. If the upper surface of the slab is not exposed, use the equation:

$$q_u = C_1(t_b - t_p) \qquad (10)$$

Table 3 .... Thermal Resistance of Bare Concrete Floor Panels

	15	0.73	0.83	0.57	1.21	0.54	1.73	0.51	2.74

Step 5. Upward and Downward Panel Resistance

Follow the procedure for Plaster Panels, Step 5, using Table 2 to find both resistances (r_{ua} and r_d).

Step 6. Mean Water Temperature and Upward Heat Flow

a. Follow the procedure for Plaster Panels, Step 6.

b. Find the heat flow upward from the panel (q_u) from Fig. 16. Add to the thermal resistance of the slab to upward heat flow (r_{ua}), the resistance to heat flow (r_{ua}) of any material between the upper surface of the slab and the space above to obtain the resistance (r_u) to be used in Fig. 16. The mean water temperature (t_{mw}) found and the air temperature of the space above the panel are the other two factors to be used.

Step 7. Design Mean Water Temperature

Select the highest mean water temperature (t_{mw}) as the design mean water temperature (t_{dmw}).

Step 8. Design Panel Output

Follow the procedure for Plaster Panels, Step 8.

Step 9. Design Panel Area

Follow the procedure for Plaster Panels, Step 9.

Step 10. Total Panel Output

Follow the procedure for Plaster Panels, Step 10.

Step 11. Fluid Circuit

Follow the procedure for Plaster Panels, Step 11.

Step 12. Boiler Size

Follow the procedure for Plaster Panels, Step 12.

Procedure for Plaster Wall Panels

A design graph has not been prepared for wall panels but a design can be approximated using the equations of heat transfer from walls together with the thermal resistance properties of plaster ceilings from Table 2. The procedure for Plaster Ceiling Panels is used as a guide.

Step 1. Heat Loss

Follow the procedure for Plaster Ceiling Panels, Step 1.

Step 2. Required Panel Output

Follow the procedure for Plaster Ceiling Panels, Step 2.

Step 3. Panel Surface Temperature

Assume a trial panel surface temperature and determine the resulting heat output from Figs. 9 and 10 as explained in the accompanying section of the test. (Additional heat flow due to the infiltration can be estimated from Fig. 12, if desired.) Assume successive trial panel surface temperatures until the temperature is found at which the combined heat transfer from the panel equals the output determined in Step 2.

Step 4. Reverse-Side Heat Flow

Follow the procedure for Plaster Ceiling Panels, Step 4.

Step 5. Panel Resistance

Follow the procedure for Plaster Ceiling Panels, Step 5.

Step 6. Mean Water Temperature

For the required panel output found in Step 2, the panel resistance found in Step 5, and the room air temperature, calculate the required mean water temperature as follows:

$$t_{mw} = t_p + r_d(q_d) \qquad (11)$$

Step 7. Design Mean Water Temperature

Follow the procedure for Plaster Ceiling Panels, Step 7.

Step 8. Design Panel Output

From equations, Step 6, and Figs. 9 and 10 find the panel output for design mean water temperature t_{dmw} by successive trials.

Step 9. Design Panel Area

Follow the procedure for Plaster Ceiling Panels, Step 9.

Step 10. Total Panel Output

Follow the procedure for Plaster Ceiling Panels, Step 10.

Step 11. Fluid Circuit

Follow the procedure for Plaster Ceiling Panels, Step 11.

Step 12. Boiler Size

Follow the procedure for Plaster Ceiling Panels, Step 12.

Procedure for Hot Water Concrete Floor Panels (Slab-On-Grade)[12]

The procedure for designing a concrete floor panel (slab-on-grade) will be illustrated by *Example 2*.

Example 2: Three rooms, A, B, and C, are to have a common water supply temperature; that is, they represent a single zone. They are to be maintained at 72 F air temperature

when the outdoor air temperature is zero F. The floors in the three rooms are covered with heavy wall-to-wall carpeting, without a pad. Insulation which has a conductance of 0.4 Btu per (hr) (sq ft) (F deg) is placed along the edge of the slab and extends downward 2 ft below it.

Step 1. Heat Loss

Calculate the heat loss of each room, following the recommendations contained in Chapter 12, Heating Load, but do not include any heat loss through the area covered by the panel.

If very large rooms are involved, the rooms should be subdivided into areas having somewhat similar heat requirements, i.e., separate the interior areas requiring little or no heat input, from the exterior areas directly influenced by outdoor weather conditions. Each such area should then be treated as a separate room for the purpose of design.

Room dimensions, exposure, and calculated heat losses are as follows:

Room	Dimensions Feet	Exposed Wall Feet	Heat Loss Btu per hr
A*	11 x 12 x 8	23	3300
B	11 x 12 x 8	12	2500
C	15 x 21 x 8	21	8000

* Compare with Room A of *Example 1*. The rooms are the same except that in this example a lower heat loss is assumed to permit the room to be heated by a floor panel alone without developing an inadmissibly high panel surface temperature (Step 2). The lower heat loss is presumably the result of adding insulation to Room A.

Step 2. Required Panel Output

Divide the heat loss of each room by the maximum floor area in the room which can be used as a heating panel. The result is the minimum heat output per square foot of panel that will satisfy the requirements of the room. The panel that requires the highest output per square foot will generally control the design, because the temperature of the water in the system must be high enough to produce the required output from that panel.

Room	Available Panel Area Sq ft	Required Panel Output (q_u) Btu/(hr) (sq ft)
A	132	25.0
B	127	19.7
C	306	26.1

Step 3. Panel Surface Temperature

From Fig. 16 find the panel surface temperature needed to yield the required heat output to each room, using the output determined in Step 2 and the design room air temperature.

Floor panel surface temperatures in excess of about 85 F are not recommended because of the probability of discomfort to the feet. If the required heat output cannot be obtained from an 85 F floor panel, heat losses should be reduced or supplementary heating should be provided.

Room	Panel Surface Temperature (t_p)
A	85.0 F
B	82.5 F
C	85.3 F

Table 4 . . . . Thermal Resistance of Floor Coverings

Description	Resistance, r_{ss} (F deg)(hr)/(sq ft)/Btu
Bare concrete, no covering	0.00
Asphalt tile	0.05
Rubber tile	0.05
Light carpet	0.6
Light carpet with rubber pad	1.0
Light carpet with light pad	1.4
Light carpet with heavy pad	1.7
Heavy carpet	0.8
Heavy carpet with rubber pad	1.2
Heavy carpet with light pad	1.6
Heavy carpet with heavy pad	1.9

Step 4. Downward and Edgewise Heat Flow

a. Determine the temperature of the surface of the concrete slab (t_s) by adding to the panel surface temperature, the temperature difference caused by the thermal resistance of the floor covering, if any:

$$t_s = t_p + (q_u \times r_{ss}) \qquad (12)$$

The value of (r_{ss}) for various floor coverings is given in Table 4.

Room	t_p	q_u	r_{ss}	t_s
A	85.0 F	25.0	0.8	105.0 F
B	82.5 F	19.7	0.8	98.3 F
C	85.3 F	26.1	0.8	106.2 F

b. Determine the downward and edgewise heat loss coefficient C_s from Fig. 17 for the insulation to be used. Insulation with a conductance of 0.4 Btu per (hr) (sq ft) (F deg) extending two feet below the slab results in a slab downward and edgewise heat loss coefficient of 0.97 Btu per (hr)(ft) (F deg)

c. Apportion the downward and edgewise heat loss uniformly across the panel as follows:

$$q_{de} = \frac{P \times C_s(t_s - t_{ma})}{A_p} \qquad (13)$$

Room	P	$t_s - t_{ma}$	A_p	q_{de}
A	23	105.0 F	132	17.7
B	12	98.3 F	127	9.0
C	21	106.2 F	306	7.1

Step 5. Upward Panel Resistance

Assume a tentative pipe or tube size and a spacing for each panel, choosing closer spacings and larger pipe or tube when higher heat outputs are required. From Table 3, find the thermal resistance (r_{ss}) of the slab of each panel, using heat flow ratios (q_u/q_{de}) calculated from the flow rates determined in Steps 2 and 4, interpolating as required. To the slab resistance (r_{ss}), add the resistance of the floor covering (r_{sc}, Step 4) to obtain the panel resistance to upward heat flow (r_u).

Room	Pipe or Tube Spacing	q_u/q_{de}	r_{ss}	r_{sc}	r_u
A	9 in.	$\frac{25}{17.7} = 1.41$	0.47	0.8	1.27
B	12 in.	$\frac{19.7}{9.0} = 2.19$	0.55	0.8	1.35
C	9 in.	$\frac{26.1}{7.1} = 3.68$	0.40	0.8	1.20

All rooms: ½-in. pipe or ⅝-in. tube; 4-in. concrete slab.

Step 6. Mean Water Temperature

For the required panel output (q_u) found in Step 2, the panel resistance (r_u) found in Step 5, and the room air temperature (t_a), find the mean water temperature (t_{mw}) from Fig. 16.

Room	t_{mw}
A	116.5
B	109.0
C	116.5

Step 7. Design Mean Water Temperature

Select a single design mean water temperature (t_{dmw}) for each group of rooms which is to comprise a zone, choosing the highest mean water temperature (t_{mw}) of the group. In the example, 116.5 F is chosen.

Step 8. Design Panel Output

From Fig. 16 find the panel output (q_u) for design mean water temperature (t_{dmw}), room air temperature (t_a), and panel resistance (r_u). Also from Fig. 16 find the design panel surface temperature. If it exceeds 85 F (see Step 3) in a room, go back to Step 5 and choose a wider spacing or smaller pipe or tube for that room.

Room	(q_u)	t_p
A	25.0	85.0 (unchanged)
B	24.0	84.5
C	26.1	85.3 (unchanged)

Step 9. Design Panel Area

Divide the room heat loss found in Step 1 by the design panel output found in Step 8.

Room	A_p
A	132 (unchanged)
B	104
C	306 (unchanged)

Step 10. Total Panel Output

Add the apportioned downward and edgewise heat flow (q_{de}) to the design panel output (q_u) and multiply by the design panel area to obtain the total panel output. If the design panel output is appreciably different from the panel output (q_u) used in Steps 3 and 4, the apportioned downward and edgewise heat flow (q_{de}) should be redetermined.

Room	q_u	q_{de}	$q_u + q_{de}$	A_p	$A_p(q_u + q_{de})$
A	25.0*	17.7*	42.7	132	5636
B	24.0	11.6**	35.6	104	3702
C	26.1*	7.1*	33.2	306	10159

* Unchanged. ** Redetermined.

Step 11. Fluid Circuit

Design the fluid circuit (panel piping and mains) for a temperature drop of 10 to 20 F deg between the water inlet (t_i) and outlet (t_o) of the panel (see Chapter 23, Hot Water Heating Systems).

Step 12. Boiler Size

Select the size of the boiler according to method contained in Chapter 35, Heating Boilers, Furnaces, and Space Heaters. The net Btu rating of the boiler should equal or exceed the total output of all panels plus any other loads on the boiler.

Procedure for Hot Water Concrete Floor Panels (Intermediate Slab)[12]

The procedure for designing a hot water concrete floor panel of intermediate slab type is given in the following 12 steps.

Step 1. Heat Loss

Follow the procedure for slab-on-grade construction, Step 1.

Step 2. Required Panel Output

Follow the procedure for slab-on-grade construction, Step 2.

Step 3. Panel Surface Temperature

Follow the procedure for slab-on-grade construction, Step 3.

Step 4. Downward Heat Flow Estimate

A. Follow the procedure for slab-on-grade construction, Step 4, part 1.

B. Estimate the heat flow downward as follows:

1. If the underside of the concrete slab is exposed to form a ceiling, find the heat output downward (q_d) from Fig. 15, using the slab surface temperature (t_s) found in Step 3 as the panel surface temperature (t_p), and the air temperature of the space below.

2. If the underside of the concrete slab is not exposed, use the equation:

$$q_d = C_s(t_s - t_b) \qquad (14)$$

Step 5. Upward and Downward Panel Resistance

Follow the procedure for slab-on-grade construction, Step 5, using Table 3 to find both resistances (r_{ss} and r_{sc}).

Step 6. Mean Water Temperature and Downward Heat Flow

a. Follow the procedure for slab-on-grade construction, Step 6.

b. Use Fig. 15 to find the downward heat flow (q_d). Add to the slab resistance to downward heat flow, (r_{ss}), the resistance to heat flow, (r_{sc}), of any material between the underside of the slab and the ceiling surface, to find the total resistance to downward heat flow (r_d) to be used in Fig. 15. The water temperature (t_{mw}) found above and the air temperature (t_b) of the space below the ceiling are the other two factors to be used.

If the heat flow downward (q_d) differs appreciably from the estimate made in Step 4, repeat Steps 5 and 6 using the calculated value.

Step 7. Design Mean Water Temperature

Follow the procedure for slab-on-grade construction, Step 7.

Step 8. Design Panel Output

Follow the procedure for slab-on-grade construction, Step 8.

Step 9. Design Panel Area

Follow the procedure for slab-on-grade construction, Step 9.

Step 10. Total Panel Output

Follow the procedure for slab-on-grade construction, Step 10, substituting heat flow downward (q_d) for the apportioned downward and edgewise heat flow (q_{de}).

Step 11. Fluid Circuit

Follow the procedure for slab-on-grade construction, Step 11.

Step 12. Boiler Size

Follow the procedure for slab-on-grade construction, Step 12.

Installation Details and Accessories

The design of the two-pipe, direct return forced circulation system which is used in a panel heating system is described generally in Chapter 28, Hot Water Heating Systems. In addition to the usual valves, a balancing valve should be installed in the supply or return connection of each panel in order to permit the heat output of the panel to be balanced with other panels in the same zone.

While all piping should be designed to minimize trapping of air or water, few panel heating systems can be installed to be completely free of air traps. For that reason, panel heating systems cannot usually be filled by flooding nor drained by gravity alone. The system can be filled and the air removed if the system is flushed with a sufficient flow of water. To empty the system a flow of compressed gas is used to assist gravity drainage of the water. Provisions for both flushing and blowing should be included in the piping. Devices for the collection and venting of the gases that will appear during operation should also be provided.

Controls

Automatic controls for panel heating differ somewhat from those described for convective heating because of the thermal inertia characteristics of the panel heating surface and the increase in the mean radiant temperature within the space under increasing loads for panel heating. However, many of the control principles for hot water heating systems described in Chapter 28 will also apply to panel heating. (See also Chapter 43.)

Panels such as concrete slabs have large heat storage capacity and continue to emit heat long after the room thermostat has shut off the supply of heating medium. In addition, there is a considerable time lag between thermostat demand and heat delivery to the space due to the large part of the heat which must first be stored in the thermally heavy radiant surface. This inertia will cause uncomfortable variations in space conditions unless controls for detecting load changes as early as possible are provided.

In general, the temperature of the heating medium supplied to the panel surface should be varied in accordance with outdoor temperature but precautions must be taken to prevent the introduction of excessively hot water which might damage the panels in the event of control failure. A manual boiler bypass or other means of reducing the water temperature may be necessary to prevent too rapid drying out of new panels (see section, Embedded Piping for Ceiling Panels, in this chapter).

Due to the increase in MRT (mean radiant temperature) within a panel-heated space which necessarily takes place as the heating load increases, the air temperature under such conditions, theoretically, should be lowered in the order of 1 or 2 degrees to maintain comfort. In ordinary structures with normal infiltration loads the required reduction in air temperature is small and, consequently, a conventional room thermostat may be used.

In panel heating systems, lowered night temperatures will produce unsatisfactory results with heavy panels such as concrete floors. These panels cannot respond to either quick increase or decrease in heating demand within the relatively short time required, with the result that there will be a very slow reduction of space temperature at night and a correspondingly slow pickup in the morning. Panels of light weight construction, such as plaster or metal ceilings and walls, may respond to changes in demand with sufficient rapidity to obtain moderately satisfactory results from lowered night temperatures. However, very little fuel saving can be expected even with the light panels unless the lowered temperature is maintained for long periods. If reduced nonoccupancy temperatures are employed, some means of providing a higher-than-normal rate of heat input for rapid warm-up is necessary, or a long warmup period should be provided, as explained in Chapter 28.

Warm Air Panels

The first three steps in the design of warm air panels are the same as those outlined for warm water panels and the same performance curves can be used. The balance of the design can be determined from the data in the Chapter on Forced Warm Air Systems and Manual 7-A of the National Warm Air Heating and Air Conditioning Association.

Electric Panels

Electric panel heating systems can be designed by using part of the procedure for warm water panels as a guide. See also Chapter 17, Electric Heating.

Step 1. Heat Loss

Follow the procedure for warm water panels, Step 1.

Step 2. Required Panel Output

Follow the procedure for warm water panels, Step 2.

Step 3. Panel Surface Temperature

Follow the procedure for warm water panels, Step 3.

Step 4. Panel Heat Loss

Determine the heat loss from the panel, using the panel surface temperature found in Step 3 and the factors in Chapter 9, Heat Transmission Coefficients of Building Materials.

CHAPTER 31

PIPE, FITTINGS, WELDING

Pipe Materials, Types of Pipe, Commercial Pipe Dimensions, Threading Practice, Pipe Fittings, Flange Facings and Gaskets, Valves, Welding, Expansion and Flexibility, Hangers and Supports

IMPORTANT considerations in the selection and installation of pipe and fittings for heating, ventilating, and air conditioning are dealt with in this chapter.

PIPE MATERIALS

Use of corrosion-resistant materials for pipe, including special alloy steels, copper, and red brass, has increased considerably during the past few years. The following brief discussion indicates the variety of pipe materials and the types of pipe available.

Wrought-Steel Pipe. Because of its lower cost, the great bulk of wrought pipe used for heating and ventilating work at the present time is of wrought steel. The material used for steel pipe is a mild steel made by the acid-bessemer, the open-hearth, or the electric-furnace process. Ordinary wrought-steel pipe is made either by shaping sheets of metal into cylindrical form and welding the edges together, or by forming or drawing from a solid billet. The former is known as *welded pipe*, the latter as *seamless pipe*.

Many types of welded pipe are available, although the smaller sizes most frequently used in heating and ventilating work are made by the lap-weld, resistance-weld, or butt-weld process. While the lap-weld and resistance-weld processes produce a better weld than the butt type, lap-weld and resistance-weld pipe are seldom manufactured in nominal pipe sizes less than 2 in. Seamless pipe can be obtained in the small sizes at a somewhat higher cost, and is listed as pressure tubing below 2 in.

Seamless steel pipe is frequently used for high-pressure work or where pipe is desired for close coiling, cold bending, or other severe forming operations. Its advantages are its greater strength which permits use of a thinner wall and, in the small sizes, its freedom from the occasional tendency of welded pipe to split at the weld when bent.

Wrought-Iron Pipe. Wrought-iron pipe may be identified by the spiral line marked into each length, either knurled into the metal or painted on it in red or other bright color. Otherwise, there is little difference in the appearance of wrought-iron and steel pipe, although microscopic examination of polished and etched specimens will readily disclose different grain structures.

Cast-Ferrous Pipe. There are now available several types of cast-ferrous metal pipe made of a good grade of cast-iron with or without additions of nickel, chromium, or other alloy. This pipe is available in sizes from 1½ in. to 6 in., and in standard lengths of 5 or 6 ft, with external and internal diameters closely approximating those of extra strong wrought pipe. Cast-ferrous pipe may be obtained coupled, beveled for welding, of with ends plain or grooved for the several types of couplings. It is easily cut and threaded as well as welded. The fact that it is readily welded enables the manufacturers to supply the pipe in any lengths practicable for handling.

Alloy Metal Pipe. Both iron and steel pipe are available in the alloy class. In the case of iron pipe when copper and molybdenum are added, the material is known as alloy wrought-iron pipe.

By common custom steel is considered to be an alloy when the maximum range of alloying elements exceed certain limits such as 1.65 percent manganese, 0.60 silicon, or 0.60 copper. Also, a steel is an alloy if any of the following elements are specified in minimal quantities or within limits: Al, B, Cr (up to 3.99), Co, Cb, Mo, Ni, Ti, W, V, Zr, or any other element added to obtain a certain alloying effect. Small quantities of certain elements are present in alloy steels and are considered as incidental and may be present to the following maximum amounts: copper—0.35 percent, nickel—0.25 percent, chromium—0.20 percent, and molybdenum—0.06 percent.

Commercially, steel is considered stainless when chromium exceeds 3.99 percent regardless of the inclusion of other alloying elements. With *tubing*, however, an alloy becomes stainless when it contains a minimum of 10.5 percent chromium.

The alloy and stainless steels are used for high temperature piping and for highly corrosive fluids and gases.

Copper Pipe and Fittings. Owing to inherent resistance to corrosion, copper and red brass pipe have always been used in heating, ventilating, and water supply installations, but the cost with standard dimensions for threaded connections has been high. The introduction of fittings which permit erection by soldering or sweating, allows the use of tube with thinner walls than would be possible with threaded connections, thereby reducing the cost of installations.

COMMERCIAL PIPE DIMENSIONS

Commercial pipe dimensions are covered in the following specifications of the American Society for Testing Materials: (1) steel—ASTM A-120 and A-53, (2) wrought iron—ASTM A-72, and (3) copper tube—ASTM A-88.

Tables 1 and 2 are based on these specifications.

In addition to the specifications for these three materials, there are standards for copper or red brass IPS, clay or concrete, and cast-iron pipe. Copies of the following specifications may be obtained from the American Society for Testing Materials: (1) steel, wrought-iron, and cast-iron—Series A, (2) copper and red brass—Series B, and (3) clay and concrete—Series C.

Table 3 lists the sizes available in each of the specifications and classes of steel pipe. Note that butt-weld is not available above 4-in. size and that lap-weld, electric-resistance-weld, and seamless are not available below 2-in. size.

[a] 3½ double extra strong is no longer considered in *ASTM* specification but some pipe of this size is still manufactured.

[a] The sizes for wrought iron are approximately the same except wall thickness is slightly heavier. See *ASTM* A-72.

[b] *American Society for Testing Materials* Schedule. The numbers 30, 40, etc., refer to the *ASTM* Schedule; the letter (s) refers to the former designation *Standard Weight*; the letter (x) refers to the former designation *Extra Strong*; the letters XX refer to the former designation *Double Extra Strong*.

[c] Weight per foot is based on plain end pipe. Threaded and coupled (*T and C*) *pipe* is slightly heavier.

[d] Working pressure for welded joints—see formula in Table 3.

(1) Working pressure based on an allowable fiber stress of 6225 psi (for 250 F).

(2) Working pressure based on an allowable fiber stress of 8400 psi (for 250 F).

(3) Working pressure based on an allowable fiber stress of 12000 psi (for 250 F).

Note: Standard-weight pipe is generally furnished with threaded ends in random lengths of 16 to 22 ft., although when ordered with plain ends, 5 percent may be in lengths of 12 to 16 ft. Five percent of the total number of lengths ordered may be jointers which are two pieces coupled together. Extra-strong pipe is generally furnished with plain ends in random lengths of 12 to 22 ft., although 5 percent may be in lengths of 6 to 12 ft.

Listed in Table 3 is the formula for allowable working pressures as given in the *American Standard Code for Pressure Piping*.[1] In this formula is a factor *c*, which is intended as an allowance for corrosion, mechanical injury, manufacturing tolerances, etc. At times this factor seems too conservative; for example, with ⅛-in., Schedule 40, steel pipe, the allowable working pressure is 314 psi. Yet this pipe is tested at 700 psi. The reasoning in establishing the factor *c* which influences the working pressure, is that after nominal use the pipe may not be as sturdy as it was at the time of manufacture. Note that the joint factor, *e*, is not included for plain end non-ferrous pipe as listed in Table 2.

In addition to IPS copper pipe, several varieties of copper tubing are in use with either flared or compression couplings or soldered joints. Dimensions of copper water tube intended for plumbing, underground water service, fuel-oil lines, gas lines, etc., have been standardized by the U. S. Government and the American Society for Testing Materials.

Copper tube is classified in accordance with the wall thickness as follows:

Type K—Heavy Wall.
Type L—Medium Wall.
Type M—Light Wall.
Type DWV—Light Wall—for drainage, waste, and vent service.

In general, Type K is used for underground services and for general plumbing service where corrosion conditions are severe. Type L is used for general plumbing and heating service where conditions may be considered normal. Type M is used for sanitary drainage and other non-pressure applications, for heating, and sometimes for other services less severe than those for which Types K or L are recommended. Type DWV is of lighter weight than Type M, and is used for sanitary drainage and other non-pressure applications. Type DWV tube should not be used underground. Type L is suitable for underground drainage applications. Unless adequately protected, no copper tube should be embedded in a cinder fill. Where flexibility is essential as in hidden replacement work, or where as few joints as possible are desired as in fuel-oil lines, the soft temper is commonly used. In new or exposed work copper tube of a hard temper is generally used. All three types are extensively used with soldered fittings.

Standard dimensions, weights, and diameter and wall-thickness tolerances for these classes of copper tube are obtainable from Table 2. Copper pipe is also available with dimensions of steel pipe.

In refrigeration lines, used in connection with air-conditioning equipment, copper tube is used extensively. For refrigeration use where tube absolutely free from scale and dirt is required, bright annealed copper tube that has been cleaned, dehydrated, and sealed is used. This tube is available in a variety of sizes and wall thicknesses.

THREADING PRACTICE

In all threaded pipe for heating and ventilating installations the American Standard taper pipe thread, ASA B2.1-1945 is used. This thread is cut with a taper of 1 in 16 measured on the diameter of the pipe so as to secure a tight joint. The number of threads per inch varies with the pipe size. Threads for fittings are the same, except that it is regular practice to furnish straight tapped couplings for Schedule 40 pipe 2 in. and smaller. For steam pressures in excess of 25 psi, it is recommended that taper-tapped couplings be used to obtain a tight joint. These may be secured by ordering *line* pipe[a] which is used for oil piping, *the couplings of which* are provided with taper-tapped threads and may be used with regular mill-threaded standard weight pipe. Thread lengths should be in accordance with ASA B2.1. Right-hand threads are used unless otherwise ordered. To facilitate drainage, some elbows have the thread tapped at an angle to provide a pitch of the connecting pipe of ¼ in. to the foot. These elbows are known to the trade as

Notes for Table 2

[a] Weight per foot is based on tube without couplings.

[b] Working pressure is based on the *American Standard Code for Pressure Piping*, published by the *ASME*, revised November, 1952 for plain end tubing (sweat joints).

$$P = \frac{2st_m}{D - 0.8t_m}$$

where P = allowable pressure, pounds per square inch, gage.
s = 6000 psi allowable fiber stress, pounds per square inch.
t_m = minimum wall thickness, inches.
D = maximum OD, inches.

[c] Types K and L furnished in both hard and soft tempers, Type M in hard only. Standard straight lengths are 20 ft. Standard coils (¼ to 1¼ inch) are 60 ft.

Table 3 .... Table of Availability for Steel Pipe

Material	Specification	Available Sizes (Inclusive) Inches Dia	Allowable Fiber Stress S[a] psi
Butt-weld	A-120	⅛ to 4	6,225
	A-53	⅛ to 4	6,750
Lap-weld	A-120	2 to 12	8,400
	A-53	2 to 24	9,000
Electric-resistance	A-53 Grade A	2 59 24	10,200[b]
	A-53 Grade B	2 to 24	12,750[b]
Seamless	A-53 Grade A	2 to 24	12,000
	A-53 Grade B	2 to 24	15,000
	A-120	2 to 12	10,400

[a] For use in the equation $P = \frac{2S(t_m - c)}{D - 0.8(t_m - c)}$

where P = working pressure, pounds per square inch.
S = fiberstress, pounds per square inch.
t_m = 0.875 x wall thickness, inches.
D = OD, inches.
c = joint factor = 0.05 for 1-in. and smaller size or 0.055 for larger than 1-in. size.

See *American Standard Code for Pressure Piping*, published by ASME, revised November, 1953.

[b] For electric resistance welded pipe for applications where the temperature is below 850 F, and where pipe furnished under this classification is subjected to supplemental tests and/or heat treatments as agreed to by the supplier and the purchaser, and whereby such supplemental tests and/or heat treatments demonstrate the strength characteristics of the weld to be equal to the minimum tensile strength specified for the pipe, the S values equal to the corresponding seamless grades may be used.

pitch elbows and are commercially available. All threaded pipe joints should be made up with a thread paste suitable for the service for which the pipe is to be used.

Table 4 contains pertinent threading data for standard weight, extra strong and double extra strong steel, and wrought-iron pipe. The normal engagement of pipe threads is given in Table 5.

PIPE FITTINGS

Pipe is joined by butt welding one length to another or by the use of fittings. Pipe fittings are made in a variety of forms (the common types are listed in Table 6), and are screwed, flanged, or welded. The type of fitting to be used is determined by the pressure of the fluid being carried, or by the intended use of the pipe line. The materials generally used are steel, cast iron, malleable iron (heat treated cast iron), copper, brass, stainless steel, alloy steel, or bronze. The material used also depends upon the pressure or characteristics of the fluid.

Fittings are designated and sized in accordance with American Standards Association specifications and are identified by their nominal pipe sizes.

In the case of reducing tees, crosses, and Y-branches (laterals), the size of the largest run opening is given first, followed by the size of the opening at the opposite end of the run. Where the fitting is a tee or Y-branch (lateral), the size of the outlet is given last. Where the fitting is a cross, the largest side-outlet opening is the third dimension given followed by the opening opposite. The straight line sketches, Fig. 1, illustrate how the reducing fittings are designated.

Where an external thread is wanted the word *male* follows the size of that opening.

Table 4 .... Threading Data for Pipe

Nominal Size[a]	Pipe OD	Standard Weight Threads per Inch[b]	Standard Weight Coupling OD	Standard Weight Coupling Length	Extra and Double Extra Strong Threads per Inch	Extra and Double Extra Strong Coupling OD	Extra and Double Extra Strong Coupling Length

Allowable pressures for solder-type fittings are given in Table 7. Allowable pressures for ferrous screwed, flanged, and welding fittings according to ASA specifications are given in Table 8.

Steel welding (butt or socket type) fittings may be used for the same pressure as the pipe, providing wall thickness (or schedule number), and also the material, are the same as the pipe on which they are used.

Screwed fittings include: couplings, elbows (45° or 90°), return bends (close and open), tees, crosses, laterals (Y-branches), *plugs, caps, lock nuts, flanges, bushings,* and reducing fittings (elbows, tees, and couplings). Reducing fittings and bushings may be eccentrically tapped to permit drainage of condensate.

Sometimes nipples are erroneously called fittings. Actually a nipple is a piece of pipe less than 12 in. long that has been threaded on both ends. Pipe 12 in. or longer is regarded as *cut pipe*. Nipples are classified as *close* or full thread, *shoulder, short,* and *long*. A close nipple is about twice the length of the pipe thread since the threads actually meet. A shoulder nipple has a shoulder between the threads and is further classified as *short* or *long*. All shoulder nipples are cut to specific lengths and sold in that manner.

As a general rule, flanged joints are used when it is expected that the line will be disassembled quite often. There are three types of joints for attaching the flange to the pipe; screwed, welded, or lapped. Types of contact surface will be discussed in the next section.

Tables 9 to 15 give data on various types of ferrous fittings.

Fittings for copper tubing are available in soldered, flared, or compression types (see Figure 2). Fittings for copper pipe of IPS dimensions are available in screwed or soldered types. Table 16 *gives size data for screwed fittings* and Tables 17 and 18 give data for solder-type fittings for copper tube and pipe.

Table 7 . . . . Service Pressure Ratings for Wrought-Copper or Bronze Solder Joint Fittings[a]

Type of Solder	Service Temp., F	Maximum Service Pressure, Psig: Water ⅛ to 1 in.[b]	Water 1¼ to 2 in.[b]	Water 2½ to 2 in.[b]	Steam (All)
50-50 Tin-lead (ASTM B32 Alloy Grade 50A)	100	200	175[c]	150[d]	—
	150	150	125[c]	100[d]	—
	200	100	90[c]	75[d]	—
	250	85	75[c]	50[d]	15[e]
95-5 Tin-antimony or 95-5 Lead-tin (ASTM B32 Alloy Grade 5A)	100	500	400	300	—
	150	400	350	275	—
	200	300	250	200	—
	250	200	175	150	15
Solders with melting point 1100 F or above	350	270	190	155	120

Note: Ratings other than specified here may be used upon the recommendation of the manufacturer as to the proper solders that should be used.

[a] Extracted from *American Standard for Wrought Copper and Bronze Solder Joint Fittings*, B16.22-1951.

[b] Standard water tube sizes except 1.3 in., which is ¼ in. OD seamless copper tubing for refrigerator service, etc. (*ASTM* B68).

[c] These pressures may be used for cast-brass fittings (*ASA* B16.18-1950) for sizes 2 in. and smaller.

[d] These pressures may be used for cast-brass fittings (*ASA* B16.18-1950) for sizes 2½ in. and above.

[e] Also allowable for cast-brass fittings (*ASA* B16.18-1950).

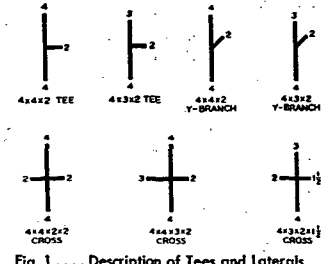

Fig. 1 . . . . Description of Tees and Laterals (ASA B16.3—1951)

Table 8 . . . . ASA Specifications and Pressures for Ferrous Screwed, Flanged, and Welded Fittings

Type of Fitting	Specification	Saturated Steam Pressure Psig[a]
Cast Iron—Flanged	B16.1	125
Cast Iron—Flanged	B16b	250
Cast Iron—Flanged	B16b1	800
Cast Iron—Flanged (refrigeration)	B16.16	300
Cast Iron—Screwed	B16.4	125 and 150
Malleable Iron—Screwed	B16.3	150
Malleable Iron—Screwed	B16.19	300
Brass or Bronze—Screwed	B16.15	125
Brass or Bronze—Screwed	B16.17	250
Steel—Flanged	B16.5	2500

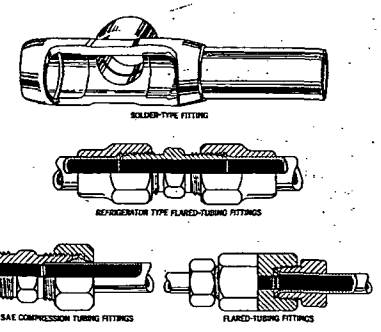
[a] Pressure may reduce with increasing sizes. This pressure is the maximum allowed in this specification for saturated steam. Higher pressures may be allowed with lower temperatures.

The compression-type fitting is generally limited to small sizes of tube, while the flared and soldered types are used in both large and small sizes. An American Standard, ASA A40.2 (1936), has been prepared to standardize dimensions of brass fittings for flared copper tube. Flared tube fittings are widely used in refrigeration work where SAE dimensions and a 45-deg flare render most fittings interchangeable, although for refrigeration use, thread fits and tolerances on thread gages must be maintained within close limits. Brass fittings with SAE dimensions are not interchangeable with the American Standard fittings for water tube.

FLANGE FACINGS AND GASKETS

There are many types of flange facings. The simplest, and the one most commonly used, is the plain face. This type of face is used with fittings shown in Table 10. Other facings, with varying complexity, are used for higher pressures. They include: male and female face (an insert type face), tongue-and-groove (an adaptation of the male and female type), *lapped pipe to flange, lapped pipe to pipe,* and *ring* and groove using neck flanges.

As it is too expensive to machine flange faces sufficiently to provide watertight joints, a gasket is usually inserted between the contact faces of the flanges. The flange bolts then draw the faces up so tight that the gasket deforms into the face imperfections and thereby provides a tight joint.



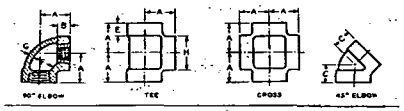


Fig. 2 . . . . Copper or Brass Tube Fittings

Gaskets are made of numerous materials, such as cork, paper, fiber, asbestos, metal (iron, steel, copper, etc.), and combinations of metal and some soft material. The proper gasket material to use depends upon the service of the pipe. The material should not be detrimentally affected by the chemical and thermal conditions of the fluid being carried.

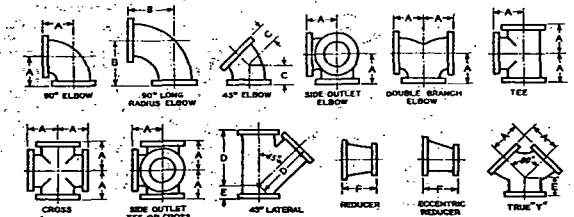
From *American Standard Dimensions of Cast-Iron Screwed Fittings*, Class 125, *AAS* B16.4-1949. All dimensions given in inches.

* This applies to elbows and tees only.

VALVES

Valves are made with the same end connections as fittings. A brief description of each type follows.



1. *Flanged Ends:* Made in sizes from ½ in. up. Used whenever line fittings are flanged and if frequent removal is contemplated. Flanged valves facilitate installation when large sizes are used.

2. *Screwed Ends:* Most common-type end. Can be used for all pressures. Usually confined to smaller size because of difficulty in making large screwed joints.

3. *Welding Ends:* Available in steel only. Generally employed for high-temperature, high-pressure work. Difficult to disassemble in a welded line. This type includes butt-welding or socket-welding. See Tables 11 and 14 for size of fittings available in each class. The valves are made in the same range.

4. *Brazing Ends:* These ends are available on brass valves. The ends have a special shape to facilitate use of brazing alloys. These valves are used for higher temperatures than solder end valves.

From *American Standard for Cast Iron Pipe Flanges and Flanged Fittings*, Class 125, *ASA* B16.1-1948. All dimensions given are in inches.
* Does not apply to true Y's or double-flanged elbows.

5. *Solder Ends:* For use with copper tube in plumbing, heating, and air conditioning. Should not be used at high temperatures.

6. *Flared Ends:* For use with light-wall tubing, either metal or plastic, and for sizes 2 in. and below. A flaring tool flares the tube end, and a ring nut pulls the flared tubing up against a seat on the valve. This makes a lap joint.

7. *Hub Ends:* Generally used for water supply and sewage piping. This type joint is used with cast-iron pipe. The joint is a socket type made by inserting the pipe in the hub, then caulking with oakum. After caulking, the joint is sealed with molten lead.

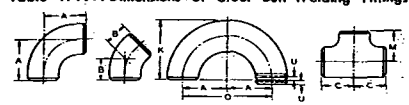
Valves are made of brass, iron, steel, and to some extent malleable iron. Brass should not be used for work requiring temperatures above 550 F. The brass used in valves is similar to that used in brass pipe and contains some tin and lead as well as copper and zinc.

Cast iron is generally provided in some alloyed state, especially in the larger sizes. Cast iron alone is not suitable for service (above 450 F).

Malleable iron, which is a cast iron heat-treated to provide some ductility, is used to some extent, primarily in place of cast iron.

Steel is used either in the cast or forged state. For corrosive service, alloy and stainless steel are used. Steel is used for high temperature, high-pressure work. Steel is the only valve material that can stand appreciable expansion stresses.

The characteristics of valves restrict their use. The five main uses for valves are listed below:



1. *Stopping flow:* The most general use for valves. *Gate* valves are generally used for this purpose. The gate valve operates by a disc moving at right angles to the path of the fluid. The fluid flows straight through the valve, hence, a gate valve offers the minimum resistance when it is fully open. The gate is moved by a stem screw attached to the handle. Gate valves are poor regulators because at nearly closed position (where best regulation is obtained) the fluid velocity either causes vibration and noise, or else tends to erode the disc.

2. *Throttling flow:* This is best accomplished by *globe* or *angle* valves. These valves cause the fluid to change direction, and consequently, offer considerable fluid resistance even when in the open position. Both the globe and angle valves operate by closing a plug into a fitted seat. The angle valve is similar to the globe valve except that the outlet face is at an angle of 90 deg from the inlet face. An angle valve takes the place of a globe valve and an elbow.

3. *Checking flow:* Preventing back flow is called checking, hence, a *check* valve is used. The basic principle of all check valves is that a reversal of flow will close the valve. Check valves are either *swing check* or *lift check*. With a swing check the fluid presses on a hinged flap. If the flow stops or reverses, the flap swings down and seats itself to close the valve. A lift check operates similarly except that the flap is replaced by a plug that is lifted—through guides—by the force of the fluid flow. The fluid changes direction of flow, as in a globe valve, and transmits a vertical thrust. If the flow stops, gravity pulls the plug downward and closes the valve. A reversal of flow will close the valve.

Two other types of valves are the relief valve and the pressure regulating valve. Relief valves are usually spring loaded in order that some predetermined pressure can force the valve to open and relieve the pressure. Pressure regulators are used to reduce a high incoming pressure to a required service pressure. These valves are designed to eliminate a fluctuation in the incoming pressure and thereby maintain a steady, lower service pressure (see Chapter 26).

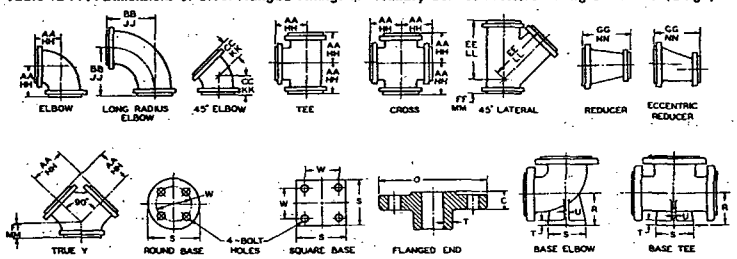
WELDING

Erection of piping in heating and ventilating installations by means of fusion welding has been commonly accepted in the past few years as an alternate method to the screwed and flanged joint. Since the question of economy of welding as against the use of screwed and flanged fittings is dependent on the individual job, the use of welding is generally recommended on the basis of: greatly reduced cost of maintenance and repair; reduced weight resulting from the use of a lighter-weight pipe; or increased economy in pipe insulation, hangers, and supports rather than any economy that might be effected in actual erection by welding on low to medium pressure heating jobs.

Fusion welding, commonly used in erection of piping, is defined as the process of joining metal parts in the molten, or molten and vapor states, without the application of mechanical pressure or blows. Fusion welding embraces gas welding and electric arc welding, both of which are commonly used to produce acceptable welds. Welding processes and procedure are described in various publications.[8]

Welding application requires the same basic knowledge of design as do the other types of assembly, but, in addition, requires a generous knowledge of welding principles and particularly the welding qualities of metal and its reaction to extremely high temperatures. The ability to select and use the proper welding rods is important. This requirement applies equally to employer and employee, with the employer accepting all of the responsibility. Thus the employer should select his welding mechanics with good judgment, provide them with first-class equipment and tools, arrange for their training and use of acceptable workmanship standards, and at regular intervals subject their work to prescribed tests.



Rules for fusion welding of pipe joints, the qualification of welding operators, welding procedures, and testing are contained in the *Standard Manual on Pipe Welding*[8] and in publications of other groups.[7, 8, 9] In general, the wall thickness and chemical analysis of the pipe are the governing factors, not the working pressure. There are a number of safety codes which govern the installation of welded piping in many cities and states.

A complete line of manufactured steel-welding fittings is now available, and a dimensional standard has been prepared under the procedure of the American Standards Association, (see Table 11) to unify heretofore divergent dimensions for the same type welding fittings produced by different manufacturers. Standard dimensions for steel butt-welding elbows, tees, caps, and lapped-joint stub ends are given in Table 11. Dimensions for eccentric and concentric reducers are not shown in Table 11, but are included in the standard.

Steel butt-welding fittings have beveled ends. For wall thicknesses less than 5/16 in., the bevel may be either 37½ deg. or cut square. For wall thicknesses of 5/16 in. to and including ¾ in. the bevel is 37½ deg. For walls larger than ¾ in. but not greater than 1¾ in., the bevel is U-shaped with a slope of 20 deg above the 5/16 in. radius fillet. For walls greater than 1¾ in., the welding ends are prepared as agreed between the manufacturer and the purchaser.

Table 19 contains data on the dimensions of flanged and welding end valves. Dimensions of other type valves can be obtained by writing to the Manufacturers Standardization Society of the Valve and Fitting Industry.

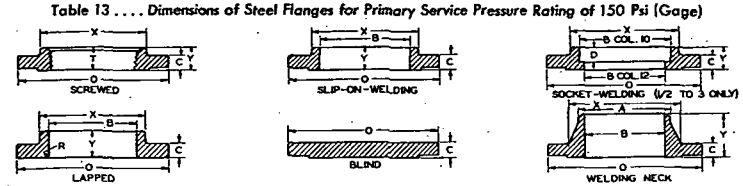
From *American Standard for Steel Pipe Flanges and Flanged Fittings*, 150, 300, 400, 600, 900, 1500, and 2500 Lb. *ASA* B16.5-1953. All dimensions given in inches.
* Actual diameter is same for sizes 1 to 12 in. and is ¾ in. less than nominal for sizes 14 to 24 in.



Flange fittings may be welded from sizes ½ to 24 in. inclusive (see Table 13).

Socket-welding fittings also are commercially available. These fittings have a machined recess for inserting the pipe which is attached by a fillet weld between the pipe wall and socket end. Use of socket-welding fittings generally is restricted to nominal pipe sizes 3 in. and smaller in which range commercial fittings are available. This type of fitting has gained rapid acceptance owing to its ease of installation, low cost, and ability to make a pressure-tight joint without weakening the pipe, as is the case with threading. Dimensions for socket-welding fittings, in accordance with ASA Standard B16.11-1946, are given in Table 14.

EXPANSION AND FLEXIBILITY

Changes in temperature cause a change in dimensions of any matter. The metals that are used for pipe have the same characteristics in that they expand with increasing temperature. If the metal is constrained so that it cannot expand, then an internal compressive stress is set up in the material.

From *American Standard for Steel Pipe Flanges and Flanged Fittings*, *ASA* B16.5-1953. All dimensions given in inches.

This stress can be calculated, just as any other stress, by using Hooke's Law.

$$F = \frac{eEA}{L} \qquad (1)$$

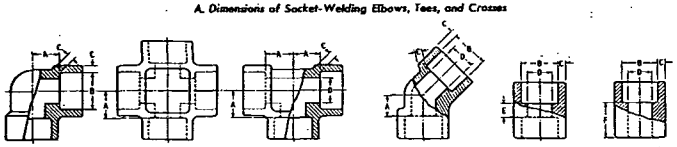
where

F = Force of constraint, pounds.
e = Deformation, inches.
E = Modulus of elasticity, pounds per square inch.
A = Area of metal, square inches.
L = Length of metal, inches.

This equation is valuable in determining the internal stress of the pipe and also the constraining force on the anchors. This equation assumes that the stress is less than the yield strength of the metal. In other words, the metal will return to its original dimension when the temperature returns to its original level.

Materials such as cast iron are not *ductile*, hence the *yield strength* is approximately equal to the ultimate strength. These materials have excellent compressive strength but poor tensile strength. For this reason, it is difficult to bend these materials appreciably. Cast iron, for example, could be put in tension and, from Table 20, it is seen that for a temperature *change of 100 deg, a compressive stress of 7140 psi would be* developed. If the pipe were straight, this stress would be handled easily. If, however, the stress caused a bending moment, then fracture might occur.

The values of stress found in Table 20 were determined by using Equation 1 and substituting Equation 2 for e



$$e = \alpha L \Delta t \qquad (2)$$

where

α = coefficient of linear expansion, inches per inch.
Δt = temperature change, Fahrenheit degrees.

This gives Equation 3

$$F = \alpha E A \Delta t. \qquad (3)$$

Values for α and E are given in Table 21 for various pipe materials, to facilitate determination of the stress in an actual pipe. The following example illustrates the computation of stress.

Example 1: What is the force set up by a 1-in. Schedule 40 steel pipe if the thermal expansion from a 100 deg temperature increase is fully constrained?

Answer: From Table 1, determine that for a 1-in. Schedule 40 steel pipe, the metal area = 0.494 sq in. Then, from Table 21, αE = 195 psi, and from Equation 3

$$F = 195 \times 0.494 \times 100$$

$$= 9630 \text{ lb.}$$

It is interesting to note that length does not enter into the determination of the constraining force. This is so because the stress is a *unit length* function and so is the expansion; therefore, they cancel each other. In other words, if a weight stretches a 10-foot wire 0.10 in., then that *same* weight would stretch a 100-foot wire one inch. In both cases the elongation was 1 part in 1200. The realization that thermal *stress* is independent of length is important, but often overlooked. Nonetheless, that concept explains the feasibility of utilizing the inherent flexibility of the pipe to take care of expansion.

Regardless of the length of pipe between anchors, it is possible to take care of the expansion by putting the force of expansion into the pipe as internal stress.

If the pipe is not straight, then the force of expansion will cause a bending moment. The pipe will then be under a combined stress. The stresses will be longitudinal and transverse, and to a small extent radial. All of these stresses tend to fracture the pipe, and therefore must be added to make up what is called *allowable combined stress*. The *Code for Pressure Piping*, ASA B31.1, published by the ASME, sets up very definite limits for the allowable combined stresses for various pipe materials. For temperatures below 400 F and for piping that is for neither district heating nor power, any standard pipe material may be used. For high-temperature or high-pressure work, some text on expansion and flexibility should be consulted. It is beyond the scope of this chapter to develop the theory of expansion caused by high temperatures.

For the simpler problems encountered for temperatures 400 F and less, which the heating engineer is more apt to encounter, there are four methods of allowing for expansion.

The first method is to use *packless* expansion joints. These joints include types of bellows expansion joints, rubber, corrugated copper and other metals.

Rubber-type joints are generally used in vacuum or low-pressure steam lines. Maximum temperature is generally 180 F. If oil is present in the line, rubber-type joints will be attacked. Travel of these joints is up to 1 inch. The travel to be expected can be calculated by using Equation 2.

The second type of expansion joint is called a *slip* joint. This joint allows for expansion by a sliding of a female member over a male member. The joint is kept tight by means of packing. The packing determines the limit of the temperature to which the joint may be subjected. The main disadvantage to this joint is that it must be continually inspected for a deterioration of the packing. By using double slip joints, the travel may go to several feet, but generally a single joint allows about a foot of expansion. It is common practice to use slip joints up to 250 psi.

The most common method of allowing for expansion in heating systems is to use the swivel joint. This is the third method. The swivel joint was first used with screwed fittings, but it is also used now with welded fittings. With welded elbows, the swivel introduces torsional stress in the elbow and in the swing piece. This type of joint is adequate for taking up the expansion in a header, and preventing fracture of the riser or heating element.

The fourth method is to allow the flexibility of the pipe to absorb the stress of expansion. A technique used to reduce the stress in the expanded pipe is to *cold spring* it before hooking it up. Cold springing can be used to absorb about one-half the stress. The technique is to install the pipe with an opposite stress. For example, if the pipe were to have a compression of 2000 psi, then the pipe would be installed with 1000 psi of tension. For refrigeration, the pipe would be cold sprung in compression.

For conditions not requiring rigorous analysis, it is permissible to use expansion bends designed by means of Equation 4

$$L = 6.16\sqrt{D\Delta} \qquad (4)$$

where

L = length of pipe, feet.

D = OD of pipe, inches.

Δ = deformation, inches (see Equation 2) fiber stress ≤ 16,000 pounds per square inch.

Equation 4 can be used for bends with two fittings, regular U-bend, and offset U-bend, as shown in Fig. 3. It gives the length of pipe, L, that must be used in the U-bend to take up the deformation, Δ. When welding fittings are used, the radii should be six times the outside diameter of the pipe. One other restriction is that the pipe should not be heavier than extra strong.

Manufacturers of pipe, or pipe fittings, often publish excellent treatises on the simplification of expansion problems. It is suggested that the engineer obtain such publications and also a text or handbook[a] on the subject before attempting to solve a problem on flexibility.

HANGERS AND SUPPORTS

In the preceding section, Equation 3 was developed to give the force of total constraint. This equation is appropriate regardless of the sign of Δt, positive or negative. It did not, however, allow for any bending moment but was for straight compression or tension.

If the compressive force is great enough, or if the line is long enough, a slight eccentricity of the load application will cause a *buckling* of the line. This buckling is identical with the action of a column under excessive compression. In fact, a pipe line in compression is identical to a column. Column criteria can therefore be used for selecting the action of supports to resist lateral thrust.

A common equation for determining safe column loads is Euler's formula:

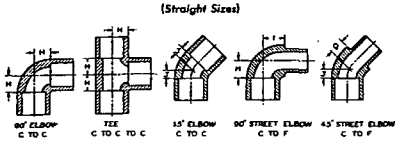
$$S = \pi^2 E \left(\frac{k}{l}\right)^2 \qquad \text{(for cast iron see Equation 8)} \qquad (5)$$

where

S = allowable column load, pounds per square inch.
k = radius of gyration, inches.
l = column length, inches.

$$k^2 = \frac{I}{A} = \frac{(OD)^2 + (ID)^2}{16}$$

Equation 5 is sometimes modified by a correction factor C to the following:



$$S = C\pi^2 E \left(\frac{k}{l}\right) \qquad (6)$$

where

C = correction factor depending on end loading in accordance with the following table:

End Conditions of Column		Value of C
One End	Other End

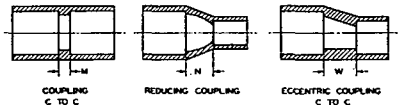
From Equation 6,

$$l = \pi k \sqrt{\frac{CE}{S}} \qquad (7)$$

This equation is not used for column construction but is sufficiently accurate for the work of a heating engineer.



The equation is modified for cast iron because of its poor tensile strength. It is generally acceptable to use one-half the value of S from Equation 5 for cast iron, so the safe column load S_1 for cast iron is

$$S_1 = \frac{\pi^2 E}{2} \left(\frac{k}{l}\right)^2 \qquad \text{for cast iron.} \qquad (8)$$

It is permissible to allow the l/k ratio for steel to go as high as 120, but for cast iron the desirable maximum is taken as 70. It is not to be understood that a fracture will occur at l/k ratios in excess of those given, rather it is to be understood that lateral support should be given for those ratios and for those magnitudes of stress. If an expansion joint is used, this will, of course, relieve the compressive stress.

Example 2: For Example 1 given in the preceding section, the constraining force for a 1-in. pipe was 9630 lb. What is a required spacing for lateral support for this pipe?

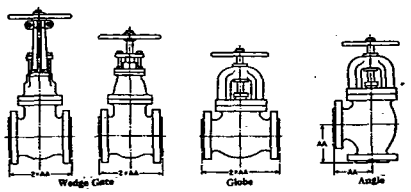
* Not standardized for wrought fittings. Consult manufacturer for dimensions.

Answer: Using Euler's formula, Equation 5 gives

$$S = \pi^2 E \left(\frac{k}{l}\right)^2$$

so

$$l = \pi k \sqrt{E/S}$$



For a 1 in. Schedule 40 steel pipe

k = 0.4205 in.
E = 30,000,000 psi.
S = 9630 ÷ 0.494 = 19500 psi.
l = 51.8 in.

Therefore, lateral supports on 4-ft centers are adequate.

The other type of load requiring some support is the bending stress due to the weight of the pipe, its insulation, and of

Notes for Table 19

From American Standard for Face-to-Face Dimensions of Ferrous Flanged and Welding End Valves, ASA B16.10-1939.

All dimensions given in inches.

Where dimensions are not given, the sizes either are not made or there is insufficient demand to warrant the expense of unification.

Female and groove joint facings have bottom of groove in same plane as *flange edge*, and center to contact surface dimensions for these facings are reduced by the amount of the raised face.

[a] These are pressure designations which refer to the primary service ratings in lb per sq in. of the connecting end flanges.

[b] The connecting end flanges of 175 lb valves are the same as those on 250 lb valves.

[c] The contact surface to contact surface dimensions and connecting end flanges for 600 lb valves 3 in. size and smaller, are identical with those of 800 lb valves; and the contact surface to contact surface dimensions and connecting end flanges for 900 lb valves 2½ in. size and smaller, are identical with those of 1500 lb valves.

Table 20 .... Thermal Stresses Due to Total Constraint

Temperature[a] Change, F Deg	Thermal Stresses, Psi					
	Steel	Wrought Iron	Cast Iron	Brass or Bronze	Copper	Aluminum
20	3900	3800	1428	2760	2980	2700
40	7800	7600	2856	5520	5960	5400
60	11700	11400	4284	8280	8940	8100
80	15600	15200	5712	11040	11920	10800
100	19500	19000	7140	13800	14900	13500

[a] For temperatures between 32 and 400 F.

Table 21 .... Physical Properties for Determining Thermal Stress

(Temperatures between 32 and 400 F)

	Steel	Wrought Iron	Cast Iron	Brass or Bronze	Copper	Aluminum
Coefficient of Linear Expansion, $a \times 10^6$	6.5	6.8	5.95	9.85	9.3	13.5
Modulus of Elasticity, E, psi $\times 10^{-6}$	30	28	12	14	16	10
Product of aE, psi	195	190	71.4	138	149	135

Example: The coefficient of expansion for steel = 0.0000065 in./in. and the modulus of elasticity = 30,000,000 psi. Therefore aE = 195 psi.

Table 22 .... Equations for Bending Stress and Deflection between Supports

Type of Support	Bending Stress, Psi S	Deflection, Inches Y
Single span (free ends)	$S = \frac{0.75\,WL^3D}{I}$	$Y = \frac{22.5\,WL^4}{EI}$
Continuous line	$S = \frac{0.5\,WL^3D}{I}$	$Y = \frac{4.5\,WL^4}{EI}$

W = Total weight (pipe, fluid, etc.) pounds per foot.
D = OD of pipe, inches.
L = Length of span, feet.
E = Modulus of elasticity, pounds per square inch.
I = Moment of inertia, (inches)^4.

$I = \frac{\pi}{64}\left[(\text{OD})^4 - (\text{ID})^4\right]$, OD, and ID in inches.

Table 23 .... Application of Pipe, Tube, and Fittings for Heating and Air Conditioning

Application	Materials Commonly Used
Chilled water	Type K or L hard copper or black steel, Schedule 40
Cooling tower	Type K or L hard copper, wrought iron, or black steel, Schedule 40
Underground water 2-in. and smaller 2½-in. and larger	Type K, soft copper or galvanized steel, Schedule 40 (for corrosive soils, a coated steel pipe should be used) Type K, soft copper, cast iron, Class 150 or galvanized steel, Schedule 40 (for corrosive soils, a coated steel pipe should be used)
City water—inside building	Type K or L, hard copper or galvanized steel, Schedule 40
Underground rain water conductors Small installations Under paved areas Large installations 8-in. and smaller 10 to 24-in. 30-in. and larger 5 feet outside bldg. and under paving	 Vitrified clay or cast-iron soil Cast-iron soil Cast-iron soil XH or vitrified clay Vitrified clay or concrete Concrete Cast-iron soil XH
Interior rain water conductors Small installations Large installations	--- Black or galvanized wrought iron or steel Schedule 40 Cast-iron soil XH, black or galvanized wrought iron or steel, Schedule 40
Panel heating[a]	Type K or L soft copper. Black steel or wrought iron, Schedule 40
Hot water heating[b]	Type K, hard copper or black steel, Schedule 40
Refrigerant[c]	Type K or L hard copper or black steel, Schedule 40
Steam heating Supply 125 psi and less 125 to 250 psi Return pipe All sizes	 Black steel, Schedule 40, standard fittings Black steel, Schedule 40. For fittings see Table 8 Black wrought iron or steel, Schedule 40. Standard fittings
Receiver vent All sizes	Galvanized wrought iron or steel, Schedule 40. Standard fittings
Sanitary[d] Small installations Waste: 1½-in. and smaller 2-in. and larger Vents: 2½-in. and smaller 3-in. and larger Large installations Waste: 2-in. and larger Vents: 2-in. and larger	 Galvanized wrought iron or steel, Schedule 40 Cast iron Galvanized wrought iron or steel, Schedule 40 Cast iron Cast iron Cast iron
Gas (all kinds) All sizes	Black steel, Schedule 40. Malleable iron fittings

[a] Panel heating copper fittings should be soldered with 95-5 solder. Steel fittings should be welded.
[b] All underground feed and return lines buried in slab, should be equipped with fittings as outlined for panel heating.
[c] Refrigerant fittings on copper pipe must be wrought copper. All welded fittings should be long turn.
[d] House sewer to main should be cast iron XH.

the fluid being carried. There is also the bending moment that may be caused by the flexure of the pipe. For this chapter, however, the flexure loading will not be treated for the reason of complexity, as previously stated for the problem of expansion.

Since hangers should always be designed to take the bending moment (including buckling) from the pipe, it is necessary to design the hangers or supports for the maximum bending stress. Even with perfect support spacing there will be some sagging; therefore, the supports should be on a gradient if it is necessary to prevent pockets. Such a condition arises for condensate piping.

Typical bending and deflection equations are given in Table 22 in order that supports can be properly sized, and if necessary, pitched. These equations are typical beam equations. If more complex loadings exist, proper beam equations can be applied. Such equations are found in standard texts on mechanics of materials.

By application of the equations given in this section and the section on Expansion and Flexibility, it is possible to determine the proper location and type of support for straight lines. The types are anchors and hangers.

Anchors are used to guide the expansion (sliding anchors) or to fix the pipe. They are needed to take the stress out of the line and translate the stresses to the foundations. In that way all stress can be taken out of the line before it can be transferred to such equipment as boilers or pumps. By means of solid anchors, the anchors can be used to divide the piping into isolated sections that cannot transmit the stresses to other sections.

Hangers are used to support the piping and to take out the bending stresses. They are of the spring, roller, or rod type. Such types generally allow the free movement of the pipe and yet maintain full support.

The *Code for Pressure Piping*, ASA B31.1, has strict requirements for the materials used in hangers and supports. The structural properties have a safety factor of five, and consequently there is little chance of failure due to a sudden change of load.

There is a type of support for almost every conceivable

requirement. Complete information can best be obtained from a hanger manufacturer.

APPLICATION OF PIPE, TUBE, AND FITTINGS

In the application of pipe, tube, and fittings it is necessary to comply with regulations contained in local codes and ordinances. Table 23 is offered as a guide to current practice in heating and air conditioning. It is based on practice in a number of consulting engineers' offices and information extracted from Reference 7. It should be borne in mind that selection of material to be used will also be influenced by the familiarity of local artisans with methods of using different materials.

CHAPTER 32

PIPE AND INDUSTRIAL INSULATION

Industrial Insulation: Uses, Properties, Temperature Range of Use, Temperature Limitations, Forms; Bare Surface Heat Loss; Conductivities; Heat Flow Calculations; Thickness for Application; Economical Thickness; Low Temperature Insulation; Insulation to Prevent Freezing; Application; Underground Insulations

THE PAST 50 years have seen an enormous increase in the use of thermal insulation by industry. Where once it was not uncommon to see hot water and steam lines, and even boiler surfaces, uninsulated, it is now rare indeed to see any surface operating more than a little above or below ambient temperature without insulation. Higher costs of fuel, increased efficiency of industrial operations, and the necessity for close control of the temperature of industrial processes are among the factors that have caused this greatly increased usage of thermal insulation.

USES OF INDUSTRIAL INSULATION

Thermal insulation serves five principal purposes: (1) to conserve heat or some other form of energy, for example, electrical energy to operate a refrigeration compressor; (2) to increase the comfort of living spaces; (3) to facilitate control of the temperature of a process; (4) to reduce the temperature of the shell of a pressure vessel; and (5) to control the external temperature of the insulated space in order to avoid danger to personnel, to protect surrounding structural members from damage by high temperature, to reduce the temperature of working spaces, and, in case of equipment operating below ambient temperatures, to prevent sweating or icing at the warmer surface. Depending on the application, one or another purpose may govern the choice of insulation; usually two or more are concurrently of importance.

PROPERTIES OF INSULATIONS

Low thermal conductivity is the property that distinguishes a thermal insulation. Thermal conductivity is defined as *the rate of heat flow through unit area of a homogeneous substance under the influence of unit temperature gradient in the direction perpendicular to the area.* Many units have been used to express thermal conductivity but the most common engineering unit is Btu (hour) (square foot) (Fahrenheit degree per inch of thickness). The usual symbol for thermal conductivity is k.

Reflective insulations, such as aluminum and steel coated with a reflecting coating, depend not upon low thermal conductivity for their resistance to heat flow, but upon the low thermal emissivity of their surfaces and subdivision of the air space. To be effective in retarding heat flow by radiation, the reflective surface must face an air space.

Thermal conductivity values of the most commonly used industrial and pipe insulations are shown in Table 1. These values have been selected as typical and useful for engineering calculations, and may or may not apply to a particular material or application. For accurate values for a particular insulation the user should consult the manufacturer or obtain the results of unbiased tests.

Other properties of thermal insulations that are of more or less importance, depending upon the use, are strength, hardness, density, compressibility, specific heat, resistance to high or low temperature, and thermal coefficient of expansion. The final choice of an insulating material for a given purpose usually involves a compromise with regard to several desirable properties. For example, an insulating firebrick must have considerable strength and must be resistant to the temperature to which it is to be exposed. The desirable properties of low conductivity and light weight must be sacrificed to some extent to achieve these necessary properties of strength and temperature resistance.

TEMPERATURE RANGE OF USE OF INDUSTRIAL INSULATION

Since thermal insulation reduces the exchange of heat energy between an insulated surface and its surroundings, it can be useful at any temperature from the lowest to the highest. Actually insulation is used in industrial processes operating at temperatures from −400 F to +3000 F and higher.

At the low end of the scale are processes involving liquefied gases, usually in vessels or piping, at temperatures from the lowest up to about −40 F. From −40 to normal atmospheric temperatures large amounts of low temperature insulation are used for enclosing freezing tunnels, cold storage rooms, and a great variety of food and industrial processes requiring low temperatures.

At normal and near-normal temperatures insulation in building structures is required for economical operation of heating and air-conditioning systems. Insulation for heating and cooling equipment and for the distribution ducts, piping, etc., is, however, usually considered as industrial. The range of temperatures is from that of chilled water or about 32 F up to steam at 100–125 psig (about 350 F).

Drying and baking ovens, small and large boilers, distillation equipment in oil refineries, and high-pressure and superheated steam piping call for insulation suitable up to 1200 F. Petroleum cracking units, heat treating furnaces, and ceramic kilns may reach 2200–2400 F. Still higher temperatures with surfaces to be insulated up to 3000 F are found on melting furnaces for glass, iron, steel, and metals of all kinds as well as furnace enclosures for combustion spaces for many kinds of heating units.

Above 3000 F the variety of materials physically suited for walls and structural parts decreases rapidly with increasing

[a] These temperatures are generally accepted as maximum. When operating temperature approaches these limits the Manufacturer's recommendations should be followed.

temperature. Insulation for conservation of heat energy must, therefore, often be applied so as to permit enough heat to escape to retain mechanical strength.

TEMPERATURE LIMITATIONS OF INSULATIONS

Probably the greatest volume of low temperature insulation is used for temperatures from minus 100 F to atmospheric. The effect of temperature alone on physical integrity is not ordinarily very important for most types in the low temperature field. There are more definite limitations for materials in the high temperature field where decomposition, excessive linear shrinkage, softening, or some other effect of temperature alone will put a maximum limit on the temperature for which a material is suited. As extremes in temperature are approached, both high and low, the selection of a material for a specific service becomes more critical and must be based on experience and factual performance data.

FORMS OF INSULATION

The physical form of industrial insulations varies from powders and loose fills which might be called *formless*, through materials with varying degrees of compressibility and flexibility, to completely rigid shapes often referred to as preformed insulation. After deciding that a material has the necessary insulating value, physical properties, and temperature resistance, the choice of the form desired will usually be governed by considerations of material and application cost. The application method and cost in turn will be greatly affected by the nature of the surface to be covered.

Loose fills such as powders and granules must be supported in place by retaining walls, coverings, etc. for application on vertical surfaces and on the underside of horizontal surfaces. Insulating cement is a loose material which when mixed with water to obtain plasticity and adhesion, may be trowelled on a surface and dried in place to serve as insulation. Both loose-fill and insulating cement are especially suited for covering uneven and irregular surfaces.

Flexible and nonrigid insulations are generally grouped as blanket insulation, and are available in many types and varieties, both organic and inorganic, with and without binders, and with reinforcing coverings on one or both sides. Only inherently fibrous materials are generally suited for blanket insulation. Such materials are wood, cotton, and hair in the organic field, and asbestos and mineral wool in the inorganic field. Coverings and facings such as paper, aluminum, asbestos sheet, wire mesh, metal lath, may be used as reinforcing, vapor barriers, reflective surfaces, or surface finishes in general. Thicknesses and shapes may be of any dimension that can be handled although standard sizes are generally used. Some blanket insulations are prepared in roll form for economical shipping.

Rigid materials are preformed during manufacture to standard lengths, widths, and thicknesses of a size that can be handled readily. In the case of insulation for pipes and cylindrical surfaces the radius of curvature is varied to suit all standard sizes of pipe and tubing. Some materials are offered in shapes curved to fit greater radii up to several feet or more. Material in rectangular dimensions is usually called block, board, or sheets, the name varying with custom for particular uses. Most common sizes of block insulation are 36 in. long, 6 in. or 12 in. wide, and in thicknesses ranging from 1 to 4 in. *Boards* in the building insulation field range up to 12 ft long by 4 ft wide with the thickness usually ½ to 1 in. but ranging up to 1½ in. Smaller *boards*, or sheets, are used on air-conditioning ducts, equipment, and in cold storage.

BARE SURFACE HEAT LOSSES—FLAT SURFACES AND PIPE

Heat losses from or to uninsulated surfaces of pipes, ducts, vessels, or furnaces may be of considerable magnitude if the temperature of the surrounding medium differs appreciably from that of the surface. Losses are increased by motion of the surrounding air or by contact of the hot or cold surface with bodies of high conductivity. Good design, therefore, must include consideration of such heat losses and provision for adequate insulation wherever needed.

The basic principles of heat loss from surfaces are discussed in Chapter 5. In that chapter radiation and convection are treated separately.

Heat losses from horizontal bare steel pipes, based on tests at Mellon Institute and calculated from the fundamental radiation and convection equations (Chapter 5), are given in Table 2. This table also gives the heat losses or surface conductances for flat vertical and horizontal surfaces for surface temperatures up to 1080 F with the surrounding air at 80 F. The surface per linear foot of pipe is given in the second column of Table 2.

Heat losses from tarnished copper pipe and tube are given in Table 3. The surface per linear foot of tube is given in Table 4. Table 3, Section A, of Chapter 9 also gives the surface conductances for flat surfaces of different emissivities and orientations in contact with still air. Table 5 gives the area in square feet of flanges and fittings for various standard pipe sizes. These tables can be used to advantage in estimating the amount of insulation required.

Examples 1 and *2* show how the annual heat loss from uncovered pipe and its dollar value may be computed from the data in Table 2.

Example 1: Compute the total annual heat loss from 165 ft of 2 in. bare pipe in service 4000 hr per year. The pipe is carrying steam at 10 psi pressure and is exposed to an average air temperature of 80 F.

Solution: The pipe temperature is taken as the steam temperature, which is 239.4 F, obtained by interpolation from Steam Tables. The temperature difference between the pipe and air = 239.4 − 80 = 159.4 F. By interpolation in Table 2 between temperature differences of 150 and 200 F, the heat loss from a 2-in. pipe at a temperature difference of 159.4 F is found to be 2.615 Btu per (hr) (sq ft) (F deg). The total annual heat loss from the entire line = 2.615 × 159.4 × 0.622 (linear ft factor) × 165 (linear ft) × 4000 (hr) = 171,100 Mb. (Mb = 1000 Btu.)

Example 2: Coal costing $11.50 per ton and having a calorific value of 13,000 Btu per pound is being burned in the furnace supplying steam to the pipe line given in the previous example. If the system is operating at an overall efficiency of 55 percent, determine the monetary value of the annual heat loss from the line.

Solution: The cost of heat per 1000 Mb supplied to the system = 1,000,000 × 11.5 (dollars) ÷ [13,000 (Btu) × 2000 (lb) × 0.55 (efficiency)] = $0.804. The total cost of heat lost per year = 0.804 × 171.1 (thousand Mb) = $137.56.

CONDUCTIVITY OF INDUSTRIAL INSULATIONS

The conductivities of various materials used for insulating steam and hot water systems are given in Table 1. They are given as functions of the mean temperatures or the arithmetic mean of the inner and outer surface temperatures of the insulations.

Values are for Flat Surfaces four square feet or more in area.

[a] To secure losses per linear foot, multiply sq ft losses in table by this factor. The losses per sq ft of pipe surface for pipes larger than 24 in. can be considered the same as the losses for the 24-in. pipe.

between the pipe and the surrounding atmosphere up to 525 F, are shown in Figs. 1, 2, and 3.

The actual thickness of many molded pipe coverings is not exactly 1 in. However, the loss through any given thickness of insulation can be obtained by interpolation.

The heat losses through 1, 1½, and 2-in. thick block, blanket, or cement insulation when applied to a flat vertical surface is given in Fig. 4.

The losses through any of the insulations given in Table 1 can be obtained by multiplying the losses obtained from Figs. 1, 2, 3, or 4 by the factors given in Table 6.

Pipes operating at high temperatures are frequently insulated to the best advantage by combining a high temperature insulation near the pipe with a moderate or low temperature insulation around it as an outer layer. By this method an efficient material may be used for each of the two temperature ranges encountered. In calculating the heat loss through such a combination the mean temperature of each layer must be determined along with the thickness of each. This is readily done in two or three calculations performed as a series of approximations, in which assumptions of thickness and mean temperature are adjusted as indicated in the discussion which follows.

In the case of a single thickness of pipe covering, the quantity of heat transferred per square foot of outer surface of the insulation is given by the equation:

$$q_o = \frac{k(t_1 - t_2)}{r_1 \log_e \frac{r_2}{r_1}} \qquad (1)$$

where

q_o = Btu per (hour) (square foot of outer surface of insulation).
r_1 = outer radius of pipe or inner radius of insulation, inches.
r_2 = outer radius of insulation, inches.
k = thermal conductivity of insulation, Btu per (hour) (square foot) (Fahrenheit degree per inch).
t_1 = temperature of inner surface of insulation, Fahrenheit.
t_2 = temperature of outer surface of insulation, Fahrenheit.

Table 3 .... Heat Loss from Horizontal Tarnished Copper Pipe[a]

Expressed in Btu per (hour) (linear foot) (Fahrenheit degree difference between the pipe and surrounding still air at 70 F)

Nominal Pipe Size (Inches)	Hot Water (Type K Copper Tube)				Steam (Standard Pipe Size Pipe)

3½	1.180	1.350	1.454	1.535	1.750	2.020	2.170
4	1.460	1.500	1.635	1.715	1.941	2.240	2.430
4½	.....	.....	.....	.....	2.131	2.465	2.650
5	1.600	1.812	1.980	2.071	2.387	2.770	2.990
6	1.840	2.125	2.270	2.430	2.740	3.210	3.440
8	2.400	2.685	2.910	3.110	3.310	4.050	4.370

It is convenient to work from the outer surface of the insulation, since the loss through the covering must be determined from the outer surface loss by means of surface loss curves such as given in Fig. 5. The curves were plotted from tests conducted at the Mellon Institute.

After the true heat loss is obtained, the loss per square foot of pipe surface can be calculated from the relationship:

$$q_i = q_o(r_2/r_1)$$

where

q_i = Btu per (hour) (square foot outer surface of pipe).

Table 4 .... External Surface per Linear Foot of Copper Tubing

Outside diameter ⅛ in. greater than nominal size

Tube Size (Inches)	Surface Area (Sq Ft)	Tube Size (Inches)	Surface Area (Sq Ft)	Tube Size (Inches)	Surface Area (Sq Ft)
⅛	0.164	2	0.556	5	1.342
¾	0.229	2½	0.687	6	1.604
1	0.295	3	0.818	8	2.128
1¼	0.360	3½	0.949	...	.....
1½	0.426	4	1.080	...	.....

The heat loss through two or more thicknesses of insulation applied to a pipe can be calculated by means of the equation:

$$q_o = \frac{t_1 - t_2}{\frac{r_2}{r_1 \log_e \frac{r_2}{r_1}}{k_1} + \frac{r_3}{r_2 \log_e \frac{r_3}{r_2}}{k_2} + \cdots} \qquad (2)$$

where

r_3 = outer radius of second layer of insulation, inches.
r_s = outer radius of last layer of insulation, inches.

The method of solving Equation 2, which is the most difficult of the two, is given in *Example 3*.

Example 3: Compute the heat loss per linear foot of pipe surface per hour from a 6-in. pipe, insulated with a 3-in. thickness of 1500 F diatomaceous earth, and a nominal 2-in. thickness of 85 percent magnesia. The pipe is operating at a temperature of 1200 F and is exposed to a room temperature of 80 F.

Solution: In figuring the heat loss from Equation 2, it is necessary to first make an assumption for the outer surface temperature t_2 and the temperature between the diatomaceous earth and 85 percent magnesia insulation, so that the mean temperature of each material can be obtained and the thermal conductivity corresponding to the mean temperature of each material substituted in the equation. First assume an outer surface temperature of 135 F and a temperature of 570 F between the two materials corresponding to a mean temperature of (1200 + 570) ÷ 2 or 885 F for the diatomaceous earth and (570 + 135) ÷ 2 or 352.5 F for the 85 percent magnesia insulation. The conduc-

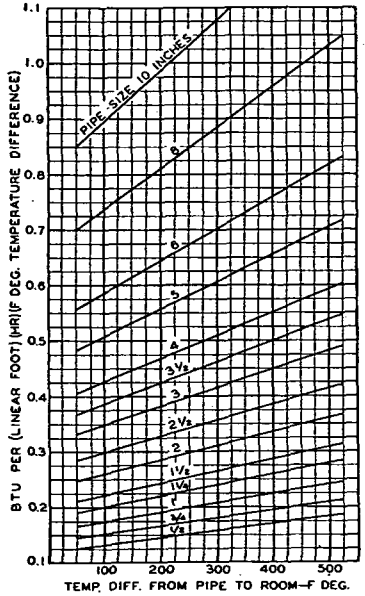

Fig. 1 .... Heat Loss through 1 In. Thick Pipe Insulation
(Use with Table 6 for Various Insulations)

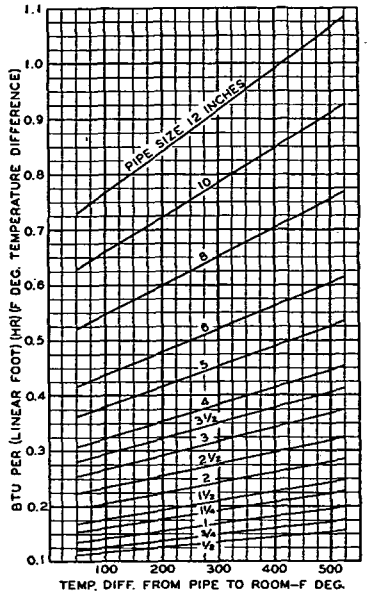

Fig. 2 .... Heat Loss through 1½ In. Thick Pipe Insulation
(Use with Table 6 for Various Insulations)

tivities of these two materials at mean temperatures of 885 and 352.5 F, interpolated from Table 1, are 0.577 and 0.466 Btu, respectively.

These values are substituted in Equation 2 and a trial calculation made.

The actual thickness of diatomaceous earth covering is 3.095 in. and that of the 85 percent magnesia is 2.125 in. For a nominal 6-in. steel pipe: $r_1 = 3.312$, $r_2 = 6.407$, and $r_3 = 8.532$. Then,

$$q_c = \frac{1200 - 135}{\frac{8.532 \log_e \frac{6.407}{3.312}}{0.676} + \frac{8.532 \log_e \frac{8.532}{6.407}}{0.466}} = \frac{1065}{8.33 + 5.24} = 78.5 \text{ Btu.}$$

The temperature drop from the outer surface of the insulation to the surrounding air for a heat loss of 78.5 Btu is found from Fig. 5 to be 49.5 deg for a 17-in. OD cylindrical surface, or 49.5 + 80 F room temperature = 129.5 F surface temperature. Since a surface temperature of 135 F was assumed, it is evident that a temperature closer to 129.5 F, or, for instance, 129 F should be used for recalculation:

$$q_c = \frac{1200 - 129}{8.33 + 5.24} = 78.9 \text{ Btu.}$$

Since the temperature drop through each material is equal to the heat flow times the actual resistance of each material, the temperature drop through the diatomaceous earth is 78.9 × 8.33 = 657 F, or the temperature between the two insulating materials is (1200 − 657) = 543 F. Since a temperature of 570 F between the two materials was assumed, it is obvious that a temperature closer to 543, or for instance 545 F may be selected. The mean temperatures of the two insulations corresponding to the new assumptions are (1200 + 545) ÷ 2 = 872.5, and (545 + 129) ÷ 2 = 337, and the interpolated conductivities corresponding to the new mean temperatures are 0.575 and 0.461 for the diatomaceous earth and 85 percent magnesia, respectively. By substituting in Equation 2

$$q_c = \frac{1200 - 129}{\frac{5.63}{0.675} + \frac{2.44}{0.461}} = \frac{1071}{8.34 + 5.30} = 78.5 \text{ Btu.}$$

Again referring to Fig. 5, it is seen that the temperature drop from the outer surface of the insulation to the surrounding air for a heat loss of 78.5 Btu = 49 deg, which corresponds to the surface temperature of 129 F last assumed. The heat loss is therefore 78.5 × 8.532 ÷ 3.312 = 202 Btu per sq ft of pipe surface. Since the surface area per linear foot of 6-in. pipe is 1.734 sq ft (Table 2), the heat loss per linear foot of pipe will be 202 × 1.734 = 351 Btu per hr.

The rate of heat loss from a surface maintained at constant temperature is greatly increased by air circulation over the surface. In the case of well-insulated surfaces, the increases in losses due to air velocity are very small as compared with increases from bare surfaces, because of the fact that air

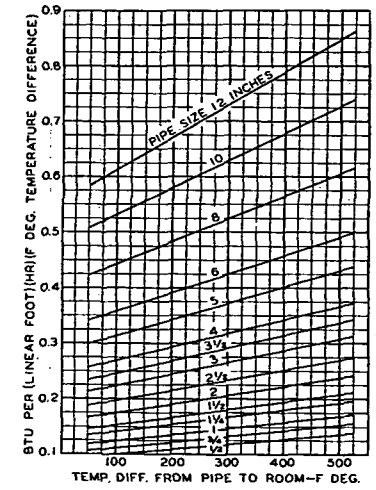

Fig. 3 .... Heat Loss through 2 In. Thick Pipe Insulation
(Use with Table 6 for Various Insulations)

flowing over the surface of the insulation can increase only the conductance of heat from surface to air, and cannot change the internal conductance of the insulation itself. The maximum increase in heat loss due to air velocity ranges from about 15 percent in the case of 1-in. thick insulation, to about 5 percent in the case of 3-in. thick insulation, provided that the insulation is thoroughly sealed so that air can flow only over the surface. If the conditions are such that the air may circulate through cracks and crevices in the insulation, the increases may be far greater than those given. Therefore, it is essential that insulation be applied in such a manner that air circulation within it, or between it and the pipe, is avoided.

Piping which is covered with a water-mixed product or insulation which will absorb moisture, particularly in damp locations, should be coated with a corrosion-resistant paint. This precaution may prevent early failure due to external pipe corrosion.

The frequent practice of omitting insulation on that portion of a pipe which passes through a masonry wall, or which may be in contact with other metals, should be avoided. Physical contact between the pipe surface and other structural materials of high thermal conductivity will result in heat transfer much greater than that shown in Tables 2 and 3 for transfer from bare pipe to air.

The saving due to use of insulation on piping is illustrated in *Example 4*.

Example 4: If the steam pipe given in *Examples 1* and *2* is covered with nominal 1 in. thick 85 percent magnesia, determine the resulting total annual loss through the insulation. Also compute the monetary value of the annual saving and the percentage of saving over the heat loss from the bare pipe.

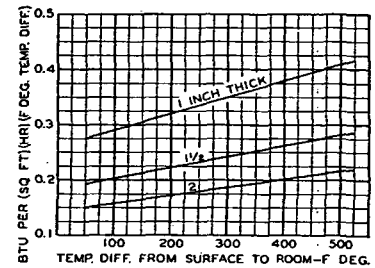

Fig. 4 .... Heat Loss through Insulation on Flat Vertical Surface
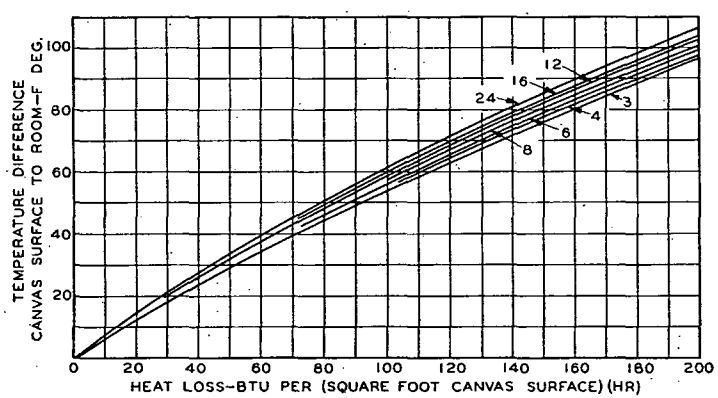
(Use with Table 6 for Various Insulations)

Solution: By referring to Fig. 1, the coefficient for 1-in. insulation on a 2-in. pipe is found to be 0.276 Btu per (hr) (linear ft of pipe) (deg temperature difference) at a temperature difference of 159.4 F. The heat insulation factor for 85 percent magnesia insulation, interpolated from Table 6, for a temperature difference of 159.4 F, is 1.085. The total hourly loss per linear foot of pipe will then be 0.276 × 159.4 × 1.085 = 47.7 Btu. The total annual loss through the insulation = 47.7 × 165 (linear ft) × (4000 hr) = 31,480 Mb. The annual bare-pipe loss as determined in the solution of *Example 1* was found to be 171,100 Mb. The saving due to insulation is then 171,100 − 31,480 = 139,620 Mb per year.

From the solution of *Example 2*, it was found that the heat *supplied to the system cost $0.804 per 1000 Mb*. Therefore, the monetary value of the saving = 0.804 (dollars) × 139.6 (thousand Mb) = $112.23 or 8.16 percent of the cost when using uninsulated pipe.

THICKNESS OF INSULATIONS TO BE APPLIED

Thermal insulation is used in a variety of thicknesses for many varied reasons. Refrigerating equipment is normally designed for minimum heat gain, and heating equipment for minimum heat loss, within economical limits. This assures minimum-sized refrigeration or heating equipment, both from the standpoint of original as well as operational cost. Present refrigeration design practice limits the heat gain to 4 to 8 Btu per (hr) (sq ft) of exposed surface. Sometimes the principal object of the insulation is to limit the heat gain or loss to a specified value to control the temperature of a manufacturing or chemical process.



Minor refrigeration and air-conditioning equipment and cold-water lines usually utilize only sufficient insulation thickness to prevent condensation on the warm surface so as to prevent dripping. Occasionally the criterion for heated equipment and pipes is the reduction of the *outer surface* to a temperature (usually a maximum of 175 F to 200 F) low enough to prevent injury to personnel.

ECONOMICAL THICKNESS OF INDUSTRIAL INSULATION

The thicknesses of insulation which ordinarily are used for various temperature conditions are given in Table 7. Where a thorough analysis of economic thickness is desired, the thickness of insulation that will give the lowest sum of annual cost of heat loss and insulation may be found by means of Fig. 6.* As the thickness of insulation increases the annual

High Superheat	600 to 700	3½ in.	3 in.	2 in.

[a] All piping located outdoors or exposed to weather is ordinarily insulated to a thickness ½ in. greater than shown in this table, and covered with a waterproof jacket.

cost of heat loss decreases, but the annual cost of insulation (first cost multiplied by percent fixed charges) increases. The sum of the two costs will first decrease with increasing thickness of insulation, and then, depending on operating conditions, will increase beyond a certain thickness. Therefore, the thickness at which the sum of the costs is a minimum, is the most economical.

The method of using the chart Fig. 6 is as follows:

From the number of hours of operation per year at the bottom of the chart proceed upward to the line showing value of heat in dollars per million Btu using the appropriate scale *A* or *B*. Proceed right to temperature difference line using either scale *A* or *B*. Move upward to the line representing conductivity of the insulation being considered, then left to discount line, upward to the percent fixed charge line, right to the pipe size or flat surface line and read the economic thickness at top on the scale corresponding to the scales selected for value of heat and temperature difference. For example; with Scale *B* heat value and Scale *A* temperature difference or vice versa, use Scale *A-B* economic thickness. If the intersection with the flat surface is on the *flat surface continued* curve, the economical thickness is read on the prime scales *A'-A'*, *A'-B'*, or *B'-B'*.

Cost of insulation refers to incremental cost in place; i.e., average incremental cost per unit thickness after the first unit. The first inch of insulation will usually cost more than each additional inch. This is due to cost of finish, contractor's setup, and operating costs, which do not increase in proportion to thickness. The first inch of insulation, except in very unusual cases, provides enough saving in heat cost out of bare surface cost to more than cover these extra first costs.

To obtain discount from insulation list price, first obtain applied prices for the desired type of insulation in one-inch, two-inch, etc., thickness. Then determine the average incremental cost per inch above one-inch thickness.

Incremental cost in percent discount from list is

$$100\left(1-\frac{X}{Y}\right)$$

where

X = average incremental cost in place per inch above one inch.

Y = list price for one inch.

In figuring pipe insulation, use the list price for one-inch thickness for a pipe size consistent with the average incremental cost per inch. For example, if the average incremental cost per inch is based on applied prices for one, two, and three inches, the incremental cost of the second and third inches would be averaged and the pipe size for list price would be that nearest the average pipe size of the second and third inch.

A rapid method for determining the economical thickness of insulation by use of tables has been published.[a]

LOW TEMPERATURE PIPE INSULATION

Surfaces maintained at temperatures lower than the surrounding air are insulated to reduce the flow of heat and to prevent condensation. The insulating material should absorb a minimum amount of moisture, because the absorption of moisture substantially increases the conductivity of the material. This property is particularly important in the insulation of surfaces that are below the dew point of the surrounding air. In such cases, due to vapor-pressure difference, it is necessary to seal the surface of the insulating material against the penetration of water vapor which would condense within the material, causing a serious increase in heat flow, possible breakdown of the material, and corrosion of metal surfaces. An insulating material with a high degree of moisture absorption might pick up moisture before application and then, when the vapor seal is in place and the temperature of the insulated surface reduced, release that moisture to the cold surface. There are a number of methods of producing vapor seals, some of which have been worked out by insulation manufacturers to suit their products, and others by appliers and users. Unless time-proven methods are known, specifications of insulation manufacturers should be obtained and followed carefully.

Equipment must be carefully protected against corrosion caused by condensation of water vapor. All metallic surfaces should be coated with a vapor-impervious barrier (some types of which have an asphaltic or tar base) without any breaks or openings in order to prevent corrosion.

The thickness of insulation required to prevent condensation on the outer surface is that thickness which will raise the temperature of the outer surface of the insulation to a point slightly higher than the dew point of the surrounding vapor. The dew point for various humidities can be readily ascertained from a psychrometric chart. The external vapor barrier must be made as nearly perfect as possible in order to prevent migration of vapor into the insulation.

The approximate required thickness of insulation to prevent condensation on pipes and flat metallic surfaces may be obtained from Fig. 7 in which a surface resistance of 0.606, corresponding to a film conductance of 1.65, was used in calculating the curves. This value provides a slight factor of safety and its use is known to give satisfactory field results. In using the chart it is advisable to specify the next thicker, rather than the next thinner, commercial insulation in cases where an intermediate thickness is indicated.

Heat gains for pipes insulated with a material having an installed conductivity of 0.30 Btu per (sq ft) (hr) (F deg per in.) are given in Table 8. This table may be used for any of the commercial insulations offered for this purpose since they have conductivities very near the 0.3 value used.

INSULATION OF PIPES TO PREVENT FREEZING

If the surrounding air temperature remains sufficiently low for an ample period of time, insulation cannot prevent the freezing of still water, or of water flowing at such a velocity that the quantity of heat carried in the water is not sufficient to take care of the resulting heat losses that will cause the temperature of the water to be lowered to the freezing point. Insulation can materially prolong the time required for the water to give up its heat so that, if the velocity of the water flowing in the pipe is maintained at a sufficiently high rate, freezing may be prevented.

Table 9 may be used for making estimates of the thickness of insulation necessary to take care of still water in pipes at various water and surrounding air temperature conditions. Because damage and service interruptions may result from frozen water in pipes, it is essential that an efficient insulation be utilized. This table is based on the use of a material having a conductivity of 0.30. The initial water temperature is assumed to be 10 deg above, and the surrounding air temperature 50 deg below, the freezing point of water (temperature difference, 60 F).

The last column of Table 9 gives the minimum quantity of water at initial temperature of 42 F that should be supplied every hour for each linear foot of pipe, in order to prevent the temperature of the water from being lowered to the freezing point. The weights given in this column should be multiplied by the total length of the exposed pipe line expressed in feet. As an additional factor of safety, and in order to provide against temporary reductions in flow occasioned by reduced pressure, it is advisable to double the rates of flow listed in the table. It must be emphasized that the flow rates and periods of time designated apply only for the conditions stated. To estimate for other service conditions, the following method of procedure may be used.

If water enters the pipe at any temperature other than 42 F, the time required to cool it to the freezing point will be equal to $(t - 32)/10$ times that given in the table, or the rate of flow of water may be changed to $10/(t - 32)$ times the indicated flow rate in the last columns of Table 9. However, if the water enters the pipe at 34 F, it will be cooled to 32 F in one-fifth of the time given in the table. It will then be necessary to increase the rate of flow so that five times the specified quantity of water will have to be supplied in order to prevent freezing.

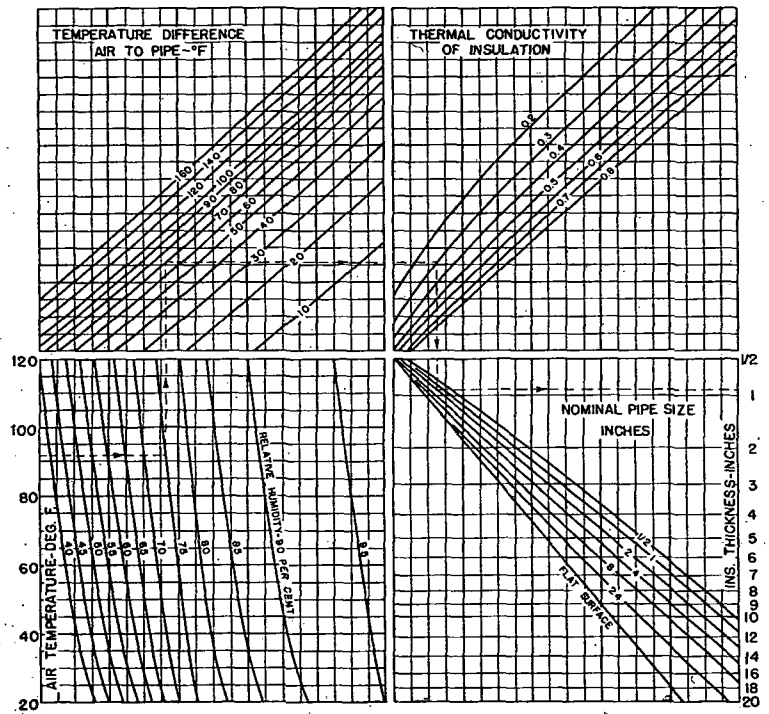
If the minimum air temperature is −38 F (temperature difference 80 F) instead of −18 F, the time required to cool the water to the freezing point will be 60/80 of the time given in the table, or the necessary quantity of water to be supplied will be 80/60 of that given.

In making calculations to arrive at the values given in Table 9, the loss of heat stored in the insulation, the effect of a varying temperature difference due to the cooling of pipe and water, and the resistance of the outer surface of the insulation to the transfer of heat to the air, have all been ne-

glected. When these factors enter into the computations it is necessary to enlarge the factor of safety. Also as stated, the time shown in the table is that required to lower the water to the freezing point. A longer period would be required to freeze the water, but the danger point is reached when freezing starts. The flow of water will stop and the entire line will be in danger as soon as the water freezes across the section of the pipe at any point.

If it is necessary to calculate the time required for the water to cool to 32 F, the following equation may be used

$$H = \frac{C_p(t_1 - 32)}{q_s\left(\frac{r}{6} \times r_s\right)} \qquad (3)$$



C_p = Capacity of pipe, lb water/lin. ft = $\frac{\pi r_s^2}{144} \times 62.4$

$$q_s = \frac{k\left[\left(\frac{t_1 + 32}{2}\right) - t_2\right]}{r_s \log_e \frac{r_2}{r_1}} \qquad (4)$$

where

H = hours for water to cool to 32 F.
r_s = inside radius of pipe, inches.
t_1 = initial water temperature.
C_p may be obtained from manufacturers' catalogs and handbooks.
See Equation 1 for definitions of other symbols.

When water must remain stationary longer than the times designated in Table 9, the only safe way to insure against freezing is to install a steam or hot water pipe parallel to the cold water pipe or to place an electric resistance heater along

* Solve problems as indicated by dotted line, entering chart at lower left-hand scale.

Fig. 7 .... Thickness of Pipe Insulation to Prevent Condensation on Outer Surface*

the side of the exposed water line. The heating system and the water line are then insulated so that the heat losses from the heating system are not excessive, and the heating effect is concentrated against the water pipe where it is needed. For this form of protection 2 in. of an efficient insulation may be applied.

APPLICATION OF INDUSTRIAL INSULATION

Small pipes are normally insulated with half-sectional insulation split horizontally and furnished with factory applied jackets forming hinge and lap. Large piping is insulated with segmental blocks, wired or banded in place, or with blanket insulations, particularly where removal for frequent servicing of the pipe is necessary. Indoors, sectional insulation is applied with the canvas lap pasted. Outdoors, it is necessary to provide a weatherproof finish. Fittings and bends are insulated with portions of standard preformed insulation, blanket insulations, or insulating cements. Fitting insulation should be carefully specified to be compatible with the pipe insulation. Insulation on lines carrying cold water, brine, or other cold fluids must be protected to prevent the infiltration of water vapor into the insulation.

Flat, curved, and irregular surfaces such as boilers, breechings, tanks, and vessels, are normally insulated with blocks or lagging, or with blanket forms of insulation. The insulation is secured in a variety of ways depending upon the form of insulation and contour of the surface to be insulated. One specification includes wiring the blocks in place, stretching a hexagonal mesh netting tightly over the insulation, and fastening securely with wires. Over the netting a coat of mineral wool or asbestos cement is applied with a second coat of asbestos cement trowelled to a smooth even finish. For outdoor installations weather protection is then applied. For insulation over surfaces at temperatures below ambient, water-vapor protection must be applied for both indoor or outdoor applications.

The application of insulation to air-conditioning ducts is accomplished in a variety of ways depending largely on ambient conditions and temperature differentials between the air in the room and conditioned air. Boards or blankets are normally used in a single layer 1 in. thick. Boards are fastened to the duct surfaces with spot or solid application of adhesive, and further reinforced with wires, bands, spindle anchors, or sheet-metal screws. Although, where the service is not too severe, it is permissible merely to point the joints with a mastic compound, in most cases the insulations should be protected against water-vapor permeation. Where blankets are used the insulation can be wrapped around the duct, and held in place with tape over all joints or with spirally wrapped twine. Again in most cases the insulation should be provided with an outer vapor barrier protection.

UNDERGROUND PIPE INSULATION

Underground steam distribution pipes may be installed in tunnels or in protective structures of various types, sizes, and shapes. Conduits for piping are described in Chapter 27.

Pipes in tunnels are covered with sectional insulation to provide maximum thermal efficiency, and are also finished with good mechanical protection in the form of metal or waterproofing membrane outer jackets. In some instances, where actual submersion of hot lines may occur, it has been found good practice to fasten the covering securely with corrosion-resistant wire, and then sew on a wire-inserted asbestos fabric jacket with wire. This jacket is porous. The principle of withstanding submersion is that water may enter as water, then actually boil at the pipe surfaces and escape as steam without rupturing the insulation or jacket. Conduit systems are in more general use than tunnels. Pipes carried in conduits may be insulated with sectional insulation; however, the more usual practice is to fill the entire section of the conduit around the pipes with high quality, loose insulating material. The insulation must be kept dry at all times, and for this purpose effective waterproofing membranes enclose the insulation. A drainage system is also provided to divert water which may tend to enter the conduit.

Table 10 .... Thickness of Loose Insulation for Use as Fill in Underground Conduit Systems

Steam Pressure Psig or Condition	Steam Temperature Fahrenheit Degrees	Minimum Thickness of Insulation in Inches					Minimum Distance Between Steam and Return
		Steam Lines			Return Lines		
		Pipes Less than 4 in.	Pipes 4 in. to 10 in.	Pipes Larger than 12 in.	Pipes Less than 4 in.	Pipes 4 in. and Larger	
Hot water, or 0 to 25	212 to 267	1½	2	2½	1½	1½	1
25 to 125	267 to 352	2	2½	3	1½	1½	1¼
Above 125, or superheat	352 to 500	2½	3	3½	1¾	1½	1½

The economical thickness of insulation for underground work is difficult to determine accurately due to the many variables which have to be considered. As a result of theories previously developed, together with other experimental data which have been presented, the usual endeavor is to secure not less than 90 percent efficiency for underground piping. A comparison of heat loss under actual conditions vs. calculated values has been published by the National District Heating Association.[5] Table 10 can be used as a guide in arriving at the minimum thickness of loose insulation fills to use for laying out conduit systems. Other factors such as the number of pipes and their combination of sizes, as well as the standard conduit sizes, are primary controlling factors in the amount and thickness of insulation for use.

When sectional insulation is applied to pipes in tunnels or conduits, usual practice is to apply the most efficient materials ½ in. less in thickness than that determined by the use of Fig. 6. The data in Fig. 6 are based on conditions of insulation exposed to the air, whereas normal ground temperature is substituted for air temperature in determining the temperature difference for use with the chart when applying it for underground pipe system estimates.

CHAPTER 33

FUELS AND COMBUSTION

Solid Fuels: Analysis, Classification of Coals, Classification of Cokes, Combustion of Solid Fuels, Firing Methods for Solid Fuels, Secondary Air, Draft Requirements and Regulations, Furnace Volume; Fuel Oils: Classification, Air Required; Fuel Gases: Classification, Heat Value, Combustion; General Combustion Principles; Air Required; Efficiency from Flue Gas Analysis; Heat Balance; Condensation and Corrosion; Soot; Air Supply to Furnace Rooms

FUELS may be classified according to their physical state as solid, liquid, or gaseous. The principal fuels used for domestic heating are coal, oil, and gas. However, coke, wood, kerosine, sawdust, briquettes, and other substances are used for heating in special applications or in localities where an adequate supply is available. Experiments are in progress in the use of a colloidal suspension of coal particles in fuel oil, but this fuel has not attained widespread usage as yet. The choice of fuel is usually based on dependability, cleanliness, availability, economy, operating requirements, and control.

SOLID FUELS

Analysis of Fuels

Coal has a complex composition that makes classification into clear-cut types difficult. Chemically it consists of carbon, hydrogen, oxygen, nitrogen, sulfur, and a mineral residue called ash. A chemical analysis provides some indication of the quality of a coal, but does not define its burning characteristics sufficiently. The coal user is interested principally in the available heat per pound of coal, the handling and storing properties, the amount of ash and dust produced, and the burning characteristics. A description of the qualities of coals and their characteristics can best be obtained from publications of the U. S. Bureau of Mines. A treatment applicable to heating boilers is given in a U. S. Bureau of Mines bulletin.[1]

There are two types of coal analyses, namely, the *proximate analysis* and the *ultimate analysis*. In the *proximate analysis* the proportions of moisture, volatile matter, fixed carbon, sulfur, and ash are determined. This analysis is quite easily made and is satisfactory for indicating most of the characteristics which are of interest to the user. For the proximate analysis the moisture is determined by observing the loss of weight of a sample of coal when dried at about 220 F. To determine the volatile matter, the dried sample is heated to about 1750 F in a closed crucible, and the loss of weight is noted. The remaining sample is then burned in an open crucible, and the accompanying loss of weight represents the fixed carbon. The unburned residue is ash. Although determined separately, the sulfur content is frequently reported with the proximate analysis because the usefulness of a coal for certain purposes depends on its sulfur content.

In the *ultimate analysis*, which is difficult to make, the percentages of carbon, hydrogen, oxygen, nitrogen, sulfur, and ash in the coal sample are determined. It is used for detailed studies of fuels, and in computing a heat balance when required in testing of heating devices. Typical ultimate analyses of the various kinds of coal are shown in Table 1.[a]

Other important qualities of coals are the screen sizes, ash fusion temperature, friability, caking tendency, and the qualities of the volatile matter. In considering these factors the following points are of interest. The volatile products given off by coals when they are heated differ materially in the ratios by weight of the gases to the oils and tars. No heavy oils or tars are given off by anthracite, and very small quantities are given off by semi-anthracite. As the volatile matter in the coal increases to as much as 40 percent of ash and moisture-free coal, increasing amounts of oils and tars are released. For coals of higher volatile content, the relative quantity of oils and tars decreases and is therefore low in the sub-bituminous coals and in lignite. The percentage of ash and its fusion temperature do not indicate the composition or distribution of the constituents.

Classification of Coals

A classification of coals is given in Table 2, and a brief description of the kinds of fuel is given in the following paragraphs, but it should be recognized that there are no distinct lines of demarcation between the kinds, and that they graduate into each other.

Anthracite is a clean, dense, hard coal which creates little dust in handling. It is comparatively hard to ignite, but it burns freely when well started. It is non-caking, it burns uniformly and smokelessly with a short flame, and it requires no attention to the fuel bed between firings.[a] Standard anthracite sizing specifications are shown in Table 3.

Semi-anthracite has a higher volatile content than anthracite. It is not so hard, and ignites somewhat more easily. Otherwise their properties are similar.

Semi-bituminous coal is soft and friable, and fines and dust are created by handling it. It ignites somewhat slowly and burns with a medium length of flame. Its caking properties increase as the volatile matter increases, but the coke formed is relatively weak. Having only half the volatile matter content of the bituminous coals, it can be burned with less production of smoke, and is sometimes called a *smokeless coal*.

Bituminous coal is a term covering a large range of coals and includes many types having distinctly different composition, properties, and burning characteristics. The coals range from the high-grade bituminous coals of the East to the poorer coals of the West. Their caking properties range from coals which melt completely, to those from which the volatiles and tars are distilled without change of form, so that they are classed as non-caking or free-burning. Most bituminous coals are strong and non-friable enough to permit the screened sizes being delivered free from fines. In general, they ignite easily and burn freely. The length of flame varies with different coals, but it is long. Much smoke and

Table 1 .... Typical Ultimate Analyses for Coals

Rank	Btu per Lb		Constituents, Percent						
	Moist, Mineral-matter-free[a]	Moist, as Received	Oxygen	Hydrogen	Carbon	Nitrogen	Sulfur	Ash	$O_2 + H_2 + C$

Table 2 .... Classification of Coals by Rank[a]

Legend: F.C. = Fixed Carbon. V.M. = Volatile Matter. Btu = British thermal units.

Class	Group	Limits of Fixed Carbon or Btu Mineral-Matter-Free Basis	Requisite Physical Properties
I. Anthracite	1. Meta-anthracite	Dry F.C., 98 percent or more (Dry V.M., 2 percent or less)	Non-agglomerating
	2. Anthracite	Dry F.C., 92 percent or more and less than 98 percent (Dry V.M., 8 percent or less and more than 2 percent)	
	3. Semi-anthracite	Dry F.C., 86 percent or more and less than 92 percent (Dry V.M., 14 percent or less and more than 8 percent)	
II. Bituminous[d]	1. Low volatile bituminous coal	Dry F.C., 78 percent or more and less than 86 percent (Dry V.M., 22 percent or less and more than 14 percent)	Either agglomerating[b] or non-weathering[f]
	2. Medium volatile bituminous coal	Dry F.C., 69 percent or more and less than 78 percent (Dry V.M., 31 percent or less and more than 22 percent)	
	3. High volatile *A* bituminous coal	Dry F.C., less than 69 percent (Dry V.M., more than 31 percent); and moist[c] Btu, 14,000[e] or more	
	4. High volatile *B* bituminous coal	Moist[c] Btu, 13,000 or more and less than 14,000[e]	
	5. High volatile *C* bituminous coal	Moist Btu, 11,000 or more and less than 13,000[e]	
III. Sub-bituminous	1. Sub-bituminous *A* coal	Moist Btu, 11,000 or more and less than 13,000[e]	Both weathering and non-agglomerating[b]
	2. Sub-bituminous *B* coal	Moist Btu, 9500 or more and less than 11,000[e]	
	3. Sub-bituminous *C* coal	Moist Btu, 8300 or more and less than 9500[e]	
IV. Lignitic	1. Lignite	Moist Btu *less than* 8300	Consolidated
	2. Brown coal	Moist Btu less than 8300	Unconsolidated

Adapted from *ASTM Standards*, 1937, *Supplement*, p. 145, American Society for Testing Materials.

[a] This classification does not include a few coals which have unusual physical and chemical properties and which come within the limits of fixed carbon or Btu of the high-volatile bituminous and sub-bituminous ranks. All of these coals either contain less than 48 percent dry, mineral-matter-free fixed carbon, or have more than 15,500 moist, mineral-matter-free Btu.

[b] If agglomerating, classify in low-volatile group of the bituminous class.

[c] Moist Btu refers to coal containing its natural bed moisture but not including visible water on the surface of the coal.

[d] It is recognized that there may be non-caking varieties in each group of the bituminous class.

[e] Coals having 69 percent or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of Btu.

[f] There are three varieties of coal in the high-volatile *C* bituminous coal group, namely, Variety 1, agglomerating and non-weathering; Variety 2, agglomerating and weathering; Variety 3, non-agglomerating and non-weathering.

Table 3 .... Standard Anthracite Specifications[a]

[a] Approved and adopted, effective July 28, 1947, by the Anthracite Committee (*Manual of Statistical Information*, Anthracite Institute.)

[b] When slate content in the sizes from Broken to Nut inclusive is less than above standards, bone content may be increased by one and one-half times the decrease in the slate content under the allowable limits, but slate content specified above shall not be exceeded in any event.

[c] Ash determinations are on a dry basis and include bone and ash.

A tolerance of 1 percent is allowed on the maximum percentage of undersize and the maximum percentage of ash content. The maximum percentage of undersize is applicable only to anthracite as it is produced at the preparation plant.

Slate is defined as any material which has less than 40 percent of fixed carbon.

Bone is defined as any material which has 40 percent or more, but less than 75 percent of fixed carbon.

soot are possible, if improperly fired, especially at low rates of burning.

Sub-bituminous coals occur in the western states; they are high in moisture when mined and tend to break up as they dry or when exposed to the weather; they are liable to ignite spontaneously when piled or stored. They ignite easily and quickly, and have a medium length flame; are non-caking and free-burning; the lumps tend to break into small pieces if poked; very little smoke and soot are formed.

Lignite is of woody structure, very high in moisture as mined, and of low heating value; it is clean to handle. It has a greater tendency than the sub-bituminous coals to disintegrate as it dries, and it also is more liable to spontaneous ignition. Freshly mined lignite, because of its high moisture, ignites slowly. It is non-caking. The char left after the moisture and volatile matter are driven off burns very easily, like charcoal. The lumps tend to break up in the fuel bed, and pieces of char falling into the ashpit continue to burn. Very little smoke or soot is formed.

Classification of Cokes

Coke is produced by the distillation of the volatile matter from coal. The type of coke depends on the coal or mixture of coals used, on the temperatures and time of distillation and, to some extent, on the type of retort or oven. *Petroleum coke* is produced as a residue from the destructive distillation of oil.

COMBUSTION OF SOLID FUELS

Firing Methods for Anthracite

An anthracite fire should never be poked or disturbed, as this serves to bring ash to the surface of the fuel bed, where it may melt into clinker.

Egg size is suitable for large fire-pots (grates 24 in. and over) if the fuel can be fired at least 16 in. deep. For best results this coal should be fired deeply.

Stove is the proper size of anthracite for many boilers and furnaces. It burns well on grates at least 16 in. in diameter, on which it is fired about 12 in. deep. The fuel should be fired deeply and uniformly.

Chestnut size coal is in demand for fire-pots up to 20 in. in diameter, and is usually fired to a depth of from 10 to 15 in.

Pea size coal is often an economical fuel to burn. When fired carefully, pea coal can be burned on standard grates. Care should be taken to shake the grates only until the first bright coals begin to fall through the grates. The fuel bed, after a new fire has been built, should be increased in thickness by the addition of small charges until it is at least level with the sill of the fire-door. A satisfactory method of firing pea coal consists of drawing the red coals toward the front end, and piling fresh fuel toward the back of the firebox.

Pea size coal requires a strong draft, and therefore the best results generally will be obtained by keeping the choke damper open, and regulating solely by means of the cold-air check and the air-inlet damper.

Buckwheat size coal, for best results, requires more attention than pea size coal, and in addition the smaller size of the fuel makes it more difficult to burn on ordinary grates. Greater care must be taken in shaking the grates than with the pea coal to prevent fuel from falling through the grate. In house heating furnaces, the coal should be fired lightly and more frequently than pea coal. When banking a buckwheat coal fire, it is advisable after coaling to expose a small spot of hot fire by putting a straight poker down through the bed of fresh coal. This will serve to ignite the gas that will be distilled from the fresh coal and prevent delayed ignition which, in some cases, depending upon the thickness of the bed of fresh coal, is severe enough to blow open the doors and dampers of the furnace. Where frequent attention can be given and care is exercised in manipulation of the grates, this fuel can be burned satisfactorily without the aid of any special equipment, except small mesh grates.

In general, it will be found more satisfactory with buckwheat coal to maintain a uniform heat output and, consequently, to keep the system warm all the time, rather than to allow the system to cool off at times and then to attempt to burn the fuel at a high rate while warming up. A uniform low fire will minimize the clinker formation and keep any clinker formed in an easily broken up condition so that it readily can be shaken through the grate. Forced draft and small mesh grates or, for greater convenience, domestic stokers are frequently used.

Buckwheat anthracite No. 2, or rice size, is used principally in stokers of the domestic, commercial and industrial type. No. 3 buckwheat anthracite, or barley, has no application in domestic heating.

Firing Methods for Bituminous Coal

A commonly recommended procedure for firing domestic heating units, called the *side-bank method*, requires the movement of live coals to one side or the back of the grate, and placing the fresh fuel charge on the opposite side. The results are a more uniform release of volatile gases, and the subjection of these gases to the high temperature of the red coals. If the fresh charge is covered with a layer of fine coal, still better results may be obtained because of slower release of volatile matter.

Bituminous coal should never be fired over the entire

fuel bed at one time. A portion of the glowing fuel should always be left exposed to ignite the gases leaving the fresh charge.

The importance of firing bituminous coal in small quantities at short intervals is discussed in a U. S. Bureau of Mines technical paper.[4] Better combustion is obtained by this method in that the fuel supply is maintained more nearly proportional to the air supply.

If the coal is of the caking kind, the fresh charge will fuse into one solid mass that can be broken up with the stoking bar and leveled from 20 min to an hour after firing, depending on the temperature of the firebox. Care should be exercised when stoking not to bring the bar up to the surface of the fuel, as this will tend to bring ash into the high temperature zone at the top of the fire, where it will melt and form clinker. The stoking bar should be kept as near the grate as possible, and should be raised only enough to break up the fuel. With fuels requiring stoking it may not be necessary to shake the grates, as the ash is usually dislodged during stoking.

It is acknowledged that it may be difficult to apply the outlined methods to domestic heating boilers of small size, especially when frequent attendance is impracticable. The adherence to these methods insofar as practicable, however, will result in better combustion.

Preventing Smoke

In general, time, temperature and turbulence are the essential requirements for smokeless combustion. Anything that can be done to increase any one of these factors will reduce the quantity of smoke discharged. Special care must be taken in hand-firing bituminous coals.

In the case of new installations, the problem of smoke abatement can be solved by the selection of the proper fuel-burning equipment and furnace design for the particular fuel to be burned, and by the proper operation of that equipment. Constant vigilance is necessary to make certain that the equipment is properly operated. In old installations the solution of the problem presents many difficulties, and may require a considerable investment in special apparatus.

Lower rates of combustion per square foot of grate area will reduce the quantity of solid matter discharged from the chimney with the gases of combustion. The burning of coke, coking coal, and sized coal from which the extremely fine coal has been removed, will not, as a general rule, produce as much dust and cinders as will result from the burning of non-coking coals and slack coals when they are burned on a grate.

Modern boiler installations are usually designed for high capacity per square foot of floor space, because such designs give the lowest cost of construction per unit of capacity. Designs of this type discharge a large quantity of dust and cinders with the gases of combustion, and if pollution of the atmosphere is to be prevented, some type of dust and cinder catcher must be installed.

Firing Methods for Semi-Bituminous Coal

The Pocahontas Operators' Association recommends the central cone method of firing, in which the coal is heaped on the center of the bed to form a cone, the top of which should be level with the middle of the firing door. This allows the larger lumps to fall to the sides, while the fines remain in the center and are coked. The poking should be limited to breaking down the coke without stirring. Grates should be rocked gently. It is recommended that the slides in the firing door be kept closed, as the thinner fuel bed around the sides usually admits the required air.

Firing Methods for Coke

Coke ignites less readily than bituminous coal and more readily than anthracite, and burns rapidly with little draft. In order to control the air admitted to the fuel it is very important that all openings or leaks into the ashpit be closed tightly. A coke fire responds rapidly to the opening of the dampers. This is an advantage in warming up the system, but it also makes it necessary to watch the dampers more closely in order to prevent the fire from burning too rapidly. In order to obtain the same interval of attention as with other fuels, a deep fuel bed always should be maintained when burning coke. The grates should be shaken only slightly in mild weather, and should be shaken only until the first red particles drop from the grates in cold weather. The best size of coke for general use, for small fire-pots where the fuel depth is not over 20 in., is that which passes over a 1 in. screen and through a 1½ in. screen. For large fire-pots where the fuel can be fired over 20 in. deep, coke which passes over a 1 in. screen and through a 3 in. screen can be used, but a coke of uniform size is always more satisfactory. Large sizes of coke should either be mixed with fine sizes or broken up before using.

SECONDARY AIR

When bituminous coal is hand-fired in a furnace, the volatile matter in the fuel is driven off by heat leaving coke on the grate. The product of combustion of the coke is CO_2 and under certain conditions some CO may arise from the bed. The combustion of the volatile matter and the CO may amount to the liberation of from 40 to 60 percent of the heat in the fuel in the combustion space over the fuel bed.

The air that passes through the fuel bed is called *primary air*, and the air that is admitted over the fuel bed in order to burn the volatile matter and CO is called *secondary air*.

This process of combustion is illustrated in Fig. 1.[4] The free oxygen of the air passes through the grate and the ash above it, and burns the carbon in the lower 3 or 4 in. of the fuel bed forming carbon dioxide. This layer noted as the oxidizing zone, is indicated by the symbols CO_2 and O_2. Some of the carbon dioxide of the oxidizing zone is reduced to carbon monoxide in the upper layer of the fuel bed, noted as the reducing zone and indicated by the symbols CO_2 and CO. The gases leaving the fuel bed are mainly carbon monoxide, carbon dioxide, nitrogen, and a small amount of free oxygen. Free oxygen is also admitted through the firing

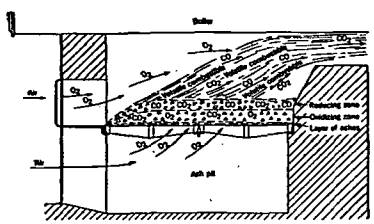

Fig. 1 .... Combustion of Fuel in a Hand-Fired Furnace

door in an attempt to burn carbon monoxide, as well as the volatile combustible distilled from the freshly fired fuel.

Size of the fuel is a very important factor in fixing the quantity of secondary air required for non-caking coals. With caking coals it is not so important, because small pieces fuse together and form large lumps. Fortunately, a smaller size fuel gives more resistance to air flow through the fuel bed, and thus automatically causes a larger draft above the fuel bed. More secondary air is drawn through the same slot openings, but, nevertheless, the smallest size of fuel will require the largest secondary air openings. For certain sizes of fuel, no secondary air openings are required, and for large sizes, too much excess air may pass through the fuel bed.

In general, the efficiency of domestic hand-fired furnaces and boilers burning either anthracite or bituminous coal, can be increased for an hour or two after firing, if some secondary air is admitted through slots of the fire door. However, unless the slots are closed when secondary air is no longer beneficial, the decrease in efficiency during the remainder of the firing cycle, because of excess air, may more than offset the gain resulting from the secondary air at the beginning of the firing period. Unless the secondary air can be readjusted between firings, it is probable that a greater average efficiency will be obtained for domestic hand-fired devices by leaving the secondary air slots closed at all times. There is usually an appreciable amount of air leakage around the firing door and secondary air slots of domestic furnaces and boilers.

Draft Requirements for Coal and Coke Firing

The draft required to effect a given rate of burning the fuel is dependent on the following factors: (1) kind and size of fuel, (2) grate area, (3) thickness of fuel bed, (4) type and amount of ash and clinker accumulation, (5) amount of excess air present in the gases, (6) resistance offered by the boiler passes to the flow of the gases, and (7) accumulation of soot in the passes.

Insufficient draft will necessitate additional manipulation of the fuel bed, and more frequent cleanings to keep its resistance down. Insufficient draft also restricts the control that can be accomplished by adjustment of the dampers. For draft requirements see Chapter 36.

Draft Regulation for Coal and Coke Firing

Since heating load demands vary in most installations, it is necessary to vary the rate of fuel burning. The maintenance of the proper air supply for the various rates of burning is accomplished by regulation of the drafts. Methods of draft regulation used for solid fuel are shown in Fig. 2.

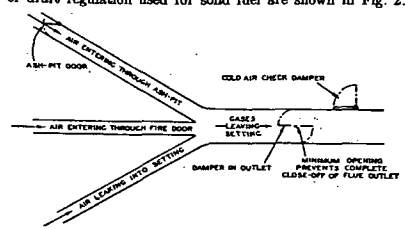

Fig. 2 .... Methods of Draft Regulation in a Hand-Fired Furnace

The air enters through the ashpit draft door, firing door, and by leakage through the setting, whereas the gases leave only through the outlet. By throttling flue gases with the damper in the outlet all the air entering by each of the three intakes is reduced in the same proportion, thus maintaining about the same percent of excess air. If inlet air is controlled by the ashpit draft door, the air admitted through the ashpit is reduced, while it is increased through the other two intake openings, resulting in an increase of excess air. A considerable increase in the efficiency of hand-fired furnaces and boilers can be realized by regulating the air supply by means of the damper in the outlet instead of the ashpit damper. Use of the ashpit damper is required, of course, for low rates of combustion. The cold air check damper is to be used only when chimney draft is excessive. It is normally closed unless the rate of combustion cannot be controlled by closing of the outlet and ashpit dampers.

Furnace Volume for Coal and Coke

The furnace volume is influenced by the kind of coal used. Bituminous coals, due to their long-flaming characteristic, require more space in which to burn the gases of combustion completely than do the coals low in volatile matter. For burning high volatile coals, provision should be made for mixing the combustible gases thoroughly, so that combustion is complete before the gases come in contact with the relatively cool heating surfaces. An abrupt change in the direction of flow tends to mix the gases of combustion more thoroughly. Anthracite requires comparatively little combustion space.

CLASSIFICATION OF FUEL OILS

Fuel oils are mixtures of hydrocarbons derived from crude petroleum by refining processes. Crude oil is distilled in towers at atmospheric pressure to produce gasoline, naphtha, kerosine and gas oil, and leave straight-run residues. The straight-run residues are distilled under vacuum to produce heavy distillates. The vacuum-flashed residue remaining can then be thermally cracked to produce more gasoline, cracked naphtha, cracked distillates, and cracked residue. The exact processes used depend on the proportions of the various end products desired, and to some extent upon the composition and characteristics of the crude oil.

Fuel oils may be designated as straight-run, thermally-cracked, catalytically-cracked, or blended, depending on the refining process used to produce them. Straight-run fuels are those produced by distillation under atmospheric pressure without decomposition of the hydrocarbons by cracking. Thermally-cracked fuels are those produced by a cracking process involving elevated temperatures (850–1100 F) and pressures (300 psig) to decompose the heavier hydrocarbons. Catalytically-cracked fuels are those produced with the aid of an alumina-silica catalyst in the cracking process at lower pressures than those used for thermal cracking. Blended fuel oils are mixtures of any of the above three types.

Grade Classification of Fuel Oils

Fuel oils are most commonly classified by dividing them into grades in accordance with the *Commercial Standard* (CS12-48) entitled *Fuel Oil* published by the *U. S. Department of Commerce*. These specifications, given in Table 4, conform to *ASTM Materials Specifications for Fuel Oils* D 396 – 48. Table 4 also shows specifications for PS 300 and PS 400 fuel oils which are numbers used in the Pacific

Table 4 .... Detailed Requirements for Fuel Oils[a]

Grade of Fuel Oil[b]	Flash Point F	Pour Point F	Water and Sediment % by Vol.	Carbon Residue on 10% Residuum %	Ash % by Wt.	Distillation Temperatures F			Saybolt Viscosity Seconds				Kinematic Viscosity Centistokes			
						10% Point	90% Point	End Point	Universal at 100 F		Furol at 122 F		at 100 F		at 122 F	
	Min.	Max.	Max.	Max.	Max.	Max.	Max.	Max.	Max.	Min.	Max.	Min.	Max.	Min.	Max.	Min.
1. A distillate oil intended for vaporising pot-type burners and other burners requiring this grade[d] API gravity 35 (min.)	100 or Legal	0	Trace	0.15		420		625					2.2	1.4		
2. A distillate oil for general purpose domestic heating for use in burners not requiring No. 1 API gravity 26 (min.)	100 or Legal	20[e]	0.10	0.35		[c]	675		40				(4.3)			
4. An oil for burner installations not equipped with preheating facilities	130 or Legal	20	0.50		0.10				125	45			(26.4)	5.8		
5. A residual type oil for burner installations equipped with preheating facilities	130 or Legal		1.00		0.10					150	40			32.1	(81)	
6. An oil for use in burners equipped with preheaters permitting a high viscosity fuel	150 or Legal		2.00[f]								300	45			(638)	(92)
PS 300	150 or Legal		1.0								40	25				
PS 400	150		2.0[f]									60				

[a] Recognizing the necessity for low sulfur fuel oils used in connection with heat-treatment, non-ferrous metal, glass and ceramic furnaces and other special uses, a sulfur requirement may be specified as 0.5% for No. 1, 1.0% for No. 2, and no limit for Nos. 4, 5 and 6.

Other sulfur limits may be specified only by mutual agreement between the buyer and seller.

[b] It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade.

[c] Lower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0 F under any condition.

[d] No. 1 oil shall pass test for corrosion made in accordance with paragraph 15 *ASTM Specifications for Fuel Oils*, D 396 - 48.

[e] The 10 percent point may be specified at 440 F maximum for use in other than atomizing burners.

[f] The amount of water by distillation, plus the sediment by extraction, shall not exceed 2.00 percent. The amount of sediment by extraction, shall not exceed 0.50 percent. A deduction in quantity shall be made for all water and sediment in excess of 1.0 percent.

PS 300 and PS 400 are Pacific Specification numbers. Balance of table from *Commercial Standard* CS 12-48 and *ASTM Materials Specification for Fuel Oils* D 396 - 48.

PS 300 is a residual oil for use without preheating in furnaces and burners requiring a low viscosity fuel, and commonly described as light fuel oil, domestic fuel oil, or low viscosity fuel oil.

PS 400 is a residual oil for use in furnaces and burners equipped with preheaters permitting a high viscosity fuel, and commonly described as industrial fuel oil, heavy fuel oil, or high viscosity fuel oil.

coast area. These oils correspond approximately to ASTM designations No. 5 and No. 6 respectively.

Oils are classified by their viscosities. Other characteristics of fuel oils which determine their grade classification in the *Commercial Standard*, and their suitability for given uses are the flash point, pour point, water and sediment content, carbon residue, ash, and distillation characteristics.

The flash point of an oil is important with regard to safety in handling and in storage. The distillation characteristics determine whether or not the oil can be completely evaporated in some types of burners, and whether cracking will be likely to occur prior to combustion. A low pour point and low water content are necessary for handling and outdoor storage in cold climates. Sediment should be low to prevent clogging of strainers. Carbon residue is related to the rate of accumulation of unburned material in some types of burners. A low viscosity allows the fuel oil to flow through supply lines readily and to be broken up into small droplets in atomizing type burners. The sulfur content is of importance because undesirable compounds of sulfur may be formed in certain industrial processes. Some of these characteristics of a fuel oil are required to lie within certain limits for each of the grades of fuel oil listed in *Commercial Standard* CS12-48. Some fuel oils do not fall into any of the grade classifications of the *Commercial Standard* because failure to comply with all of the requirements of one grade does not automatically place the fuel oil in the next lower grade, unless it meets all of the requirements of the lower grade.

Table 5 .... Approximate Gravity and Calorific Value of Standard Grades of Fuel Oil

Commercial Standard No.	Approximate Gravity API	Weight lb per gallon	Calorific Value Btu Per Gallon
1	38–45	6.951–6.675	137,000–132,900
2	30–40	7.296–6.870	141,800–135,800
4	12–32	8.212–7.206	153,300–140,600
5	8–20	8.448–7.778	155,900–148,100
6	6–18	8.571–7.882	157,300–149,400

By ultimate analysis the No. 1 and No. 2 fuel oils contain 84 to 86 percent carbon, up to 1.0 percent sulfur, and the remainder predominantly hydrogen. The heavier grades of fuel oil, Nos. 4, 5 and 6, may contain as much as 88 percent carbon, as low as 11 per cent hydrogen, and considerably more sulfur than is permissible in the domestic grades.

Due to variation in the constituents of different fuel oils and the different refining methods used, the API gravities and calorific values of the different grades of fuel oil cover a range in each grade with some overlapping between domestic grades and between commercial and industrial grades. API *gravity*, generally used when referring to specific gravity of oil, is obtained by the following formula in which the term *specific gravity at 60/60 F* indicates the ratio of the weight of a given volume of oil at 60 F to the weight of the same volume of water at 60 F:

$$\text{Degrees API} = \frac{141.5}{\text{specific gravity at } 60/60 \text{ F}} - 131.5$$

The API gravity of water at 60 F is 10.0. The relation between the API gravity of fuel oils and their calorific value is shown in Table 5. Grades No. 1 and No. 2, which are distillates, are used predominantly in domestic heating equipment whereas grades 5 and 6 are used in commerical and industrial burners. Grade 6 requires preheating to increase its fluidity and to permit atomization, whereas grade 5 may be used in some burners without preheating. Grade 4 fuel oil does not require preheating and can even be burned satisfactorily in a limited number of domestic burners.

Sources and Properties of Residual Fuel Oils

Fuel oils Nos. 5 and 6 always contain residues remaining from the refining of crude oils. No. 4 oil will sometimes consist entirely of heavy distillates but generally contains residual stocks.

The residues may be classified, in accordance with their previous processing, as straight-run, vacuum-flashed, or cracked residues. Straight-run residues are the materials in crude oil that cannot be distilled at atmospheric pressure without appreciable decomposition and hence are removed as bottom fractions from crude topping units. These materials, often referred to as *topped* or *reduced* crude, are sometimes blended into fuel oil, but more frequently are processed, either by vacuum distillation or by thermal cracking, to produce additional distillates. Residues from vacuum distillation processes are widely used as residual fuel blending stocks. Vacuum-flashed residues from some crudes must be subjected to a mild thermal cracking, known as viscosity-breaking, before they can profitably be blended into fuel oils. Residues produced by thermal cracking of straight-run or vacuum-flashed residues or by thermal reforming of heavy naphthas, also are used in residual fuel oils.

In processing reduced crudes and other stocks that yield residual fuel-blending stocks, the refiner evaluates the severity of treatment against, among other factors, the effect on certain properties of the residues. Perhaps the most significant of these properties is viscosity. Maintenance of fuel viscosity within a certain range by preheating of the oil is necessary to obtain satisfactory combustion efficiency with most burners for heavy oil. In most instances there is a maximum temperature to which the oil should be preheated. Consequently a maximum viscosity is usually placed on the finished product.

The second property of oil that is markedly sensitive to refining procedures is specific gravity. Residues may have gravities on either side of API 10, i.e., they may be either lighter or heavier than water. Since residual fuels in many instances are stored and used in the presence of water the densities of the fuel oils must differ sufficiently from water to assure their separation into distinct layers.

The limits imposed by viscosity and specific gravity specifications are met in part by refining practices and in part by blending residues with distillates. These distillates may be straight-run gas oils and distillates produced by thermal or catalytic cracking. Blending of residues and distillates generally entails down-grading of the latter. Consequently efforts are made to reduce to a minimum the quantities of *cutter stock* (the refinery term for distillates used for this purpose) necessary to meet manufacturing specifications. Heavy catalytically- or thermally-cracked distillates are generally used as cutter stock, not only because they are of less value for further processing than straight-run gas oils, but also because they have greater solvency for asphaltic materials in cracked residues.

This discussion of residual fuel oils has been concerned principally with No. 6 fuel oil, the heaviest grade of residual fuel. Two other grades of residual fuels, Nos. 4 and 5, are produced and marketed. These fuels have lower viscosities and higher gravities than No. 6 fuel oil. Generally these specifications are met by increasing the ratio of cutter stock to residue, but occasionally these lighter fuels are made by blending No. 6 and No. 2 fuel oils.

Sometimes No. 4 oil will consist entirely of heavy distillates but generally this grade of fuel contains residual stocks. Due to their higher distillate content both No. 4 and No. 5 grades bring higher prices than No. 6 fuel oil, and frequently they are priced on a different basis, i.e., in cents-per-gallon rather than dollars-per-barrel.

Oil Burning Indexes

A number of indexes have been used, or proposed, as an indication of the burning qualities of distillate fuel oils based on one or more physical measurements made on the oil. These may be summarized as follows:

A. Indexes based on a single physical test: (1) API gravity,[a] (2) Aniline point,[a] (3) Institute of Petroleum smoke test, (4) Carbon-Hydrogen ratio based on flue gas analysis or ultimate analysis, and (5) Percent aromatics determined by sulfuric acid absorption tests.[a]

B. Indexes based on two or more physical tests: (1) Diesel index[a] based on API gravity and aniline point, (2) Institute of Petroleum cetane number[a] based on the API gravity and 50 percent distillation point, (3) Universal Oil Products characterization factor[a] based on specific gravity and average

boiling point, (4) Burning index[20] based on API gravity and 50 percent distillation point, and (5) Estimated Carbon-Hydrogen ratio[21] based on API gravity aniline point, and boiling point.

Various investigators have shown correlation between one or more of these indexes and the performance of fuel oils in oil burners. Experiments conducted with the Oil Heat Institute Reference Test Unit[12] indicated good correlation between the smoking tendency of fuel oils and API gravity, burning index, Diesel index, and hydrogen-carbon ratio for a limited number of oils in laboratory apparatus simulating a pressure-atomizing burner. These results are shown graphically in Fig. 3. Smoking tendency is given here in terms of smoke-spot

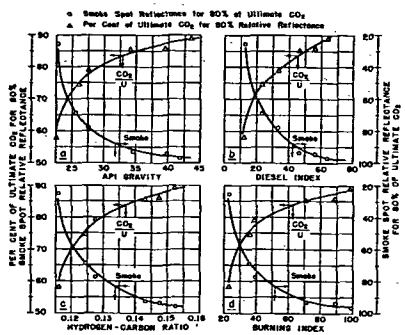

Fig. 3 .... Correlation of Burning Qualities of Fuel Oils with Four Combustion Indexes

reflectance, the light reflectance of a smoke-soiled filter paper. A high reflectance, relative to a clean filter paper, indicates low smoking tendency. CO_2/U is the observed CO_2 divided by the ultimate or maximum theoretical CO_2 expressed as a percentage. Reid and Hersberger[20] have related burning qualities and burning index for various oils in a wall-flame burner. Cauley and Delgass[21] cite test results on combustion indexes obtained with vaporizing burners. The present experimental data are probably too meager as yet to correlate adequately any one of these indexes with burning qualities of oil fuel for all types of burners. Few attempts have been made to suggest limits for any of these fuel oil indexes for particular applications, even though correlations between them and burning qualities have been observed.

Experiments have shown that the rate of thermal decomposition or cracking of hydrocarbons becomes appreciable at a temperature of approximately 680 F at atmospheric pressure. Thus distillate fuel oils, whose end point approximates this temperature, cannot be completely evaporated in vaporizing-type oil burners at atmospheric pressure without leaving a residue. A complete distillation curve cannot usually be determined for fuel oils containing fractions that evaporate above 680 F.

Since No. 1 grade fuel oil in *Commercial Standard* CS12-48 has a maximum end point of 625 F, although an end point this high is rare, it can in most cases be completely evaporated in atmospheric vaporizing burners without cracking, although occasionally an oil is found that undergoes cracking at temperatures below 625 F. By the same criterion, No. 2 grade fuel oil in the *Commercial Standard*, which can have a maximum distillation temperature of 675 F at the 90 percent point, would generally be cracked in a vaporizing burner. Vaporizing-type burners, therefore, can use only No. 1 fuel oil with assurance that thermal decomposition will not occur during combustion. On the other hand either No. 1 or No. 2 fuel oils may be employed in high- or low-pressure atomizing burners when the temperatures developed in the combustion chamber are high enough to assure complete combustion, even if the fuel oil is thermally decomposed.

In vaporizing burners there is complete evaporation of fuel before it is exposed to intense heat. Thorough mixing of the air and gasified fuel promote complete combustion without smoke and with a minimum of excess air. In pressure-type burners good atomization of the fuel, good mixing of the atomized oil with the air, air turbulence, and high combustion chamber temperatures (preferably red hot) promote smokeless combustion with a minimum of excess air.

Natural draft burners depend on the motivating force of a chimney to induce enough air into the burner for complete combustion. Forced draft burners are supplied with combustion air by means of a blower or fan; the chimney merely conducts the flue gases outdoors and prevents leakage of flue gases into the building. More details on the operation of the different kinds of oil burners and on chimneys and draft will be found in Chapters 34 and 36 respectively.

FUEL GASES

Fuel gases employed for various heating and air conditioning processes throughout the United States fall into three broad classifications: natural, manufactured, and liquefied petroleum. Natural gas is a mixture of several combustible gases and, usually, a small percentage of inert gases obtained from geologic formations. Manufactured gas is made by the distillation or cracking of oil or coal, by the steam-carbon reaction, or by combinations of these processes. Liquefied-petroleum gases (propane and butane) are higher hydrocarbon gases normally obtained as a by-product of oil refineries or by stripping natural gas. These two compounds are generally gaseous under usual atmospheric conditions although they can be liquefied by the application of moderate pressures at normal temperatures.

In American gas practice the heating value of a gas and also appliance efficiencies are based on the gross heating value. This value is the number of Btu liberated by complete combustion, at constant pressure, of one cubic foot of gas saturated with water vapor and measured at 60 F and 30 in. of mercury, with air at the same temperature and pressure. Products of combustion are cooled to the initial temperature of the gas and air and the water formed by combustion of free and combined hydrogen is condensed to the liquid state.

Classification of Gases

Representative properties of gaseous fuels commonly employed for domestic heating processes are shown in Table 6.[12, 14, 15, 16]

Natural gas contains from 55 to 98 percent methane with various percentages of higher hydrocarbons, chiefly ethane. In addition to these components, small quantities of non-combustible gases such as carbon dioxide, nitrogen, and helium are sometimes present. Percentages of the different components vary with the area from which natural gas is withdrawn. They may even vary slightly from any given well

This table abstracted from *Gaseous Fuels*, American Gas Association, and from A.G.A. Laboratories Data.

[a] At 60 F and 30 in. mercury, absolute pressure. [b] Divided 16.5% isobutane, 50.1% n-butane. [c] Divided 33.3% isobutane, 70.7% n-butane.

during its lifetime but these variations are inconsequential insofar as the utilization of the gas is concerned. Heating values of natural gases vary from 900 to 1400 Btu per cu ft but the usual range for use is from 1000 to 1050 Btu (gross) per cu ft. A typical analysis is given in Table 6.

Manufactured gases commonly produced are listed in Table 6. Gross, or higher, calorific values of typical send-out gases made from these manufactured gases generally range from 500 to 600 Btu per cu ft. Due largely to the greatly increased demand for city gases the tendency during recent years has been to increase rather than to decrease heat content of manufactured gases, thus making it possible to serve more customers through the existing distribution system.

Mixed gases are a result of increased distribution of natural gas, through transcontinental transmission lines, into areas having existing manufactured gas facilities. In such instances some gas companies supply a 600 to 800 Btu mixture (see Table 6). In some territories these mixtures are distributed as an intermediate step in changing over from manufactured gas to natural gas. Although the burden of adjusting installed heating and air-conditioning equipment and supplying new orifices and burner equipment is generally assumed by the gas companies when the gas is changed, it is advisable to consult the local gas company to insure that equipment is provided with proper orifices and burners when installed.

Most states enforce legislation through their public service commissions to require delivery of a gas of specified average or minimum heating value within their respective limits. Any given heating value within reason fortunately may be maintained and yet permit considerable latitude in the composition of the gas distributed. Hence the constituents of city gases are not necessarily the same in different districts nor even at successive stations in the same district. In every community, however, the objective is to maintain variations in composition and gas pressure within limits that will provide satisfactory operation and performance of all common types of gas burning equipment.

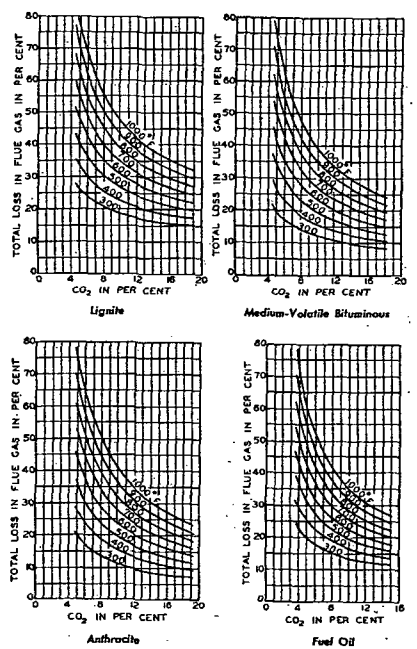
Liquefied petroleum gases, such as propane and butane or mixtures thereof have calorific values ranging from 2500 to 3200 Btu per cu ft. These fuels are often supplied as liquids under pressure in tanks or bottles. In such cases the liquid evaporates when pressure is relieved, the heat necessary for vaporization being obtained from the surrounding air or ground. As butane boils at 32 F some provision is necessary for maintaining the gas above this temperature or for lowering the partial pressure by dilution if the gas is utilized in colder climates. Propane, with a boiling point of −40 F, may be served in localities where temperatures substantially below freezing are encountered. When employed for heating purposes, these gases are usually stored in high pressure tanks and delivered by tank truck in much the same manner as fuel oil. Both gases, mixed with air, or in undiluted form, are also extensively employed by gas companies to augment their base load supplies during peak load periods. In some smaller communities, where gas manufacturing plants are not economically feasible and natural gas is unavailable, liquefied petroleum gases or liquefied petroleum gas-air mixtures are supplied through mains in much the same manner as manufactured or natural gas.

COMBUSTION OF GASEOUS FUELS

Gas burners employed in domestic heating appliances are generally of the non-luminous flame or Bunsen type. Part of the air required for combustion is inspirated as *primary air* into the burner mixing tube where it mixes with gas, and then takes part in combustion at the burner ports. As the amount of primary air is seldom sufficient to support complete combustion, additional air is supplied to the burner flames around the periphery of its ports. This *secondary air* is induced into the appliance and around the base of each separate burner flame by force of the issuing mixture of gas and primary air and by draft inspiration inherent in the heat of the flames. If a Bunsen type burner is properly adjusted, its flames will generally have a clear, blue appearance. Yellow flames are indicative of insufficient primary air supply, and possibly of incomplete combustion. An appreciable updraft is seldom, if ever, present even in flue-connected gas heating appliances, because most appliances of this kind are equipped with a draft hood which reduces the chimney draft at the appliance. It is important to note that gas furnaces and boilers, as well as most other classes of heating equipment, are designed to create their own draft.

The air-to-gas ratio in a Bunsen burner head has a decided effect on the rate of flame propagation. The gas-air mixture must flow from the burner ports faster than the flame burns, otherwise flashback will occur. The flashback condition normally results either from an excess amount of primary air or insufficient gas or both. Conversely, the velocity of the issuing mixture must not be so high that the flame will be blown from the ports, a condition known as *lifting*. Fortunately, contemporary types of such burners have a rather wide range of flexibility in capacity and adjustment. In addition to this characteristic, gas supply is normally so uniform that if a gas heating appliance is properly adjusted when it is installed, its burners, with occasional cleaning, should provide trouble-free service for years. When problems incident to changeover of the gas supply are involved, they are generally assumed by the local utility providing the supply of gas. In many instances when the gas supply is changed, it is necessary to change the burners to those suitable to burn the new kind of gas. It should be recognized that a change in fuel gas will change the operating CO_2 value. For example, an appliance operating on carburetted water gas at 20 percent excess air will have 14.2 percent CO_2 in the flue gases. If a change is made to coke oven gas at the same gas input rate, with the excess air maintained at 20 percent, the operating CO_2 would drop to 9.2 percent.

Luminous flame burners are occasionally used in central heating gas appliances. With these devices all air required for complete combustion is supplied to the flames as secondary air. Two fundamental advantages of this type of burner are that the possibilities of flashback are eliminated, and that a much higher gas velocity is needed to blow the flames off the ports. On the other hand, if there is any appreciable amount of flame impingement on any portion of the heating surface, or if secondary air is not effectively supplied to the flames, soot may be formed and also combustion may be incomplete.



In some types of gas burners radiant baffles are used to convert part of the energy formed during the process of combustion to radiant heat. These baffles may also serve to direct the flow of products of combustion along the heat-absorbing surface.

Gas-designed furnaces and boilers approved by the American Gas Association are certified for operation at the rating shown on the nameplate. Considerations relating to safety, performance, and service life, require that such appliances be adjusted at inputs that do not exceed the nameplate input rating. These appliances normally draw in from 20 to 50 percent excess air, depending on the type and general design. As has been indicated, some excess air is necessary to insure complete combustion at all times and also to provide a reasonable degree of flexibility in performance.

Various types of appliances used for gas space heating purposes are described in Chapter 34.

FUNDAMENTAL PRINCIPLES OF COMBUSTION

Regardless of the type of fuel under consideration, its combustion results in the production of gaseous products. Many kinds of solid fuels contain minerals which cannot be burned and are therefore left as a residue commonly called ash. Moreover, unless sufficiently high temperatures are employed and an ample supply of oxygen properly distributed is present, the combustible constituents of solid, liquid, and even gaseous fuels cannot be completely burned. Incomplete or partial combustion of all fuels produces toxic gases, such as carbon monoxide, with smaller quantities of aldehydes,

Flue Gas Temperature Shown. Loss is Based on 65 F Room Temperature

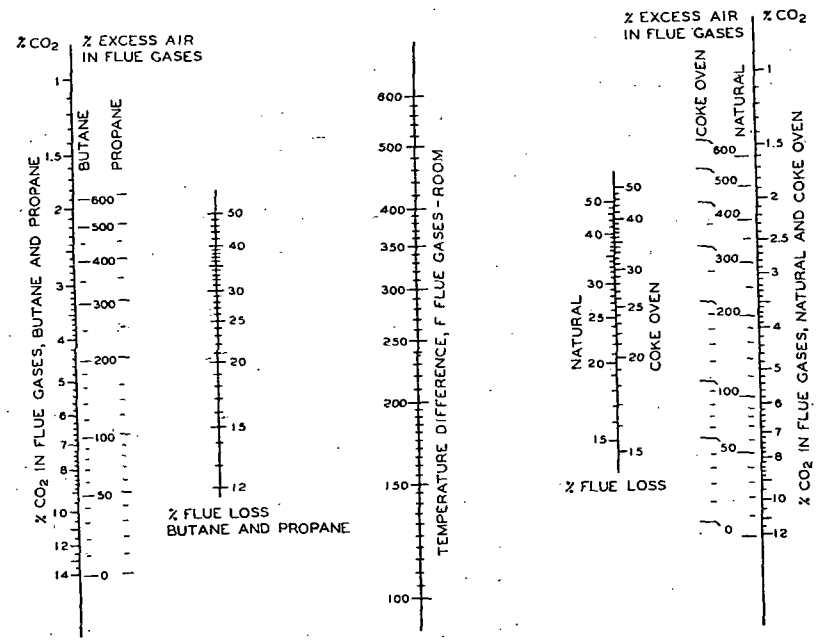


Fig. 4 .... Flue-Gas Losses with Various Fuels[3]

ketones, and other hydroxylated hydrocarbon compounds. This fact indicates that, while combustion processes involving common types of fuel may be regulated by experienced operators to produce the most efficient results, normal combustion processes can be so unbalanced as to create hazards unless both design and operation are planned with a knowledge of the fundamental principles of combustion.

Combustion may be defined as the chemical combination of a substance with oxygen resulting in the evolution of heat, and usually some light. The rate of combustion depends upon the rate of reaction of the substance with oxygen, upon the rate at which oxygen is supplied, and upon the temperature obtained due to surrounding conditions. This is combustion in its simplest form. All solid, as well as liquid and even gaseous fuels generally contain several combustible elements in combination with others which, depending on their nature, affect oxygen requirements and thus govern the combustion process. For a continuous reaction, as in heating processes, it is necessary to establish an effective balance between rates of removing heat and of supplying fuel and air or oxygen to keep the reaction going. In establishing such a balance, consideration must be given to the removal or venting of products of combustion, so that the entire process is one of flow wherein draft conditions in the combustion space are important.

Complete combustion is obtained when all combustible elements in a fuel are oxidized by all of the oxygen with which they will combine. All oxygen or air supplied is generally not utilized, and this excess portion is commonly referred to as *excess oxygen* or *excess air*. Excess air is usually expressed as a percentage of the air required for perfect combustion.

Perfect combustion results when the exact amount of oxygen required for complete combustion of all elements of a fuel is supplied and utilized. The percentage of carbon dioxide contained in the products of combustion from such a reaction is obviously the maximum attainable and is referred to as the *ultimate CO_2 or maximum theoretical percentage of carbon dioxide*. This condition of perfect combustion, without having excess air or oxygen left from the reaction, is seldom, if ever, realized in practice. Most types of heating equipment must be sufficiently flexible in performance to provide complete combustion with not only variations in the quality of a fuel but also changes in the rate at which it is supplied. This situation makes it advisable, from a practical standpoint, to insure *complete com-*

[b] Gas measured at 60 F and 30 in. Hg. [c] Value from National Bureau of Standards.

bustion but not *perfect combustion* in the sense expressed above. To attempt to do so would undoubtedly result eventually in unsatisfactory performance especially from a safety standpoint. Consequently, common types of heating equipment are usually designed, installed, and adjusted to operate with some excess air. The exact percentage of such air depends on the type of fuel being utilized, as well as anticipated variations in its quantity and quality. Despite these practical limitations, however, it should not be inferred that common types of fuels cannot be utilized economically. Reference to flue loss charts such as Figs. 4 and 5 for gas burning equipment and to the air requirements discussion in Chapter 34 shows that reasonable quantities of excess air can be used without appreciable reductions in operating efficiencies.

Oxygen combines with the combustible elements and compounds of any fuel in accordance with fixed laws. The reactions and resultant products of perfect combustion of common fuel constituents are shown in Table 7. All of the oxygen required for combustion is normally obtained from the surrounding air, which is a mechanical mixture of nitrogen and oxygen with small amounts of carbon dioxide, water vapor and inert gases. For practical combustion calculations, air is considered to consist of 20.9 percent oxygen and 79.1 percent nitrogen by volume, or 23.15 percent oxygen and 76.85 percent nitrogen by weight. The nitrogen, being inert, passes through the reaction without change. Table 7 gives the air quantities corresponding to the oxygen required for perfect combustion.

Air supplied to the combustion reaction is in most instances introduced in two ways. *Primary air* is introduced through or with the fuel, and *secondary air* is supplied to the flames issuing from the fuel.

Incomplete combustion is obtained when any of the combustible elements are not completely oxidized in the combustion reaction. This condition not only represents inefficient use of the fuel but also presents a hazard because carbon monoxide is usually one of the products of incomplete combustion. For example, a hydrocarbon may not oxidize completely to carbon dioxide and water, as indicated in Table 7, but may also form alcohols, ketones, aldehydes, or carbon monoxide depending on where and how the reaction is interrupted. Too low a temperature (such as may be caused by flame impingement on a cold surface), a poor oxygen supply to the flames (due to insufficient or poorly located air supply, or smothering by products of combustion not properly vented), or insufficient mixing of the air and fuel, are the primary causes of incomplete combustion.

Heat of Combustion

As previously stated, the process of combustion results in the evolution of heat. The heat generated by the complete combustion of a unit of fuel is constant for a given combination of combustible elements and compounds, and is known as the *heat of combustion*, *calorific value*, or *heating value* of the fuel. The heat of combustion of the several substances found in the more common fuels is given in Table 7.

The calorific value of a fuel may be determined either by direct measurement of the heat evolved during combustion in a calorimeter, or it may be computed from the ultimate analysis and the heat of combustion of the several chemical elements in the fuel. When the heating value of a fuel is determined in a calorimeter, the water vapor is condensed and the latent heat of vaporization is included in the heating value of the fuel. The heating value so determined is termed the *gross* or *higher* heating value, and this is what is ordinarily meant when the heating value of a fuel is specified. In burning the fuel, however, since the products of combustion are not cooled to the dew-point and the higher heating value cannot be utilized.

When combustion is complete, the carbon in the fuel unites with oxygen to form carbon dioxide, CO_2, the hydrogen unites with oxygen to form water vapor, H_2O, and the nitrogen, being inert, passes through the reaction without change. When combustion is incomplete, some of the carbon may unite with oxygen to form carbon monoxide, *CO*, and some of the hydrogen and hydrocarbon gases may not be

burned at all. When carbon monoxide or other combustible gases are present in the flue gases, there is a loss of heat produced per unit of fuel consumed, and consequently, a lower combustion efficiency is obtained. Incomplete combustion may result from any or all of the following three conditions: (1) inadequate air supply, (2) insufficient mixing of air and gases, and (3) a temperature too low to produce ignition or maintain combustion.

AIR REQUIRED FOR PERFECT COMBUSTION

Air requirements for combustion of solid and liquid fuels are ordinarily expressed in pounds. On the other hand similar requirements for gaseous fuels are usually stated on a cubic foot basis. For solid and gaseous fuels this method of treatment corresponds to the standards of measurement commonly employed by these two industries.

The weight of air required for perfect combustion per pound of solid or liquid fuel may be calculated after substitution of the proper percentages by weight of the various elements obtained from an ultimate analysis of the fuel in Equation 2. For gaseous fuels see Equation 3 for volume of air required.

Solid or Liquid Fuels:

Pounds air required per pound fuel

$$= \frac{34.56}{100}\left[\frac{C}{3} + \left(H - \frac{O}{8}\right) + \frac{S}{8}\right] \quad (2)$$

For Gaseous Fuels:

Cubic feet air required per cubic foot gas

$$= 2.39\,(CO + H_2) + 9.53\,CH_4 + 16.68\,C_2H_6 + 23.82\,C_3H_8 + 30.97\,C_4H_{10} + 11.91\,C_2H_2 + 14.29\,C_2H_4 + 7.15\,H_2S - 4.78\,O_2 + 30.47 \text{ Illuminants} \quad (3)$$

Gaseous fuels may contain a wide variety of components classified as *illuminants*, which are not separated by the usual methods of gas analysis. The principal illuminants in addition to ethylene (C_2H_4) and acetylene (C_2H_2) which are included in Equation 3, with the air required per cubic foot of gas are: propylene, 21.44; butylene, 28.58; pentene, 35.73; benzene, 35.73; toluene, 42.88; and xylene, 50.02. Since toluene and xylene are normally scrubbed from the gas before distribution, they may be disregarded in computing air required for a fuel gas. An approximate value of 30.47 (as shown in Equation 3) may, therefore, be employed. If ethylene and acetylene are included as *illuminants*, it is suggested that the value 19.65 be used.

If it is desired to make the gas calculations on a weight basis the equation is expressed as follows:

Pounds air required per pound fuel

$$= 2.47\,CO + 34.34\,H_2 + 17.27\,CH_4 + 16.12\,C_2H_6 + 15.70\,C_3H_8 + 15.49\,C_4H_{10} + 13.30\,C_2H_2 + 14.81\,C_2H_4 + 6.10\,H_2S - 4.32\,O_2 \quad (4)$$

Where approximate results only are desired, values appearing in Table 8 may be substituted for Equations 2, 3, and 4; or the air required for perfect combustion may be estimated by assuming that 0.9 cu ft air is required per 100 Btu of fuel.

Where extreme precision is involved it is suggested that the reader refer to scientific literature published on the subject of combustion and related topics by the various industries concerned. If approximate values for theoretical air requirements suffice, or if complete information on the fuel is not available, the following values should also be found helpful:

1. *Solid Fuels* (Pounds air per pound fuel): Anthracite, 9.6; Semi-Bituminous, 11.2; Bituminous 10.3; Lignite 6.2; and Coke 11.2.

2. *Fuel Oil* (Pounds air per gallon): Commercial Standard No. 1, 102.6; No. 2, 105.5; No. 5, 112; No. 6, 114.2.

3. *Gaseous Fuels* (Cubic feet of air per cubic foot): Natural, 10.0; Mixed Natural and Manufactured, 8.0; Manufactured, 4.7, Propane, 23.8, Butane, 31.0.

COMBUSTION EFFICIENCY FROM THE FLUE-GAS ANALYSIS

Excess Air

A commonly employed index of efficiency of combustion is the relation existing between the amount of air theoretically required for perfect combustion and the amount of air actually supplied. Since the difference between air supplied for combustion and theoretical air required is characterized as excess air, its percentage may be calculated by use of the following equation,

Percent excess air

$$= \left(\frac{\text{Air supplied} - \text{Theoretical air}}{\text{Theoretical air}}\right) \times 100 \quad (5)$$

The amount of dry air supplied per pound of fuel burned may be obtained from Equation 6 which has reasonable precision for most solid and liquid fuels. Values for CO_2, *CO* and N_2 are percentages by volume from the flue-gas analysis, and *C* is the weight of carbon burned per pound of fuel, corrected for carbon in the ash.

Pounds dry air supplied per pound of fuel

$$= \frac{3.04N_2}{(CO_2 + CO)} \times C \quad (6)$$

Because excess air calculations are almost invariably made from Orsat analysis results, and theoretical air requirements

Table 8 .... Approximate Air Requirements for Theoretically Perfect Combustion of Fuels[a]

Type of Fuel	Air Required for Perfect Combustion: Lb per Lb Fuel	Air Required for Perfect Combustion: Cu Ft per Unit[b] Fuel	Approximate Precision, %	Exceptions
Solid	Btu per lb × 0.00073	Btu per lb × 0.0097	3	Fuels containing more than 30% water
Liquid	Btu per lb × 0.00071	Btu per lb × 0.0094	3	Results low for gasoline and kerosine
Gas	Btu per lb × 0.00067	Btu per cu ft × 0.0089	5	Gases of 300 Btu per cu ft or less

[a] Values in table taken from page 378 of *Gaseous Fuels*, 1948, published by *American Gas Association*.
[b] Units for solid and liquid fuels in pounds, for gas in cubic feet.

are not always known, another convenient method of expressing the relation of Equation 5 is as follows:

$$\text{Percent excess air} = \frac{100(O_2 - CO/2)}{N_2 \times 0.264 - (O_2 - CO/2)} \quad (7)$$

As measurement standards for gaseous fuels are almost universally expressed in cubic feet, Equation 8 may be employed for computing excess air on a percentage basis for gases.[7]

$$\text{Percent excess air} = \frac{(U - CO_2)}{CO_2} \times 100\,\frac{P}{A} \quad (8)$$

where

U = ultimate carbon dioxide, percent of flue gases resulting from perfect combustion.
CO_2 = carbon dioxide content of flue gases, percent.
P = dry products from perfect combustion, cubic feet per cubic foot of gas burned.
A = air theoretically required for complete combustion, cubic feet per cubic foot of gas burned.

As the ratio of P/A is approximately 0.9 for most city gases, a value of 90 may be substituted for 100(P/A) in Equation 8 for rough calculation.

Carbon-hydrogen ratios of different fuels vary considerably, hence the maximum or ultimate CO_2 attainable also varies. Where they are unknown, theoretical maximum CO_2 values may be calculated from a flue-gas analysis by use of Equation 9.

Maximum theoretical % CO_2

$$= \frac{\%\ CO_2 \text{ in flue gas sample} \times 100}{100 - \left(\dfrac{O_2 \text{ in same sample}}{0.21}\right)} \quad (9)$$

Approximate maximum CO_2 values for perfect combustion of several common types of fuel are shown in Table 9 together with values of CO_2 that will be attained with different amounts of excess air. Desirable values to be attained in practice depend upon the fuel, the method of firing, and other considerations. In general, fuels burned in suspension, such as gas, oil, and pulverized coal, can be burned with a lower amount of excess air than fuels burned on grates.

Table 9 . . . . Approximate Maximum Theoretical CO_2 Values, and CO_2 Values for Various Fuels with Different Percentages of Excess Air

Type of Fuel	Maximum Theoretical or Ultimate Percent CO_2	Percent CO_2 at Given Excess Air Values		
		20%	40%	60%
Coke	21.0	17.5	15.0	13.0
Anthracite	20.2	16.8	14.4	12.6
Bituminous Coal	18.2	15.1	12.9	11.3
No. 1 and 2 Fuel Oil	15.0	12.3	10.5	9.1
No. 6 Fuel Oil	16.5	13.6	11.6	10.1
Natural Gas	12.1	9.9	8.4	7.3
Carburetted Water Gas	17.2	14.2	12.1	10.6
Coke Oven Gas	11.2	9.2	7.8	6.8
Mixed Gas (Natural and Carburetted Water Gas)	15.3	12.5	10.5	9.1
Propane Gas (Commercial)	13.9	11.4	9.6	8.4
Butane Gas (Commercial)	14.1	11.6	9.8	8.5

To produce heat efficiently by burning any common fuel, a number of basic requirements must be met: (1) adequate heat absorbing surface of proper shape and construction is necessary in the appliance, (2) heat transfer surfaces must be clean, (3) a minimum amount of excess air must be present, (4) air employed for combustion and combustible gases must be properly mixed, and (5) flue-gas losses must be reduced to a safe minimum.

If insufficient heating surface is employed, or if heat transfer surfaces are covered with soot, ash, or scale, flue losses will generally be excessive due to the large amount of sensible heat escaping to the chimney. Too much excess air dilutes flue gases excessively and increases sensible flue gas loss. On the other hand, a deficiency of excess air will in all probability cause incomplete combustion, and consequent escape of some unburned combustible gases from the appliance. Highest combustion efficiency is obtained when sufficient excess air is supplied and properly mixed with the combustible gases. Even with appliances connected to an effective flue every reasonable precaution should be taken to insure as complete combustion as possible at all times. This is of vital importance in unvented equipment such as a gas space heater, for example. It is considered good practice to supply from 20 to 50 percent excess air, the exact amount depending on the kind of fuel burned and especially on the type of equipment in which it is utilized.

Flue Gas Analysis

As radiation, convection, and conduction losses from common types of central heating appliances are largely employed in heating occupied spaces, flue-gas losses logically become the item of principal concern. Another reason for their importance is the fact that they are usually larger than all other heat losses combined. These important considerations and others indicate not only the desirability but absolute necessity of a reasonably accurate method for determining flue losses even if only approximate operating efficiencies are to be computed.

Customary procedure in arriving at flue-gas losses is to make an analysis of a representative sample of flue gases and to measure their temperature. This information will enable the observer to compute the amount of flue gases produced, the excess air, the actual quantity of air supplied for combustion, and the flue losses. While the analysis of flue gases has been well described in several governmental and other scientific publications, the subject is of such importance that it warrants brief repetition here. Carbon dioxide and oxygen content are of principal interest in determining flue losses. Either or both of these values may be employed in such calculations. While the former constituent is probably most commonly employed, special considerations may make the latter of greater interest. Fortunately, both can be determined readily by use of an Orsat gas analysis apparatus, a device of reasonably simple construction and design. For field testing and burner adjustment, simple portable devices are available for determining carbon dioxide only. See Chapter 44 for details regarding the operation of the Orsat apparatus.

The weight of dry flue gas per pound of fuel burned is

widely used in combustion loss calculations. For solid fuels this item may be determined by application of Equation 10.

Pounds dry flue gas per pound fuel

$$= \frac{11CO_2 + 8O_2 + 7(CO + N_2)}{3(CO_2 + CO)} \times C \quad (10)$$

Values for CO_2, O_2, CO, and N_2 are percentages by volume from the flue gas analysis, and C is the weight of carbon burned per pound of fuel, corrected for carbon in the ash.

Total dry gas volumes of flue gases resulting from the combustion of one cubic foot of gaseous fuels for various percentages of CO_2 may be determined by application of Equation 11:

Cubic feet dry flue gases per cubic foot fuel gas

$$= \frac{\text{Cubic feet } CO_2 \text{ produced per cubic foot of gas burned} \times 100}{\text{Percent } CO_2 \text{ by analysis}} \quad (11)$$

After obtaining the quantity of flue gases from Equations 10 or 11, the excess air quantity may be determined by subtracting the quantity of dry flue gases which would result from perfect combustion. Computations of flue losses are described in the next section on Heat Balance.

Application of the preceding equations and tables are illustrated by *Examples 1* and *2*.

Example 1: The analysis of the flue gases resulting from the burning of a natural gas is 10.0 percent CO_2, 3.1 percent O_2, and 86.9 percent N_2 by volume. The analysis of the fuel is 90 percent CH_4, 5 percent N_2, and 5 percent C_2H_6 by volume. Find U the maximum theoretical percent CO_2 and the percent excess air.

Solution: From Equation 9:

$$U = \frac{(10.0)(100)}{100 - \left(\dfrac{3.1}{0.21}\right)} = 11.8\%\ CO_2$$

From Equation 8,

$$\text{Percent Excess Air} = \frac{(11.8 - 10.0) \times 90}{10} = 16.2$$

Example 2: For the analyses in *Example* 1 find, per cubic foot of fuel gas, the cubic feet of dry air required for combustion, the cubic feet of each constituent in the flue gases, and the total volume of dry and wet flue gases.

Solution: From Equation 3 (or Table 7) the volume of dry air required for combustion is: $(9.53)\ (CH_4) + (16.68)(C_2H_6) = 9.53 \times 0.90 + 16.68 \times 0.05 = 9.41$ cu ft/cu ft gas.

From Table 7, the constituents per cubic foot of gas are:

Nitrogen, N_2:

From methane = $(0.9\ CH_4)(9.53 - 2.0) = 6.78$
From ethane = $(0.05\ C_2H_6)(16.68 - 3.5) = 0.66$
Nitrogen in fuel = 0.05
Nitrogen in excess air = $0.791 \times 0.162 \times 9.41 = 1.20$
Total Nitrogen 8.69 cu ft

Oxygen, O_2:
Oxygen in excess air = $0.209 \times 0.162 \times 9.41 = 0.32$ cu ft

Carbon dioxide, CO_2:
From methane = $(0.9CH_4)(1.0) = 0.90$
From ethane = $(0.05C_2H_6)(4.0/2.0) = 0.10$
Total Carbon Dioxide 1.00 cu ft

Water vapor, H_2O (does not appear in Orsat analysis):
$(0.9\ CH_4)(2.0) = 1.8$
$(0.05\ C_2H_6)\ (6.0/2.0) = 0.15$
Total water vapor = 1.95 cu ft

Total volume of dry gas per cubic foot of gas:

$$8.69 + 0.32 + 1.00 = 10.01 \text{ cu ft}$$

Total volume of wet gases per cubic foot of gas (neglecting water vapor in combustion air):

$$10.01 + 1.95 = 11.96 \text{ cu ft}$$

The cubic feet of dry flue gas per cubic foot of fuel gas may also be computed from Equation 11 as follows:

$$\frac{(1.00)(100)}{10.0} = 10.0 \text{ cu ft}$$

HEAT BALANCE

The usual practice in analyzing the performance of heating appliances is to make an accounting, insofar as possible, of the disposition of all heat units available in the quantity of fuel burned. This accounting is called a *heat balance*. Various components of this balance are generally expressed in terms of Btu per pound of fuel burned, or as a percentage of its calorific value. Components of special interest are listed as items 1 to 7 inclusive.

1. Useful heat transferred to heating medium, usually computed by determining the rate of flow of the heating fluid through the heating device, and the change in enthalpy of the fluid (heat added) between the inlet and outlet.

2. Heat loss in the dry chimney gases.

$$h_1 = w_g c_p\,(t_g - t_a) \quad (12)$$

3. Heat loss in water vapor formed by the combustion of hydrogen.

$$h_2 = \frac{9H_2}{100}\,(1089 - t_a + 0.455t_g) \quad (13)$$

4. Heat loss in water vapor in the air supplied for combustion.

$$h_3 = 0.455\ M\ w_a\,(t_g - t_a) \quad (14)$$

5. Heat loss from incomplete combustion.

$$h_4 = 10143C\left(\frac{CO}{CO_2 + CO}\right) \quad (15)$$

6. Heat loss from unburned carbon in the ash or refuse.

$$h_5 = 14600^a\left(\frac{C_a}{100} - C\right) \quad (16)$$

7. Radiation and all other unaccounted for losses.

Radiation and convection losses from a heating appliance are not usually determined by direct measurement. For this reason they, together with any other losses not measured, are determined by subtracting the total of items 1 to 6 from the heat of combustion of the fuel. If the heating appliance is located within the heated space, however, radiation and convection losses may be considered as useful heat rather than lost heat. They may, therefore, be omitted from calculations of heat losses, or added to item 1. If there is CO in the flue gases, small amounts of unburned hydrogen and hydrocarbons will probably also be present. The small losses

due to incomplete combustion of these latter gases would also be included in item 7.

Symbols used in Equations 12 to 16 inclusive are:

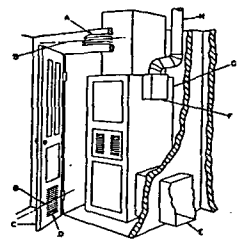
h_1 = heat loss in the dry chimney gases, Btu per pound of fuel.
h_2 = heat loss in water vapor from combustion of hydrogen, Btu per pound of fuel.
h_3 = heat loss in water vapor in combustion air, Btu per pound of fuel.
h_4 = heat loss from incomplete combustion of carbon, Btu per pound of fuel.
h_5 = heat loss from unburned carbon in the ash, Btu per pound of fuel.
w_g = weight of dry flue gas per pound of fuel (from Equation 10), pounds.
c_p = mean specific heat of flue gases at constant pressure (c_p ranges from 0.242 to 0.254 for flue gas temperatures from 300 F to 1000 F),[3] Btu per pound.
t_g = temperature of flue gases at exit of heating device, Fahrenheit.
t_a = temperature of combustion air, Fahrenheit.
H_2 = percentage of hydrogen in fuel by weight from ultimate analysis of fuel burned.
1091.8 = enthalpy of saturated water vapor at a temperature of 70 F, Btu per pound.
M = humidity ratio of combustion air, pounds of water vapor per pound of dry air.
w_a = weight of combustion air per pound of fuel used, pounds, from Equations 2, 4, 5, 6, 7 and 8.
CO, CO_2 = percentages of CO, CO_2 in flue gases by volume.
C = weight of carbon burned per pound of fuel corrected for carbon in ash, pounds.

$$C = \frac{WC_a - W_aC_a}{100W} \qquad (17)$$

where

C_a = percentage of carbon in the fuel by weight from the ultimate analysis.
W_a = weight of ash and refuse, pounds.
C_a = percent of combustible in ash by weight (combustible in ash is usually considered to be carbon).
W = weight of fuel used, pounds.

Flue-gas losses for solid and liquid fuels, listed as items 2, 3 and 4 of the heat balance, may be determined with sufficient precision for most purposes from curves shown in Fig. 4,[3] if CO_2 content and temperature of flue gases are known. Values of the losses plotted for fuel oil were computed from the ultimate analysis of a typical fuel oil used in domestic burners, while those presented for the several ranks of coal were computed from the typical ultimate analyses shown in Table 1. The curves for medium-volatile bituminous coal may be used for high-volatile bituminous coal with negligible error.



Utilization of gaseous fuels, for numerous reasons, is generally a more simple process than is the case with either solid or liquid fuels. Accordingly, the determination of a practical heat balance is also a more simple procedure in that items 5 and 6 do not generally apply to gas installations. A series of typical alignment charts has been combined in Fig. 5 for use in determining flue losses of items 2, 3 and 4 from common types of gas burning appliances. To determine flue losses place a straight edge extending from the corrected temperature reading to the percent CO_2 recorded. Percent flue loss is indicated where the straight edge intersects the flue loss column. The operating efficiency of a gas appliance can then be computed with sufficient precision by application of Equation 18.

Table 10 .... Average Flue Gas Dew Point for Various Fuels[4]

Type of Fuel	Average Dew Point Temperature, F
Anthracite	68
Semi-Bituminous Coal	84
Bituminous Coal	93
Oil	111
Natural Gas	127
Manufactured Gas	137
Propane Gas (2500 Btu/cu ft)	119
Butane Gas (3200 Btu/cu ft)	124
Butane-Air Gas Mixture (535 Btu/cu ft)	121

Percent Combustion Efficiency =

$$\frac{\left(\begin{matrix}\text{Gross Btu of fuel}\\ \text{gas per cubic foot}\end{matrix}\right) - \left(\begin{matrix}\text{total flue losses per}\\ \text{cubic foot fuel gas}\end{matrix}\right)}{\text{Gross Btu of fuel gas per cubic foot}} \times 100 \qquad (18)$$

A. Ventilating air outlet register for appliance room, 1 sq in. free area for each 1000 Btu per hr appliance input located above relief opening of draft hood. Register must not be blocked by drapes or other furnishings.

B. Both registers must either face same large ventilated interior space or extend to such space by means of ducts. Vertical distance C/L to C/L of registers should be not less than 3½ ft.

C. Suggest room access door be not less than 6 ft high by a width sufficient to provide for installation or removal of appliance. At least 3 ft horizontal clearance should be provided in front of appliance when closet door is open, or 18 in. when door is closed.

D. Combustion and ventilation air inlet register for appliance room, 1 sq in. free area for each 1000 Btu per hr appliance input, located at or below combustion air inlet to appliance. Register must not be blocked by drapes or other furnishings.

E. Air circulated by appliance must be handled by ducts which are sealed to appliance casing and are entirely separate from means provided for supplying combustion and ventilation air.

F. Spacing between draft hood and wall at least 6 in. (unless approved for closer spacing). If flue products may be directed toward wall, 12 in. spacing recommended.

G. No part of appliance casing closer than 6 in. to wall (unless approved for closer spacing).

H. Flue should terminate above peak of roof and above nearby walls to assure satisfactory flue performance.

* A value of 14600 applies in calculating ash pit loss; in calculating heat of formation of carbon compounds use 14093 Btu per lb.

Fig. 6 .... Illustration Showing Air Openings Necessary to Supply Air for Combustion When Appliance is Installed in Confined Space

Table 11 .... Permanent Openings for Air Supply to Spaces Containing Fuel-Burning Equipment

	Fuel-Burning Equipment	Free Area of Ventilating Opening*	
		Air Inlet	Air Outlet
Gross output capacity exceeding 250,000 Btu per hr	Equipment in a large enclosure having adequate air infiltration	None required	None required
	Equipment in a large enclosure having unusually tight construction	Total free area communicating with outdoor air not less than ½ sq in. per (1000 Btu) (hr) furnace input	Total free area communicating with outdoor air not less than ½ sq in. per (1000 Btu) (hr) furnace input
	Equipment in a small enclosure in a building having adequate air infiltration	Opening in party wall or door, (above draft hood) with free area of not less than 1 sq in. per (1000 Btu) (hr) furnace input	Opening in a party wall or door, (below combustion air inlet to appliance) with free area of not less than 1 sq in. per (1000 Btu) (hr) furnace input
	Equipment in a small enclosure in a building of unusually tight construction	Grilled opening connecting directly with outdoors, through duct if necessary; free area not less than ½ sq in. per (1000 Btu) (hr) furnace input	Grilled opening connecting directly with outdoor air, through duct if necessary. Area and location same as above.
Gross output capacity not exceeding 250,000 Btu per hr	Equipment in an enclosure having adequate air infiltration	Total free area equivalent to not less than the combined area of the flue outlets of all fuel-burning equipment in the space	None required
	Equipment in an enclosure having unusually tight construction	Total free area equivalent to not less than twice the combined area of the flue outlets, of all fuel-burning equipment in the space	None required

* Operation of exhaust fans, kitchen ventilation systems, fire places, etc. may require special consideration. For residential closet installations see Fig. 6.

Reference to Table 9 will show that ultimate CO_2 percentage values of fuel gases vary. While personal errors involved in CO_2, temperature, and chart determinations, would doubtless more than offset any inaccuracies due to universal use of the alignment charts shown, precise laboratory work may require a more exact method. For more complete information the reader is referred to *combustion*, 3rd Edition, and *Gaseous Fuels*, (published by American Gas Association) and particularly to tables covering various properties of different commercial gases included in these publications.

CONDENSATION AND CORROSION

Sulfur dioxide or sulfur trioxide, formed by the combustion of sulfur in fuels, are the principal corroding substances in flue gases. They become active whenever sufficient moisture is present for the formation of sulfurous or sulfuric acid,[18] and they lower the dew points of flue gases appreciably. Therefore, unless heating equipment is designed for operation at flue-gas temperatures below the dew point, which is seldom the case, it is always advisable to maintain temperatures above this value in all parts of the appliance. Excessive spot temperatures in the combustion chamber or elsewhere, on the other hand, are also destructive in that they may result in rapid oxidation of ordinary heating surfaces. *American Standard Requirements* for gas furnaces, floor furnaces, and recessed heaters, for example, specify that minimum spot heating surface temperatures during normal operation must neither fall below 178 F (50 F above average dew point) nor exceed 830 F to 1230 F on any portion of the heating surface, depending on the type and thickness of the metal. In any event it is usually desirable to maintain flue-gas temperatures within the limits indicated not only throughout the appliance, but in its connecting vent, flue, or chimney as well. Otherwise, excessive condensation and corrosion problems, with resultant customer dissatisfaction, will in all probability be the result. Average dew-point temperatures of flue gases resulting from the combustion of various fuels, when burned with the amount of excess air normally supplied to insure complete combustion, are shown in Table 10.

SOOT

The deposit of soot on the flue surfaces of a boiler or heater acts as an insulating layer over the surface, and reduces the heat transmission to the water or air. The *Bureau of Mines Report of Investigations* No. 3272[19] shows that the loss of seasonal efficiency is not so great as has been believed, and usually is not over 6 percent because the greater part of the heat is transmitted through the combustion chamber surfaces. The *Bureau of Standards Report* BMS 54[20] points out that, although the decrease in efficiency of an oil fired boiler, due to soot deposits, is relatively small, the attendant increase in stack temperature may be considerable.

The soot accumulation clogs the flues, reduces the draft, and may prevent proper combustion. Soot can probably be most effectively removed by a jet of compressed air, by means of a brush, or a vacuum cleaner. However, it has been found that copper chloride, lead chloride, tin chloride, zinc chloride, common salt and some other salts are partially effective in removing soot from furnaces and boilers when properly used.[21] A discussion of instruments and methods of evaluating smoke will be found in Chapter 44.

AIR SUPPLY TO FUEL-BURNING EQUIPMENT

All rooms or spaces containing boilers, furnaces, water heaters, or any other fuel-burning equipment must be provided with a constant supply of combustion air at adequate static pressure to insure proper combustion in the fuel burners. Additional air is required to replace air entering chimneys through draft hoods and barometric draft dampers, and also to provide ventilation in closely confined boiler and furnace rooms.

Experience has shown that the ventilating air openings

required in heater rooms depend not only on the size of the heating plant but also on the type of fuel being burned, the relative size of the equipment room, the tightness of building construction, and the operation of exhaust fans or other devices which affect the static pressure in a building.

Because of the number of variables involved in establishing air requirements, and the variations in building construction and arrangement, there is no universally accepted rule for providing ventilating openings. However, the importance of providing proper ventilation should not be underestimated, and a failure to do so may result in erratic or even dangerous operating conditions for equipment.

Rules for providing air supply openings are found in technical standards,[22, 23] in state and municipal building codes and in service and installation bulletins published by various manufacturers of fuel-burning appliances. Table 11 is a compilation of reasonably consistent data taken from a number of these sources, and should be used only as an aid to independent judgment for any particular installation.

Ventilating air requirements are particularly critical for residential type appliances in closely confined rooms. Fig. 6 illustrates minimum requirements for this type of installation.

CHAPTER 34

AUTOMATIC FUEL-BURNING EQUIPMENT

Classification of Stokers, Combustion Process and Adjustments, Furnace Design, Rating; Classification of Oil Burners, Combustion Process, Combustion Chamber Design; Commercial and Industrial Oil Burners, Types of Burners; Storing and Handling Heavy Fuel Oil; Oil Storage Tanks and Piping; Classification of Gas-Fired Heating Equipment, Combustion Process, Ratings; Sizing of Gas Piping, Commercial and Industrial Gas Equipment; Fuel-Burning Rates; Controls for Automatic Equipment

AUTOMATIC mechanical equipment for the combustion of solid, liquid, and gaseous fuels is considered in this chapter. The type of fuel to be burned affects the design of the heat exchanger (furnace, boiler, etc.); therefore, one should refer to Chapter 35, Heating Boilers, Furnaces, Space Heaters when considering fuels and fuel-burning equipment. Some heat exchangers are designed specifically for one type of fuel. As a result, maximum efficiency and best performance require the simultaneous consideration of fuel and fuel-burning equipment during the initial stages of equipment selection.

MECHANICAL STOKERS

A mechanical stoker is a device that feeds a solid fuel into a combustion chamber, provides a supply of air for burning the fuel under automatic control and, in some cases, incorporates a means of removing the ash and refuse of combustion automatically. Coal can be burned more efficiently by a mechanical stoker than by hand firing because the stoker provides a uniform rate of fuel feed, better distribution in the fuel bed, and positive control of the air supplied for combustion.

In many cities, measures for control of excess smoke require installation of stokers even in residences, unless fuel used contains less volatile matter than bituminous coal.

Classification of Stokers According to Capacity

Stokers may be classified roughly according to their coal burning capacities, as follows:

Class 1	10 to 100 lb per hr
Class 2	100 to 300 lb per hr
Class 3	300 to 1200 lb per hr
Class 4	over 1200 lb per hr

Class 1 Stokers

These stokers are used primarily for home heating and are designed for quiet, automatic operation. Simple, trouble-free construction and attractive appearance are desirable characteristics of these small units.

A common stoker in this class (Fig. 1) consists essentially of a coal hopper, a screw for conveying the coal from the hopper to the retort, a fan that supplies the air for combustion, a transmission for driving the coal feed worm, and an electric motor for supplying power for coal feed and air supply.

Air for combustion is admitted to the fuel through tuyeres at the top of the retort which may be either round or rectangular. Stokers in this class are made for burning anthracite, bituminous, semi-bituminous, and lignite coals, and coke. The U. S. Department of Commerce has issued commercial standards for household anthracite stokers.[1]

Units are available in either the hopper type, as shown in Fig. 1, or in the bin-feed type as shown in Fig. 2. Some stokers, particularly those designed for use with anthracite, automatically remove ash from the ashpit and deposit it in an ash receptacle. Most of the bituminous models, however, require hand removal of the ash from the fuel bed after it is fused into a clinker.

Stokers in this class feed coal to the furnace intermittently in accordance with temperature or pressure demands. A special control is used to insure sufficient stoker operation to maintain a fire during periods when no heat is required.

Class 2 Stokers

Stokers of this class are usually of the underfeed motor-driven screw type, Fig. 3, and are used extensively for heating apartments, schools, hotels, and industrial plants. They are also built in plunger-feed type, Fig. 4, with electric motor or steam or hydraulic cylinder coal feed drive. The tuyeres and retort design vary according to the fuel and load conditions. They are available for burning all types of anthracite, bituminous and lignite coals.

Stationary type grates or dead plates surround the retort of bituminous models to collect the ash and clinkers which are removed periodically by hand. Anthracite stokers in this class may be equipped with moving grates that discharge the ash into a pit, below the grates, having capacity for several weeks of ash accumulation.

Class 3 and 4 Stokers

These stokers are: underfeed side cleaning, underfeed rear cleaning, overfeed flat grate, or overfeed inclined grate type.

Underfeed side cleaning stokers are made in sizes up to about 500 boiler horsepower (or approximately 17 million Btuh). They are not so varied in design as those in the smaller classes, although the principle of operation is similar. A stoker of this type is illustrated in Fig. 4.

The rear cleaning underfeed stoker is usually of the mul-

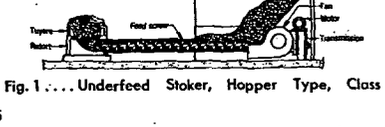

Fig. 1 . . . . Underfeed Stoker, Hopper Type, Class 1

tiple retort design. It is used in some of the largest industrial plants and central power stations. Zoned air control has been applied to these stokers, both longitudinally and transversely of the grate surface.

The overfeed flat grate stoker is represented by the various chain- or traveling-grate stokers.

Another distinct type of overfeed flat-grate stoker is the spreader type in which coal is distributed either by rotating paddles (Fig. 5) or by air over the entire grate surface (Fig. 6). This type of stoker is adapted to a wide range of fuels and has a wide application on small sized fuels, and on fuels such as lignites, high-ash coals, and coke breeze.

The overfeed inclined-grate stoker operates on the same general combustion principle as the flat-grate stoker, the main difference being that rocking grates, set on an incline, are provided in the former to advance the fuel during combustion.

Combustion Process

In anthracite stokers of the Class 1 underfeed type, burning takes place entirely within the stoker retort. The refuse of combustion spills over the edge of the retort into an ashpit or receptacle from which it may be removed either manually or automatically. Anthracite for stoker firing is usually pea, buckwheat, rice, or barley size (see Chapter 33 for a description of size).

Because the majority of the small bituminous coal stokers operate on the underfeed principle, a general description of their operation is given. When the coal is fed into the retort, it moves upward toward the zone of combustion and is heated by conduction and radiation from the burning fuel in the combustion zone. As the temperature of the coal rises, it gives off moisture and occluded gases, which are largely noncombustibles. When the temperature increases to around 700 or 800 F the coal particles become plastic, the degree of plasticity varying with the type of coal.

A rapid evolution of the combustible volatile matter occurs during and directly after the plastic stage. The distillation of volatile matter continues above the plastic zone where the coal is coked. The strength and porosity of the coke formed will vary according to the size and characteristics of the coal. While some of the ash fuses into particles on the surface of the coke as it is released, most of it remains on the hearth or grates and, as this ash layer becomes thicker with time, that portion exposed to the higher temperatures surrounding the retort fuses into a clinker. The temperature in the fuel bed, the chemical composition and homogeneity of the ash, and the time of heating govern the degree of fusion.

Most bituminous coal stokers of Classes 1, 2, and 3 require manual removal of the ash in clinker form.

In the underfeed side-cleaning stokers the fuel is introduced at the front of the furnace to one or more retorts, and is advanced away from the retort as combustion progresses,

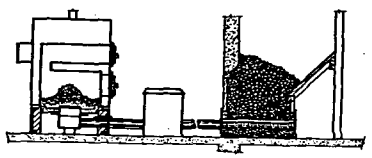

Fig. 2 .... Underfeed Stoker, Bin Feed Type, Class 1

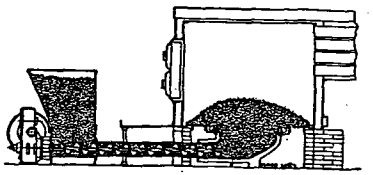

Fig. 3 .... Underfeed Screw Stoker, Hopper Type, Class 2 or 3

while finally the ash is disposed of at the sides. This type of stoker is suitable for all bituminous coals, while in the smaller sizes it is suitable for small sizes of anthracite. In this type of stoker the fuel is delivered to a retort beneath the fire and is raised into the fire. During this process the volatile gases are released, are mixed with air, and pass through the fire where they are burned. The ash may be continuously or periodically discharged at the sides.

The underfeed rear-cleaning stoker accomplishes combustion in much the same manner as the side-cleaning type, but consists of several retorts placed side by side and filling up the furnace width, while the ash disposal is at the rear. In principle, its operation is the same as the side-cleaning underfeed type.

Overfeed flat-grate stokers receive fuel at the front of the grate in a layer of uniform thickness and move it horizontally to the rear of the furnace. Air is supplied under the moving grate to carry on combustion at a sufficient rate to complete the burning of the coal near the rear of the furnace. The ash is carried over the back end of the stoker into an ashpit beneath. This type of stoker is suitable for small sizes of anthracite or coke breeze, and also for bituminous coals, the characteristics of which make it desirable to burn the fuel without disturbing it. This type of stoker requires an arch over the front of the fuel bed to maintain ignition of the incoming fuel, and frequently a rear combustion arch.

Overfeed inclined-grate stokers are provided with rocking grates and ash plates on which ash is accumulated and dumped periodically. This type of stoker is suitable for all types of coking fuels, but preferably for those of low volatile content. Its grate action keeps the fuel bed broken up, thereby allowing free passage of air. Because of its agitating effect on the fuel, it is not desirable for badly clinkering coals. It usually should be provided with a front arch to ignite the volatile gases.

Combustion Adjustments

The coal feeding rate and air supply to the stoker should be regulated so as to maintain a balance between the load

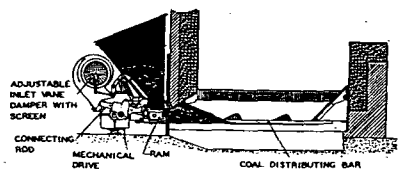

Fig. 4 .... Underfeed Side Cleaning Stoker

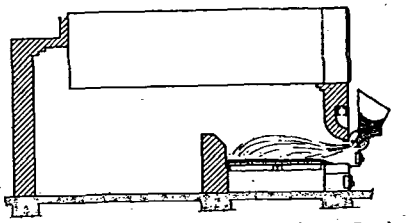

Fig. 5 .... Overfed Spreader Stoker (Rotor Type)

demand and the heat liberated by the fuel. Under such conditions, no manual attention to the fuel bed should be required, other than the removal of clinker in stokers which operate on this principle of ash removal.

As in all combustion processes, the maintenance of the correct proportions of air and fuel is essential. It is desirable to supply the minimum amount of air required to properly burn the fuel at the rate of feed.

While there may be only slight variations in the rate at which the coal is being fed, due to variations in the size or density of the coal, there may be wide variations in the rate of air flow as the result of changes in fuel-bed resistance. These changes in resistance may be caused by changes in the porosity of the fuel bed due to variations in size or friability of the coal, ash and clinker accumulation, and variations in depth of the fuel bed. Because of this variable fuel bed resistance, many bituminous stokers, even in the smaller domestic sizes, incorporate air controls which automatically compensate for these changes in resistance and maintain a constant air-to-fuel ratio. The efficiency of combustion may be determined by analyzing the flue gases, as explained in Chapters 33 and 44.

It is desirable on most stoker installations to provide automatic draft regulation in order to reduce air infiltration and provide better control during the banking, or off, periods of the stoker. It is imperative that adequate combustion air be supplied and, therefore, it is usually necessary to provide a direct outdoor opening for this purpose. (See Chapter 33.)

Combustion Chamber Design

The Stoker Manufacturers Association has published standard recommendations on setting heights for stokers having capacities up to 1200 lb of coal per hour.[a]

The empirical formulas for determining these setting heights are:

For burning rates up to 100 lb coal per hour

$$H = 0.1125\ B + 15.75 \qquad (1)$$

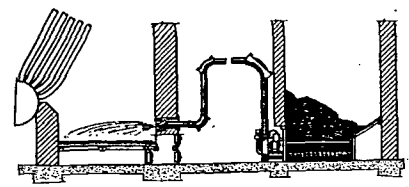

Fig. 6 .... Overfeed Spreader Stoker (Pneumatic Type)

For burning rates from 100 to 1200 lb coal per hour

$$H = 0.03\ B + 24 \qquad (2)$$

where

H = minimum setting height, inches, measured from dead plates to crown sheet for steel boilers. For cast-iron boilers height may be ⅓ H.

B = burning rate coal per hour, pounds.

Standards for minimum firebox dimensions and base heights have been formulated by the Stoker Manufacturers Association as shown in Fig. 7.[a]

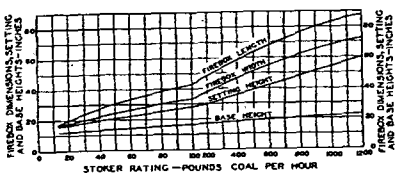
In considering these recommendations, it should be understood that they show the average recommended minimum. There are many factors affecting the proper application of stokers to various types of boilers and furnaces, and, in certain instances, setting height or firebox dimensions shown in the standards may be modified without impairing performance. Such modification will depend upon the experience of the installer or designer with a particular stoker, the type of fuel used, and the construction of the boiler or furnace.

Installation of stokers (particularly smaller sizes) on the side of the boiler or furnace may facilitate clinker removal.

Rating and Sizing Stokers

The Stoker Manufacturers Association[a, 9] has suggested a method for rating solid fuel stokers as follows:

$$\frac{\text{Load (Btu per hour)}}{\text{Heating value of coal (Btu per pound)} \times \text{overall efficiency of stoker and boiler or furnace}} = \text{Stoker burning rate required (pounds of coal per hour)}$$



In determining the total load placed on a stoker-fired boiler by a steam or hot water heating system, a piping and pickup factor of 1.33 is commonly used in sizing the stoker, but this factor should be increased at times due to unusual conditions.

Controls

The control of coal-fired equipment is discussed in the section Controls for Automatic Fuel-Burning Equipment.

DOMESTIC OIL BURNERS

An oil burner is a mechanical device for the oxidation of hydrocarbon liquids (fuel oil) and air under controlled con-

[a] For reference in selecting or designing boilers and furnaces for stoker firing. Dimensions shown are for net inside clearance at grate level using coal with heating value of not less than 13,000 Btu per pound. Under certain conditions smaller fireboxes will permit satisfactory performance but these dimensions are preferred normal minimums.

Fig. 7 .... Suggested Minimum Firebox Dimensions and Base Heights[a]

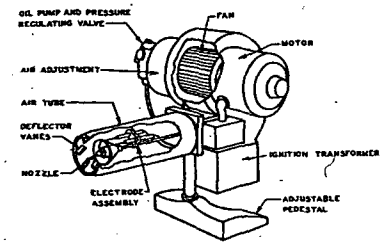


Fig. 8 .... High-Pressure Atomizing Oil Burner

conditions. Two methods, atomization and vaporization, are employed for the preparation of the fuel oil for the combustion process. Air for combustion is supplied by a blower or by draft produced by the chimney. Ignition is accomplished by an electric spark, electric resistance wire, gas pilot flame, or oil pilot flame. Burners of different types operate with luminous or non-luminous flame. Operation may be intermittent or continuous with high-low flame.

Oil burners must be used with a sealed heat exchanger (warm air furnaces, boilers, water heaters, space heaters, etc.), and must have a proper venting system.

While most oil burners operate from automatic temperature-*censing controls*, some of the simpler types are operated manually.

Classification of Burners

Domestic oil burners may be classified by type of design or operation into the following groups: pressure-atomizing or gun, rotary, and vaporizing or pot. These are further classified as mechanical draft, and natural draft.

Pressure Atomizing (Gun-Type) Burner

Gun-type burners are usually designed to burn No. 1 or 2 grade fuel oil. They may be divided into two classes: high-pressure and low-pressure atomization.

The *high-pressure atomizing* type, illustrated in Fig. 8, is characterized by an air tube, usually horizontal, with oil supply pipe centrally located in the tube and arranged so that a

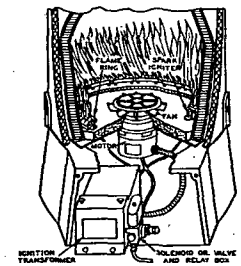

Fig. 9 .... Wall Flame Vertical Rotary Burner

spray of atomized oil is introduced at about 100 psi, and mixed in the combustion chamber with the air stream emerging from the air tube.

The oil rate can be changed by replacing the nozzle with one of different rating. *Oil nozzles* are precision devices for metering the oil and discharging the oil in a fine spray or mist. Small oil-rate changes can be made by adjustment of pump pressure. Good atomization is affected at pressures between 75 and 140 psig. Since the objective is to mix intimately the oil spray particles and air, a variety of baffles or mixing devices are employed in the air tube. The air velocity and direction is important in this mixing.

The oil pump can perform both as a suction pump (oil tank below burner), and a pressure pump for atomization.

A blower is used to supply the air for combustion. A damper or other adjustable means at the burner and a draft regulator maintain a proper air supply. Ignition is established by a high-voltage electric spark that may be operative

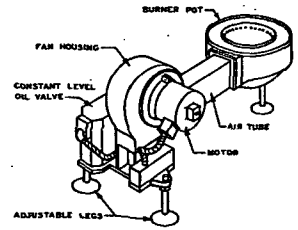

Fig. 10 .... Vaporizing Forced-Draft Pot-Type Burner

continuously while the burner is running, or just at the beginning of the running period. The burner operates on the intermittent *on-off* principle, and with a luminous flame.

The combustion process is completed in a chamber constructed of refractory material, or stainless steel, this being a part of the installation.

The *low-pressure atomizing* burner differs from the high-pressure type mainly by having means for supplying a mixture of oil and primary air to the burner nozzle. The air pressure before mixing and the pressure of the oil-air mixture at the nozzle vary with different makes of burners, but are in a low range of 1 to 15 psig for the air and 2 to 7 psig for the mixture, respectively. The various parts of the burner, except for oil and air mixing parts, are the same as shown in Fig. 8.

Rotary Burner

Most of the smaller rotary burners are of the vertical wall flame type (Fig. 9), and are used with No. 1 or 2 grade fuel oil. Oil is conveyed by gravity to the burner and is centrifugally thrown and mixed with air to a periphery ring of stainless steel or refractory material. A refractory hearth is used to prevent excessive heat loss below the burner and to prevent air leakage. Oil rate and air quantity can be adjusted to suit requirements.

The vertical rotary burners are further characterized by their installation within the ashpit of the boiler or furnace. Various types of ignition are utilized, gas and electric, either

spark or hot wire. The air for combustion is supplied partially by natural draft, and partially by fan effect of the central spinner element.

Vaporizing Burner

In the vaporizing burner, fuel oil is ignited (manually or electrically) and vaporized in a vessel or pot which is open at the top. Heat for vaporization is supplied by the combustion process. Openings in the side walls of the burner admit primary air which forms a rich mixture of air and oil vapors in the burner. Adjacent to the outlet opening, sufficient additional or secondary air is admitted to complete combustion. The openings for admitting air are arranged to obtain gradual and intimate mixing of air and oil vapor for combustion.

Fuel is fed by gravity from a constant level control valve, and the flow is either *on* (at rated capacity) or *off* (at pilot flow), according to the demand of the thermostat. However, the high fire can be reduced and the pilot fire can be increased to give almost any desired control characteristic within the range of the burner. The majority of vaporizing

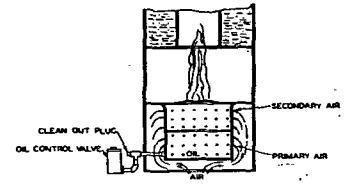

Fig. 11 .... Vaporizing Gravity Pot-Type Burner

burners are manufactured in sizes up to one gallon per hour input. Most vaporizing burners are limited to use with No. 1 fuel oil having a maximum end point of 625 F and a minimum API gravity of 35 deg.

A barometric draft regulator is required to maintain the recommended draft. A draft of not more than 0.06 in. of water column is recommended for most natural draft burners. When burners are equipped with mechanical forced draft, a slightly lower chimney draft can be used. A burner of this type is illustrated in Fig. 10. A gravity type is shown in Fig. 11.

Oil-Fired Boiler and Furnace Units

A number of types of specially designed oil-fired boiler-burner and furnace-burner units are available. Various locations of burners will be noted in such units; some having the combustion chamber and burner at the top, some at the bottom, and some at the center of the appliance. Typical combination units are shown in Figs. 12 and 13. The coordinated design of boiler (or furnace) and burner elements insures the optimum in operating characteristics, and the maintenance of balanced performance. This type of equipment usually has more heating surface, and better flue proportions and gas travel than conventional boilers or furnaces. Some of the better conversion installations, however, may equal the unit type in performance.

Operating Requirements for Oil Burners

The U. S. Department of Commerce, in conjunction with the oil burner and heating appliance industries, has established commercial standards for conversion burners and burner-appliance units which cover installation, construction and performance tests.*

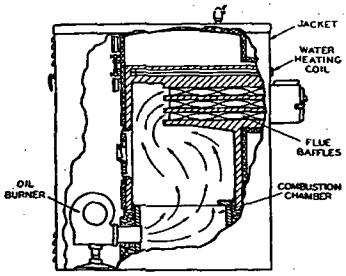

Fig. 12 .... Typical Boiler-Burner Unit

Combustion Process

Efficient combustion must produce a clean flame and use a relatively small excess of air, i.e., between 25 and 50 percent. This can be done only by vaporizing the oil quickly and completely, and mixing it vigorously with air in a combustion chamber hot enough to support the combustion. A vaporizing burner prepares the oil for combustion by transforming the liquid fuel to the gaseous state by the application of heat.

In an atomizing burner, the oil is mechanically separated into very fine particles so that the surface exposure of the liquid to the radiant heat of the combustion chamber is vastly increased and vaporization thereby promoted. The result is the ability to burn more and heavier oil within a given combustion space. Because the air enters the combustion chamber with the liquid fuel particles, mixing, vaporization, and burning occur all at once in the same space. This produces a luminous flame. A deficient amount of air is indicated by a dull red or dark orange flame with smoky tips.

An excessive supply of air may produce a brilliant white flame or a short ragged flame with incandescent sparks flashing through the combustion space. While extreme cases may be detected, it is not possible to distinguish, by eye, the effect of the finer adjustment which competent installation requires.

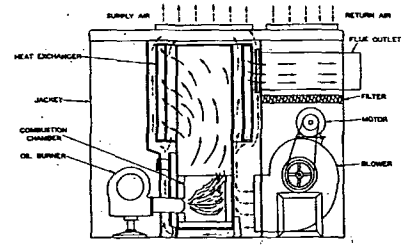

Fig. 13 .... Typical Oil-Fired Furnace Unit

Combustion Adjustments

The present-day oil burner with mechanical oil and air supply, properly installed and equipped with an automatic draft regulator, is capable of maintaining efficient combustion for a considerable period following the initial adjustments of oil and air. Eventually, certain changes will occur, and may be such that the amount of excess air will decrease below allowable limits. A decrease in air supply while the oil delivery remains constant, or an increase in oil delivery while the air supply remains constant, will make the mixture of oil and air too rich for clean combustion. The more efficient the adjustment, the more critical it will be. The oil and air supply rates must remain constant.

The following factors may influence the oil delivery rate: (1) changes in oil viscosity due to temperature change or variations in grade of oil delivered; (2) erosion of atomizing nozzle; (3) fluctuations in bypass relief pressures; and (4) possible variations in methods of atomization. Any change due to partial stoppage of oil delivery will increase the proportion of excess air. This will result in less heat, reduced economy, and possibly a complete interruption of service.

The following factors may influence the air supply: (1) changes in combustion draft due to a variety of causes (i.e., changes in chimney draft because of weather changes, seasonal changes, back drafts, failure or inadequacy of automatic draft regulator, use of chimney for other purposes, possible stoppage of the chimney, and changes in draft resistance of boiler due to partial stoppage of the flues); and (2) changes in air inlet adjustments at the fan.

There should be no air leakage into the boiler or furnace setting. The overfire draft should be reduced as low as is consistent with the proper disposal of the products of combustion. When using mechanical draft burners with average conditions, the combustion chamber draft should not be allowed to exceed 0.02–0.05 in. water. An automatic draft regulator is necessary in order to maintain constant draft conditions which, in turn, improve efficiency of operation. The draft regulator should be adjusted in accordance with the manufacturer's instructions.

Even though a fan is generally used to supply the air for combustion, in most oil burners, the importance of a proper chimney should not be overlooked. The chimney should have sufficient height and size to insure a uniform draft within the limits given, if maximum efficiency throughout the heating season is to be maintained.

Measurement of the Efficiency of Combustion

Since efficient combustion is based upon a clean flame and definite proportions of oil and air employed, it is possible to determine the results by analyzing the combustion gases. It is customary to analyze only for carbon dioxide (CO_2) and to obtain the temperature of the stack gas. A showing of 10 to 12 percent indicates the best adjustment, if the flame is clean. Most of the good installations operate with 8 to 10 percent CO_2. Taking into account the potential hazard of low excess air (high CO_2), a setting to give 10 percent CO_2 constitutes a reasonable standard for most oil burners. *Commercial Standard* CS-75 requires that oil burners labeled as complying with the standard shall obtain smoke-free combustion at 10 percent CO_2. In all cases smokeless combustion is a requirement for oil burners.

Combustion Chamber Design

With burners requiring a refractory combustion chamber, the size and shape should be in accordance with the manufacturer's instructions. It is important that the chamber be as nearly airtight as is possible, except when the particular burner requires a secondary supply of air for combustion.

The atomizing burner is dependent upon the surrounding heated combustion chamber surfaces to vaporize the oil and support combustion. Unsatisfactory combustion may be due to inadequate atomization and mixing. A combustion chamber can only compensate for these things to a limited extent. If liquid fuel continually reaches some part of the firebrick surface, a carbon deposit will result. The combustion chamber should enclose a space having a shape similar to the flame, but large enough to avoid flame contact. The nearest approach in practice is to have the bottom of the combustion chamber flat, but far enough below the nozzle to avoid flame contact, the sides tapering from the air tube at the same angle as the nozzle spray, and the back wall rounded. A plan view of the combustion chamber resembles in shape the outline of the flame. This insures quick vaporization, rapid combustion and better mixing by eliminating dead spaces in the combustion chamber. An overhanging arch at the back of the fire pot is sometimes used to increase the flame travel and give more time for mixing and burning, and sometimes to prevent the gases from going too directly into the boiler flues. When good atomization and vigorous mixing are achieved by the burner, combustion chamber design becomes a less critical matter. Where secondary air is used, combustion chamber design is quite important. When installing some of the vertical rotary burners, the manufacturer's instructions must be followed carefully when installing the hearth upon which class successful performance depends in this type of burner.

Boiler Settings

Since the volume of space available for combustion is a determining factor in oil consumption, it is general practice to remove grates and extend the combustion chamber downward to include or even exceed the ashpit volume; in new installations the boiler may be raised to make added volume available. Approximately 1 cu ft of combustion volume should be provided for every developed boiler horsepower, and in this volume from 1.5 to 2.5 lb of oil per hour can properly be burned. This corresponds to an average liberation of about 38,000 Btuh per cu ft. At times much higher fuel rates may be satisfactory. For best results, care should be taken to keep the gas velocity below 40 fps. Where checkerwork of brick is used to provide secondary air, good practice calls for about 1 sq in. of opening for each pound of oil fired per hour. Such checkerwork is best adapted to flat flames, or to conical flames that can be spread over the floor of the combustion chamber. The proper bricking of a large or even medium sized boiler for oil firing is important, and frequently it is advisable to consult an authority on this subject. It is essential in combustion chamber design to prevent flame impingement upon either metallic or firebrick surfaces. Manufacturers of oil burners usually have available detailed plans for adapting their burners to various types of boilers, and such information should be utilized.

Controls

The control of oil-fired equipment is discussed in the section Controls for Automatic Fuel-Burning Equipment.

COMMERCIAL AND INDUSTRIAL OIL BURNERS

Oil-burning equipment for commercial and industrial applications is usually designed for burning the lower cost heavy fuel oils such as U. S. Commercial Standard Grades Nos. 4, 5, and 6. The viscosity of these oils is much greater than that of the lighter domestic grades and, therefore, the equipment required for satisfactory storage, pumping, and combustion differs greatly from that used in the typical domestic oil-burning system.

Both the initial cost and the operating cost of an oil-burning system may be affected materially by the characteristics of the industrial fuel oil to be used. These characteristics should, therefore, be given careful consideration when preparing the specifications of the fuel oil for which the system is to be designed.

Classification of Burners

Oil burners are usually classified according to the method used for atomizing the oil as (1) horizontal rotary-cup atomizing, (2) mechanical pressure-atomizing, (3) steam-atomizing, and (4) air-atomizing.

Horizontal Rotary-Cup Burner

In this type of burner, oil is delivered into a horizontal cup that is rotated at high speed. As the thin film of oil is spun from the rim of the cup, it enters a cone of high velocity primary air where very effective atomization is obtained. In most applications secondary air for combustion is supplied by natural draft through checkered openings in the floor of the combustion chamber. In some applications, however, the secondary air is admitted through openings surrounding the burner nozzle and may be supplied by forced draft.

The rotary-cup burner has been the most popular type in the capacity range from approximately 25 to 500 boiler horsepower. Its principal advantages are that it is a self-contained integral unit; it is readily adaptable to manual, semi-automatic, or fully-automatic control; and the firing rate may be easily modulated through a wide range while maintaining high combustion efficiencies. These burners are frequently used for firing packaged steam generator units.

Mechanical Pressure-Atomizing Burner

In this burner oil is atomized by passing it through a specially designed nozzle under pressures of approximately 100 to 250 psig. The air for combustion may be supplied by either natural or forced draft, and is usually admitted through an air register surrounding the burner nozzle or through checkered openings in the floor of the combustion chamber. This burner is popular for marine service and for large capacity multiple installations. It is not readily adapted to fully automatic operation.

Steam-Atomizing Burner

High-pressure steam is used in this burner for atomizing the oil. Oil is delivered to the nozzle at pressures ranging from approximately 5 to 50 psig, and steam at approximately 50 to 150 psig is admitted to the nozzle by various methods to assist in the atomization. Combustion air is usually supplied by natural draft through checkered openings in the floor of the combustion chamber or through an air register surrounding the nozzle. This burner is relatively low in first cost but is not adapted to fully automatic operation or wide variations in firing rate.

Air-Atomizing Burner

The air-atomizing burner is similar to the steam-atomizing type, except that air under pressure instead of steam is used for atomization. The performance characteristics of the two burners are also similar but higher temperature oil is usually required when using air for atomization.

STORING AND HANDLING HEAVY FUEL OILS

Preheating of Heavy Fuel Oils

Unlike the lighter grades of fuel oils that can be pumped, atomized, and burned efficiently without prior preheating, the heavier grades of residual fuel oils require conditioning by the application of heat before use. Preheating is employed to reduce the viscosity of the oil so that it can be pumped and atomized properly by the burner. The function of the burner is to atomize the oil and mix it thoroughly with the proper amount of air for prompt ignition and efficient combustion. The optimum viscosity will vary from 100 to 450 seconds Saybolt Universal viscosimeter, with the type of burner and is reached at different temperatures for different grades of oil. The range of atomizing viscosity is about as follows for normal grades of oil:

Type of Burner	Range of Atomizing Viscosities
Mechanical-Atomizing	100–300 SSU
Steam-Atomizing	200–250 SSU
Rotary-Cup-Atomizing	250–450 SSU

Table 1 lists temperatures needed to bring various oil viscosities to the proper atomizing levels. These can be used with some variation to suit individual operations.

The correct degree of preheat must be used for each grade of oil. Underheating or overheating affects the terminal vis-

Table 1 .... Preheating Temperatures to Obtain Suitable Viscosities for Atomizing

Viscosity of Oil[a]		Oil Temperature (Fahrenheit) Required				
		Desired SSU Viscosity				
In SSF at 122 F	In SSU at 100 F	100	150	200	300	450
..	100	100	80	70	61	50

[a] SSF = seconds Saybolt Furol viscosimeter. SSU = seconds Saybolt Universal viscosimeter.

From *Fuel Oil Manual*, by Paul F. Schmidt (The Industrial Press) 1951, p. 105. Columns for 300 and 450 viscosity from Davis Engineering Corp.

cosity and actually interferes with the atomizing process. Underheated oil is too viscous for proper atomization, resulting in poor combustion, the generation of smoke and soot, and an excessively high oil consumption. Overheated oil, on the other hand, is too fluid for correct atomization and is subject to the same type of poor operating results as the underheated oil.

No. 4 fuel oils, with a maximum viscosity of 125 seconds Saybolt Universal at 100 F, as a rule do not require any preheating before atomization. They are sufficiently fluid at normal ambient temperatures for good burner operation.

No. 5 fuel oils are of two types: a light grade having a viscosity ranging between 150 and 200 seconds Saybolt Universal, that does not require preheating and hence is known as a *cold* No. 5; and a heavier grade having a viscosity ranging between 200 and 800 seconds Saybolt Universal, that requires preheating and hence is termed a *hot* No. 5 oil.

No. 6 fuel oils (also known as Bunker C) always require preheating, as their viscosities range from 900 to 10,000 seconds Saybolt Universal (50 seconds to 300 seconds Saybolt Furol).

A number of factors affect the selection of a fuel oil preheating method. The three basic factors are:

1. Type of installation (commercial heating, industrial process, power generating, etc.).
2. Type of operation (automatic, semi-automatic, manual, intermittent, continuous).
3. Type of fuel (No. 5, No. 6, Bunker C).

The pour point of an oil is another characteristic that could influence the preheating requirements, especially in areas subject to severe winter temperatures. An oil with a sufficiently high pour point may require preheating and continuous circulation at temperatures above its pour point at all stages between storage tank and burner to insure its easy pumpability. Oil specifications should be checked for this characteristic and limitations imposed, if feasible. Otherwise the oil piping system must be designed with this high pour specification in mind.

Four mediums for preheating fuel oil are in common use: steam, hot water, gas, and electricity.

With steam as the heating medium the heater may be of shell-and-tube (either straight or U-tube) type or the heaters may be of a bayonet type inserted in the oil tank. In a bayonet-type heater an open-end tube is enclosed in a larger tube which has a closed outer end. Steam enters through the inner tube while condensate is drained from the outer tube. A heater of bell-shaped type may also be connected into the oil suction line at the tank for the purpose of raising the temperature of the oil drawn from the tank.

The steam preheating method has several limitations. Mainly, it is dependent upon continuity of burner operation to keep steam available to prevent viscosities beyond pumpability. Therefore, its practicability and economy are limited to installations having continuous operation. Another limitation is that the relatively high temperature of steam may cause changes in the chemical structure of lighter grades of residual fuel oils. To prevent excessively high viscosities in the fuel oil piping, constant oil circulation is maintained or the oil piping is enclosed with steam lines in the same thermal insulation. The economy of the steam preheating method is also dependent on the availability of steam at the pressure and quantity required, and on the distance from boiler to storage tank.

The hot water preheating method utilizes equipment similar to that used for steam. Because of the possibility that oil may penetrate into the boiler through faulty heat exchanges, some devices have been developed to prevent this condition. Double-transfer heaters and fuel-oil detectors are those most frequently used. Similarly, as with steam, continuity of burner operation, or cycling burner operation, is needed to maintain the temperature of the heating medium. Since oil heating is limited by the water temperature in the boiler less transmission and transfer losses, such losses must be taken into account, particularly on installations having a considerable length of oil piping.

The indirect gas-fired preheating method is a package arrangement that uses gas as the primary energy source. It generates its own supply of low-pressure steam in a closed vapor-condensate cycle. The oil is pumped through the steam oil heater as required to compensate for radiation losses in the oil-circuit lines, whenever pumping action stops. During the layover period, the main boilers and oil burners are entirely inactive. If separate oil transfer pumps are not available, a small circulating oil pump is added to the package to provide circulation in the oil lines during the gas-firing periods.

The electrical preheating method involves use of immersion heaters plus one of two special arrangements for heating the fuel oil piping. One special arrangement is a heating cable (soil cable or plastic covered wire) wrapped around the supply line or all oil piping together with a vertical-element immersion heater in the suction pipe in the oil tank. The closeness and evenness of the spiral winding of the cable determine the heat input. The on-off periods are thermostatically controlled. For protection of the heating cable, the temperature of the oil piping has to be limited and usually must not exceed 170 F. Where pipe and oil temperatures permit wrapping of all oil piping, constant oil circulation is not required. The efficiency of this preheating method is lower than for element-immersion or electric-impedance heating because of transfer losses between the heating element and the pipe.

The other special arrangement for electrical preheating is a packaged system of electric-impedance heating for all oil piping together with immersion element heating sufficient to heat the oil used. Low-voltage high-amperage alternating current of the 60-cycle frequency is passed through the oil piping itself, generating an even amount of heat in the pipe walls. The majority heating effects are due to hysteresis and eddy currents. When removing oil from unheated storage hot excess oil is returned to blend with cold oil from storage in a special tank unit. Since all oil piping is kept at design temperature under all conditions of flow or standby, constant oil circulation or cycle precirculation is not needed. The thermostatic control of pipe and oil temperature results in fully automatic operation.

Oil burners designed for automatic operation on No. 5 or No. 6 oil are generally equipped with thermostatically controlled electric immersion heaters. The function of a burner-immersion heater is to heat the oil at the rate being burned from the transportation temperature (usually at 120 F level for No. 6 oil) to the temperature required for efficient combustion. This temperature ranges from 130 F to 220 F, depending on the grade of fuel oil and design of burner. In an emergency, the burner-immersion heater may be used alone to heat a modulated, very low quantity of oil for combustion. However, in a normal operation, it functions in conjunction with the primary preheating system.

Maintaining Piping and Tank Temperature

In using No. 5 and No. 6 oils it is necessary to make special arrangements to keep the oil fluid in the piping at all times and to keep at least a portion of the oil in the storage tank fluid as well.

The *piping* may be heated by one or more of the following methods:

1. Wrapping the supply line with electrically heated tape.
2. Passing a current through the supply line itself.
3. Enclosing the supply line with a steam or hot water line in the same envelope.
4. Insulating the supply line so as to decrease the thermal losses.
5. Setting up a dual system in which the primary preheaters have a capacity greater than the burner requirement and returning the excess heated oil continually to the fuel oil tank.

The oil *in the tank* or a portion of it may be heated by one of the following methods:

1. By steam coils in the bottom of the tank.
2. By hot water coils in the bottom of the tank.
3. By a suction-bell, which is provided with either steam or hot water coils, in the bottom of the tank.
4. By providing a hot-well that extends from the top to the bottom of the tank, and provides enough heated oil to supply the burner under a full load.
5. By submerging an electric preheater in the wall or bottom of the tank.

Pipe Sizes for Heavy Oil

Table 2 gives recommended good practice pipe sizes for handling No. 5 and No. 6 oils.

Oil Storage Tanks and Piping

Storage tanks, also the piping and pumping facilities for delivering the oil from the tank to the burner, are very important considerations in the design of an industrial oil-burning system. The construction and location of the tank and oil piping are usually subject to local regulations which should always be consulted, and to the standards of the National Board of Fire Underwriters, such as *NFBU Pamphlet* No. 31.

The size of the storage tank is usually based on the rate at which oil is to be consumed, the space available, method of oil delivery (truck or tank car) and the ease with which deliveries can be made under all weather conditions. A minimum capacity of at least the maximum weekly usage is desirable. If deliveries are to be made by tank car, the capacity should not be less than 15,000 gal.

The 275-gal oil storage tank is commonly used for domestic installations. In most localities it may be installed in basements without being enclosed. Where a greater storage capacity is necessary, local regulations usually permit inside installation of two tanks of 275 gal each in accordance with *NBFU Standards Pamphlet* No. 31.

Controls

The control of oil-fired equipment is discussed in the section Automatic Control of Fuel-Burning Equipment.

GAS-FIRED HEATING EQUIPMENT

A gas burner is defined by the American Gas Association as "a device for the final conveyance of the gas, or a mixture of gas and air, to the combustion zone." Burners used for domestic heating are of the atmospheric injection, luminous flame, or power burner types.

Because of the ease with which gas fuel may be controlled, automatic gas-fired heating equipment has become very widely used, and is available in a number of types of domestic gas heating appliances and systems. These may be classified in types designed for central heating plants and those for unit application. Gas-designed units and conversion burners are available for the several kinds of central systems in which gravity and forced warm air furnaces or steam and hot water boilers are used, and for other applications where warm air floor furnaces and room heaters are installed in the space being heated.

Central Heating Systems

Boilers and furnaces specially designed for gas-firing incorporate design features for obtaining maximum efficiency and performance. Small flue passes to secure good heat transfer, the use of materials resistant to the corrosive effects of products of combustion, and draft hoods are notable features. Control equipment includes gas-pressure regulators, automatic pilots, and limit controls designed to protect the appliance and to insure safety of operation. A boiler designed for gas-burning is illustrated in Fig. 14.

Gas-designed boilers for hot water or steam heating are available in cast-iron, steel, and non-ferrous metals. The burners are located beneath the sections, and the flue gases pass upwards between the sections to the flue collector. Some boilers are designed to provide domestic hot water through the use of tankless or instantaneous heaters.

Warm air furnaces are of two types, gravity and forced

Table 2 .... Recommended Minimum Suction and Return Pipe Sizes for Fuel Oil Lines[a]
(For Nos. 5 and 6 Fuel Oil)[b]

Equivalent Length of Suction Line Feet[c]	Pump Capacity, Gallons per Hour													
	50		100		150		200		300		600		900	
	Grade of Oil (Number)													
	5	6	5	6	5	6	5	6	5	6	5	6	5	6
	Diameter of Pipe, Inches													
10–50	1¼	1¼	1¼	2	2	2	2	2	2	2	2½	3	3	4
60–100	1¼	1¼	2	2	2	2	2	2½	2½	2½	3	3	3	4
110–150	1¼	2	2	2	2	2½	2½	2½	2½	3	3	4	4	4

[a] Pipe sizes shown are based on vertical suction lift not to exceed 10 ft from bottom of storage tank to oil pump.
[b] A suction line length in excess of 100 linear feet is not recommended for systems using No. 5 or No. 6 oil. Where the length is greater a separate pump should be installed near the storage tank.
[c] Equivalent length of pipe includes all horizontal and vertical measured piping plus proper allowance for valves and fittings as follows:
Multiply pipe diameter in inches by factor below to obtain equivalent pipe length in feet.
Elbow = Factor 3; Tee = Factor 5; Gate Valve = Factor 1½; Globe Valve = Factor 9.

air. The former depends upon a thermal head to provide circulation of air over the heat exchanger and thence directly to the space to be heated, usually through ducts. Most gravity furnaces can be equipped with humidifiers. Forced warm air furnaces utilize a motor-driven blower to circulate air over the heat exchanger and through the ducts. A common type is quite similar to Fig. 13 except that gas burners, pilots, controls, and gas pressure regulator are substituted for the oil burner, and a draft hood is attached to the outlet of the furnace. Due to the pressure developed by the blower, ductwork becomes smaller and the location of the furnace less critical than in gravity systems. Designs of forced air furnaces vary from the conventional types that deliver heated air to overhead ductwork to the downflow types

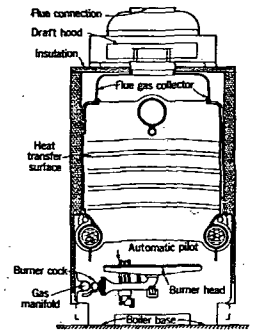

Fig. 14 .... Gas-Fired Boiler

wherein the heated air is delivered at the bottom of the furnace, this latter type being designed for perimeter or radiant-panel heating. Several types of low height horizontal furnaces are available for installation in attics or under floors of unexcavated houses. These furnaces are designed for compactness. The A.G.A. listed output at the boiler nozzle or at the bonnet for forced air furnaces is 80 percent of the approved input to the burners. The corresponding output for gravity furnaces is 75 percent.

Conversion Burners

Conversion burners are complete burner and control units designed for installation in existing boilers and furnaces. A typical gas conversion burner is shown in Fig. 15. Atmospheric conversion burners may have drilled-port, slotted-port, or single-port burner heads. Single-port types have become increasingly popular in the last few years due to their simplicity of construction and ease of installation. In rectangular or round, drilled and slotted-port burners, baffles of clay or metal are usually used to direct the products of combustion toward the side walls of the combustion chamber. In single-port burners the flame usually impinges on a horizontal cast-iron, stainless steel, or ceramic flame spreader which directs the products of combustion toward the side walls. For certain applications, particularly wet-base boilers, a horizontal single-port burner is utilized. This design produces a horizontal flame which strikes a curved baffle that spreads the flame in a fan shape.

Several power burners in domestic sizes are available. These are of gun-burner design and feature small mechanical blowers for supplying all the air required for combustion. These are particularly desirable for handling restricted flue boilers or furnaces where an atmospheric burner cannot obtain the desired output.

Conversion burners for domestic application are available in sizes ranging from 50,000 to 400,000 Btuh capacity. It should be noted that the American Standard Listing Requirements are limited at present to conversion burners having input capacities up to 400,000 Btuh. Burners of larger capacity, for use in large steel boilers, are usually engineered by a contractor specializing in this type of work, or by the local utility company. They are available in a large number of sizes and types. In some cases the burner may be an assembly of multiple burner heads filling the entire firebox. For conversion burner installation in boilers requiring more than 400,000 Btuh input, reference should be made to the current *American Standard Requirements for Installation of Gas Equipment in Large Boilers*, ASA Z21.33.

Domestic sizes of conversion burners should conform to current *American Standard Listing Requirements for Domestic Gas Conversion Burners*, ASA Z21.17. As the successful and safe performance of a gas conversion burner depends on numerous factors other than those incorporated in such equipment, installations of this kind must be made in strict accordance with current *American Standard Requirements for Installation of Domestic Gas Conversion Burners*, ASA Z21.8. Also, draft hoods conforming to current *American Standard Listing Requirements for Draft Hoods*, ASA Z21.12, should be installed (in place of the dampers used with a solid fuel) on all boilers and furnaces converted to burn gas. The A.G.A. estimates the output of conversion burners at 72 percent efficiency. This value is based on average installations and average heating equipment performance.

Floor Furnace

The floor furnace is used to supply central heating in mild climates, or for auxiliary heating or heating of single rooms in colder climates. It is used for heating first floors, or where heat is required in only one or two rooms. A number may be used to provide heat for the entire building where

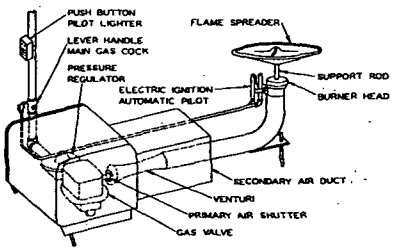

Fig. 15 .... Typical Single-Port Gas Conversion Burner

all rooms are on the ground floor, thus giving the heating system flexibility.

In floor-furnace applications, the heating element, gas piping, and flue vent piping are suspended below the floor, and the only part in the room being heated is the circulating air register which may be of the single type installed in the floor, or of the dual type installed in a partition, and heating two rooms. The A.G.A. output rating of floor furnaces is based on an efficiency of 70 percent for the gravity-type and 75 percent for the fan-type unit.

Another type of heating appliance is the vented recessed heater which is either a gravity or fan-type appliance designed for installation in or permanent attachment to a wall, floor, ceiling, or partition. Such heaters may have short stub ducts to conduct heated air to adjacent rooms. They are installed primarily in new homes, usually being plastered into the wall as a permanent part of the building. The A.G.A. heat output rating is required to be 75 percent of the approved heat input to the burners for fan-type units, and 70 percent for gravity-type units.

Space Heaters

Space heaters are defined as heating units that take the air for combustion from the space being heated. They may be broadly classified as room heaters and units heaters.

Room heaters are used for heating single rooms or connecting rooms with good circulation between them and, except for wall-type heaters, they are semi-portable. Unvented-type room heaters should not be used unless space is properly ventilated to prevent excess moisture and to provide sufficient combustion air to prevent formation of carbon monoxide. All types of room heaters are capable of automatic control, although they are generally controlled manually. When equipped for automatic control, they must have an automatic pilot as part of the control equipment. Room heaters may be classified as follows:

Circulators, vented and unvented, that heat the room mainly by convection, although some have radiants over the burner, with windows in the front to allow some heat by radiation.

Radiant heaters, usually unvented, although some vented types are available, have a refractory directly above the burners which is heated to incandescence, and gives off an appreciable part of its heat in the form of radiant energy.

Wall heaters, vented or unvented, are usually a type of radiant heater constructed with sufficient insulation (either solid or circulating air) to prevent overheating of the casing, and are built into a wall with the front flush with the wall surface. Their heat input rating is limited to a maximum of 25,000 Btuh.

Although an output rating is not required by *A.G.A.*, the efficiency of a vented room heater must be not less than 70 percent when rated above 20,000 Btuh input, and 65 percent when rated at less than 20,000 Btuh input.

Unit heaters are used extensively for heating large spaces such as stores, garages, and factories. These heaters consist of a burner, heat exchanger, fan for distributing the air, draft hood, automatic pilot, and controls for burners and fan. They are usually mounted in an elevated position from which the heated air is directed downward by louvers. Some unit heaters are suspended from the ceiling, and others are free-standing floor units of the heat tower type. Unit heaters are classified for use with, or without, ducts depending on specific A.G.A. approval. When connected to ducts they must have sufficient blower capacity to deliver an adequate air quantity against the duct resistance. Heat output is required to be at least 75 percent of heat input to the burners.

Duct furnaces are usually of the unit heater type without the fan, and are used for heating air in existing duct systems where blowers are provided for moving the air through the system. Duct furnaces are tested for operation at much higher static pressures than are obtained in unit heaters.

Combustion Process and Adjustments

Most domestic gas burners are of the atmospheric injection (Bunsen) type in which primary air is introduced and mixed with the gas in the throat of the mixing tube. For normal operation of most atmospheric type burners, 40 to 60 percent of the theoretical air as primary air will give best operation. Slotted-port and ribbon burners may require from 50 to 80 percent primary air for proper operation. The amount of excess air required in practice depends upon several factors, notably: uniformity of air distribution and mixing, direction of gas travel from burner, and the height and temperature of combustion chamber. With power type burners utilizing motor driven blowers to provide both primary and secondary air, the excess air can be closely controlled while securing proper combustion.

Secondary air is drawn into gas appliances by natural draft. As with other fuels, excess secondary air constitutes a loss, and should be reduced to a proper minimum, which usually cannot be less than 25 to 35 percent, if the appliance is to meet ASA approval requirements. Yellow flame burners depend upon secondary air, alone, for combustion.

The flame produced by atmospheric injection burners is non-luminous. Air shutter adjustments for manufactured gas should be made by closing the air shutter until yellow flame tips appear, and then by opening the air shutter to a final position at which the yellow tips just disappear. This type of flame obtains ready ignition from port to port, and also favors quiet flame extinction. When burning natural gas, the air adjustment is generally made to secure as blue a flame as is obtainable without lifting of flames from burner ports. Manufacturers' instructions for burner adjustment should be followed.

Gas-designed equipment does not usually incorporate any means for varying the secondary air supply (and hence the CO_2). The amount of effective opening and baffling is determined by A.G.A. tests and cannot be varied. Gas conversion burners, however, do incorporate means for controlling secondary air to permit adjustment over a wide range of inputs according to the type of installation encountered. The manufacturer's specific instructions contained in the installation manual required to be supplied with each burner should be followed. It is possible through the use of suitable indicators to determine whether carbon monoxide is present in flue gases. For safe operation carbon monoxide should not exceed 0.04 percent (air-free basis) when operating at the maximum gas input to the burners.

During recent years, the use of fuel gas (natural, manufactured, and liquefied petroleum) has become increasingly popular for heating tourist cabins and motels. Due largely to the intermittent use of such equipment and the fact that so many of the users are entirely unfamiliar with the fundamentals governing its operation, many special and unusual problems arise. The importance of safeguarding the public interest has prompted some state and city officials to adopt and enforce legislation governing not only the manner in which these appliances are installed but the extent to which they must be equipped with reliable safety devices.

for example, connection to an effective flue is mandatory. Furthermore, all such heating equipment must incorporate an automatic ignition pilot that will shut off gas supply to the main burner or burners in the event of pilot outage. If liquefied petroleum gas is used, the automatic pilot must cut off all gas supply to the appliance, including the pilot burner, in case the pilot flame becomes extinguished.

Rating and Sizing Gas Appliances

Input rating for a gas appliance is established by demonstrating that the appliance can meet the Approval Requirements of the ASA. The tests are conducted at the A.G.A. Testing Laboratories. Output rating is determined from the approved input and a minimum required efficiency stated in the Approval Requirements, and is the heat available at the outlet.

Although gas-burning equipment usually is completely automatic, maintaining the temperature of rooms at a predetermined figure, there are some manually controlled installations. In order to overcome effectively the starting load and losses in piping, a manually-controlled gas boiler should have an output as much as 100 percent greater than the equivalent standard radiation which it is expected to serve.

Boilers under thermostatic control, however, are not subject to such severe pick-up loads and consequently, it is possible to use a lower selection factor. For a gas-fired boiler or furnace under thermostatic control, a factor of 20 to 25 percent is usually sufficient for pick-up allowance.

In those installations, in mild climates where 100 percent outdoor air is used, furnaces should be of larger size in order to provide adequate capacity and quick pickup under intermittent heating conditions.

The factor to be allowed for loss of heat from piping will vary somewhat, the proportionate amount of piping installed being greater for small installations than for large ones. For selection factors to be added to installed radiation under thermostatic control, see Chapter 35.

Appliances used for heating with gas should bear the approval seal of the A.G.A. Testing Laboratories on the manufacturer's nameplate; together with the official input and output ratings. It is not permissible to operate a gas heating unit above its stated rating. It may be necessary to operate below this rating at elevations above 2000 ft. Installations should be made in accordance with recommendations of the American Gas Association, as shown in current *American Standard for Installation of Gas Piping and Appliances in Buildings*, ASA Z21.30, and in accordance with local regulations.

Sizing of Gas Piping

Piping for gas appliances should be of adequate size, and so installed as to provide a supply of gas sufficient to meet the maximum demand without undue loss of pressure between the point of supply (the meter) and the burner. The size of gas pipe required depends upon the following:

1. Maximum gas consumption to be provided.
2. Length of pipe and number of fittings.
3. Allowable loss in pressure from the outlet of the meter to the burner.
4. Specific gravity of the gas.

To obtain the cubic feet per hour of gas required by the burner, divide the Btu input rate at which the burner will be adjusted, by the average Btu heating value per cubic foot of the gas.

Capacities of different sizes and lengths of pipe, in cubic feet per hour, with a pressure drop of 0.3 in. of water column for a gas of 0.60 specific gravity, are shown in Table 3. In adopting a 0.3 in. pressure drop, due allowance for an ordinary number of fittings was made.

To convert the values given in Table 3 to capacities for another gas of different specific gravity, multiply the tabular values by the multipliers shown in Table 4.

Pipe capacities for gas flow up to 100,000 cfh for various lengths of pipe are given in Fig. 16 which is based on a specific gravity of 0.60. The capacity at a given pressure loss for a different specific gravity may be obtained by multiplying Fig. 6 capacities by a multiplier obtained from Table 4.

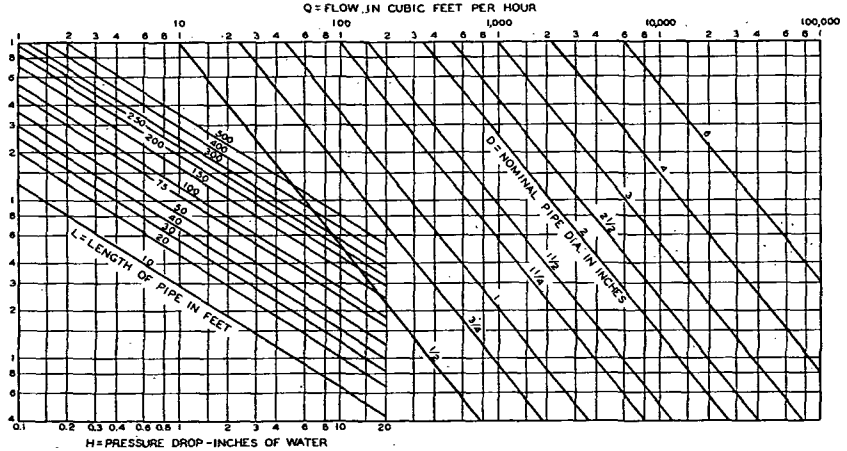
COMMERCIAL AND INDUSTRIAL GAS EQUIPMENT

No attempt can be made, due to space limitation, to describe or classify the varied types of equipment used for commercial and industrial applications. Much of the equipment utilized is custom built to suit a particular process. Certain standard parts such as venturi and burner head sets, ring burners, proportional mixers, or compressors, are purchased for assembly in existing equipment, usually by the installer. Furnaces to provide particular atmospheres or for annealing, soaking pits, metal melting, etc. are usually engineered by industrial gas-equipment manufacturers.

Burners utilized in industrial equipment often operate at gas pressures higher than encountered in domestic usage. High-pressure gas provides flexibility of control required in the production of constant temperatures. In addition, air-gas ratios can be closely maintained under throttling conditions, and heat liberation per cubic foot of combustion space is considerably greater than can be achieved with lower pressures.

A few of the many basic types of burners used are as follows: single-pipe high-pressure, proportional mixing, premix, two-pipe high-pressure, and atmospheric.



The *single-pipe high-pressure burner system* utilizes gas delivered to the orifice of a venturi at pressures from 10 to 50 psig. A constant pressure compressor, sometimes remotely placed, is occasionally used to increase the gas pressure. The velocity of the gas issuing from the orifice entrains primary air which is controlled by an air shutter on the venturi tube. An advantage of this system is that when the gas pressure is reduced (lowering the input) the air-gas ratio will remain constant over a fairly wide range.

In the *proportional mixing burner*, an enclosed type venturi is used and high-pressure air is delivered through an orifice. The resulting partial vacuum entrains the gas which is supplied through a zero pressure governor. When the air pressure is reduced, the amount of gas entrained is similarly reduced, thus maintaining a constant air-gas ratio over a wide fuel capacity range.

The *pre-mix burner system* embodies a compressor which mixes air and gas intimately and discharges the mixture through pipes to the burners where it is discharged through orifices and burned. The pre-mix compressor can be remotely installed and the mixture can be closely controlled.

The *two-pipe high-pressure burner* system utilizes both air and gas under pressure, both being delivered through orifices and mixed prior to delivery to the burner.

The *atmospheric burner* system is not commonly used. It consists of a burner supplied with gas at a pressure of 2

Based on Spitzglass Friction Factor and 0.60 Specific Gravity. To convert for other specific gravity see Table 4.

Fig. 16 .... Flow vs. Pressure Drop for Low Pressure Natural Gas

to 12 in. water. A portion of the air or primary air required for combustion is entrained from the atmosphere by the stream of gas issuing from an orifice, and the air-gas mixture is delivered through a venturi mixing tube to the burner head and parts. About 40 to 60 percent of the air required for combustion is in the form of primary air and the remainder, known as secondary air, is supplied from the air surrounding the flame.

Each system embodies characteristics essential for certain applications. It is important that proper and qualified engineering authorities be consulted prior to the purchase, installation, or operation of industrial gas equipment.

FUEL BURNING RATES

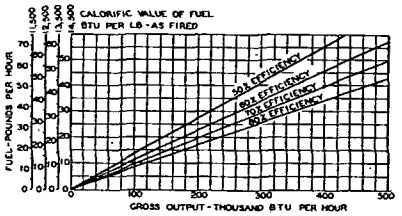
The burning rate for automatic fuel-burning devices is determined by the gross heat output required of the boiler, or furnace, to carry the net heating load, plus allowances for system losses and pickup. General values for these allowances have been given in preceding text. Detailed information for piping and pickup allowances for steam and hot water systems, is given in Chapter 35, and for warm air systems, in Chapter 18.

When the gross output, operating efficiency, and heat value of the fuel are known, the required rate of burning can be determined by means of Figs. 17, 18, and 19 for the several fuels. As the rate of fuel-burning is directly proportional to the load for a given efficiency, these charts can be extended by moving the decimal points the same number of digits in both vertical and horizontal scales.

The correct fuel-burning rate can be determined directly from the several charts for oil or gas burning installations, as these customarily operate on a strictly intermittent basis. These fuel burning devices usually introduce the fuel at a single fixed rate during the *on* periods, and this rate should be sufficient to carry the gross load. In the case of coal stokers, which are usually capable of variable rates of firing, it is desirable to operate at as low a rate as weather conditions will permit, but the maximum firing rate of the stoker should be sufficient to carry the gross load. This rate may be determined by the same method as used for oil or gas.

CONTROLS FOR AUTOMATIC FUEL-BURNING EQUIPMENT

Controls for the automatic fuel-burning equipment described in this chapter are outlined here. The basic requirements for oil burners, gas burners and coal burners (stokers) are included and the term *burner* refers to all three types of fuel-burning equipment. Controls for these burners can be classified as *operating controls, limit controls* and *primary controls*. The schematic diagrams shown in Fig. 20 indicate the relationships of the basic components. The *power supply* may be line voltage for each type of burner. In control systems for domestic burners the line voltage may be reduced by means of a transformer for those portions of the circuits indicated by dotted lines. Such transformers are usually built into the stoker and oil burner *primary controls*. Control systems for domestic gas burners frequently contain a separate transformer as shown. There are domestic gas burner control systems which obtain their electrical power supply from the conversion of heat to low-voltage electrical energy, in which case no transformer would be required. As the burner sizes increase, the tendency to use all line voltage controls increases in each of these general categories.



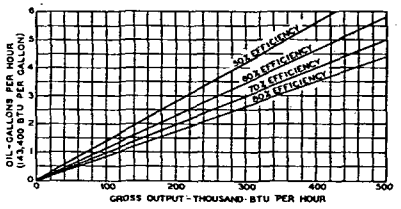


Fig. 17 .... Coal Fuel-Burning Rate Chart

* This chart is based upon No. 2 oil having a heat content of 143,400 Btu per gallon. If other grades of oil are used multiply the value obtained from this chart by the following factors: No. 1 oil (139,000 Btu per gallon) 1.032; No. 4 oil (144,500 Btu per gallon) 0.992; No. 5 oil (148,000 Btu per gallon) 0.982; and No. 6 oil (150,000 Btu per gallon) 0.956.

(O = *Operating Control*; P = *Primary Control*; L = *Limit Control*)

Fig. 20 .... Schematic Diagrams of Some Typical Burner Control Systems

Operating Controls

Operating controls initiate the starting and stopping of the burner and on larger burners they usually vary the fuel and air input to the combustion chamber in response to varying load demands. For residential and small commercial heating plants with fuel inputs up to aproximately 500,000 Btuh, the *operating controller* is usually some form of room thermostat which automatically starts and stops the burner through the primary control as the *limit controls* permit. As the size of the heating system increases, the use of a room thermostat as the *operating controller* for the burner becomes less common. An insertion thermostat (for furnaces), immersion thermostat (for hot water boilers) or pressure controller (for steam boilers) may be applied as an *operating controller*. Also, such devices as submaster and compensated controllers (which are reset from outdoor temperature for governing the bonnet temperature in large furnaces or the water temperature in a boiler) come into more frequent use on the larger installations. The still larger burners are usually equipped to vary the rate of fuel and air input in response to varying load demands.

Limit Controls

Limit controls guard against unsafe temperature, pressure or water level to assure that safe conditions prevail for the operation of the burner. Regardless of the type of fuel burned, draft controls increase combustion efficiencies and reduce flue gas loss by maintaining proper draft conditions at all times. For fuel input requirements above approximately 1,000,000 Btuh, some additional factors become common to all types of burners. For example, the draft in the firebox is controlled at a suitable constant for all firing rates, including the *off* period, by measuring the draft conditions in the firebox and actuating a *damper operator* to position the damper at the boiler outlet. Where necessary, provision may be made to open the boiler outlet damper wide before permitting the burner to start and then to return this damper to automatic control after the burner has been started. Also, the firing rate of these larger burners is frequently automatically adjustable. Provisions are made for always starting the burner on its low firing rate, with facilities for increasing the firing rate slowly after the burner has been started. It is not recommended and codes seldom permit the use of one and the same instrument as both an *operating controller* and a *high limit control*. In such cases an *operating controller* will be adjusted to control at the desired set point while the *high limit control* will be adjusted to stop the burner at some higher point in the event that the *operating controller* fails to stop the burner before the higher shut-off point is reached. For example, to maintain a constant water temperature in a hot water boiler, the operating controller may be set to stop the burner when the boiler water temperature reaches 180 F. The *high limit control* should then be set to stop the burner at about 200 F.

Various interlocks or limit controls are usually included to assure safe operation of these larger burners. A latch-switch interlock prevents burner operation if the burner is not in its proper firing position. Another interlock must prove that the burner is in its low-fire position before the burner can be started. Safe draft conditions should be proved before the burner can be started or allowed to run, especially where induced draft fans are involved. A smoke detecting device may sound an alarm and stop the burner if excessive smoke is produced. Also, protection against electrical overloads must be provided.

Primary Controls

Primary controls provide for the safe start and operating procedure of the burner. They are somewhat different for each of the three types of fuel burners.

1. *Stokers.* Stokers are equipped with refueling, or *hold-fire*, controls. These *primary controls* cause the stoker to intermittently feed a predetermined amount of coal during the long *off* periods of the *operating controller* to maintain ignition and to reduce the possibility of having idle fuel beds damage stoker castings. In some cases the *primary control* system includes an *out-fire* feature which stops the feeding of coal into the firebox if the fire goes out.

2. *Oil Burners. Primary controls* required for oil burners depend on the size and type of burner. Some of the more common *primary controls* are discussed in following paragraphs a to d.

a. Domestic oil burners of the vaporizing type usually require a *primary control* that will (1) meter the correct amount of oil into the burner to maintain the pilot flame; (2) regulate the required amount of oil into the burner for its high flame operation; and (3) completely shut off the flow of oil in the event of a flame failure.

b. Domestic oil burners of the pressure-atomizing type require a *primary control* that will (1) energize the burner motor and electric ignition; (2) test for the establishment of main burner flame and stop the burner and ignition if flame has not been established; (3) cut off the ignition after a safe burner flame has been established (does not apply to constant ignition type burners); (4) monitor the flame continuously during burner operation and stop the burner in the event of flame failure (manual reset is necessary following a flame failure lock-out); and (5) stop the burner when either the *operating controller* or *limit control* requires it.

c. Commercial and industrial oil burners of the pressure atomizing type have *primary controls* that are essentially the same as those outlined for domestic oil burners of the pressure atomizing type. In addition, some models are equipped with a solenoid oil-shut-off valve to provide a pre-purge period, if desired, and a quick shut-off of the oil flow when the burner is stopped.

d. Commercial and industrial oil burners of the horizontal rotary-cup type are usually equipped with a more elaborate *primary control* system. The primary control is often described as a programming combustion safety control. Its most important operations include (1) starting the burner upon a call for heat; (2) providing a pre-purge period before activating the gas-electric ignition; (3) proving the presence of proper ignition before permitting the flow of oil to the main burner; (4) proving the presence of a stable main burner flame within a predetermined period of time; (5) shutting off the gas-electric ignition after a predetermined length of time has elapsed; (6) monitoring the main burner flame during its entire *on* period and stopping the burner quickly in the event of a flame failure (it is usually required that the flow of oil through the burner be stopped within four seconds following a flame failure); (7) stopping the flow of oil through the burner when either the *operating controller* or a *limit control* requires it; (8) operating the burner for a predetermined length of time after the main fuel valve has been closed; and (9) locking out on a flame failure shutdown (the programming control then must be manually reset prior to a restart).

When steam-, air-, or mechanical-atomizing burners are

automatically controlled, their sequence of control is similar to that described for horizontal rotary-cup burners.

3. *Gas Burners.* Some of the more common *primary controls* for gas burners are as follows.

a. Domestic gas burners of the atmospheric type require a *primary control*, to insure safe starting and operating conditions, which will (1) prevent opening of the gas valve unless the pilot is operating properly, and (2) stop the flow of gas through the burner if safe ignition conditions do not prevail at all times.

b. Commercial and industrial gas burners of the atmospheric type require a *primary control* whose function is similar to that for domestic sizes of these burners except in the rate of response to a pilot flame failure. The pilot flame burns constantly and, in general, the primary control system will (1) ensure operation only when ignition of the main burner will be safe; (2) start and stop the main burner when required to do so by either the *operating controller* or a limit control; and (3) close the safety shut-off valve in the gas supply line to the burner upon a flame failure or an electrical power failure.

c. Commercial and industrial gas burners of the power type equipped with electric ignition require a *primary control* whose most important operations include: (1) starting the burner motor upon a call for heat by the *operating control*; (2) providing a prepurge period before activating the gas-electric ignition; (3) proving the presence of proper ignition before allowing gas to flow to the main burner or shutting off the electric ignitor; (4) closing the safety shut-off valve in the event of a flame failure (it is usually required that the flow of gas be stopped within four seconds following a flame failure); (5) stopping the burner when either an *operating controller* or a *limit control* requires it; and (6) locking out on a flame failure shut-down (the programming control then must be manually reset prior to a restart).

CHAPTER 35

HEATING BOILERS, FURNACES, SPACE HEATERS

BOILERS: Construction, Types, Design Considerations, Rating and Testing Codes, Efficiency, Rating, Selection, Space Limitations, Connections and Fittings, Erection, Operation and Maintenance. FURNACES: Types, Materials and Construction, Ratings, Testing and Rating Codes, Efficiency, Design Considerations, Humidification Equipment. SPACE HEATERS: Types: Solid Fuel, Oil, Gas; Materials and Construction, Testing and Rating, Design Considerations, Installation

IN presenting the subject of Boilers, Furnaces, and Space Heaters this chapter is divided into three parts; the first dealing with boilers, the second treating warm air furnaces, and the third covering space heaters.

HEATING BOILERS

Steam and hot water boilers for low-pressure heating are built of steel or cast iron in a wide variety of types and sizes, many of which are illustrated in the Catalog Data Section.

The nationally recognized code governing the construction of low-pressure steel and cast-iron heating boilers is the *ASME Boiler Construction Code for Low Pressure Heating Boilers*. Some states and municipalities have their own codes which apply locally, but these are usually patterned after the ASME Code.

The maximum allowable working pressures are limited by the *ASME Code for Low Pressure Heating Boilers* to 15 psi for steam and 160 psi for hot water heating boilers, with a maximum temperature limitation of 250 F. Hot water boilers are generally designed for a working pressure of 30 psi and may be supplied for higher working pressures, for either heating purposes or for hot water supply, only when designed, tested, and stamped for the higher pressure.

TYPES OF HEATING BOILERS

Heating boilers are classified in a number of different ways, such as:

1. According to materials of construction. These are steel and cast iron. Very few nonferrous boilers are made.

2. According to the fuels for which the boilers are designed. These are coal, hand-fired or stoker-fired; oil; gas; or wood. Some boilers are designed specifically for one fuel, but many boilers are designed for more than one fuel.

3. According to the specific purpose or application for which the boiler is used, such as space heating or domestic hot water supply.

4. According to the design or construction of the boiler such as sectional, round, fire-tube, water-tube, magazine-feed, Scotch, *etc.*

Cast-Iron Boilers

Cast-iron boilers are generally classified as:

1. Square or rectangular boilers with vertical sections and rectangular grates, commonly known as sectional boilers.

2. Round boilers with horizontal pancake sections and circular grates.

Cast-iron boilers are usually shipped in sections, and assembled at the place of installation. However, some small boilers are shipped factory assembled. In the majority of boilers the sections are assembled with push nipples and tie rods but external headers and screw nipples are also used successfully. Many sectional boilers are provided with large push nipples at top to permit the circulation of water between adjacent sections at both the water line and bottom of the boiler, which is necessary to enable the use of an indirect water heater with the boiler for summer-winter hot water supply. Round and sectional boilers may be increased in size by the addition of sections and corresponding plate work.

Small sectional type boilers are available with *wet-base construction*, wherein the ashpit or combustion chamber sides and bottom are surrounded by extensions of the water legs of the boiler sections, and thus no separate base is required. This type of construction permits the boiler to be set directly on a wood or composition floor without danger of fire. The *wet-base* also provides some additional heating surface.

Capacities of cast-iron boilers range generally from capacities required for small residences up to about 12,000 sq ft of steam radiation but boilers are made with capacities up to approximately 32,000 sq ft EDR (steam).

Steel Boilers

Steel boilers may be of the fire-tube type, in which the gases of combustion pass through the tubes and the boiler water circulates around them, or of the water-tube type, in which the gases circulate around the tubes and the water passes through them. Either the fire-tube or water-tube type may be designed with integral water-jacketed furnaces, or arranged for refractory lined brick or refractory lined jacketed furnaces. Those with integral water-jacketed furnaces are called portable firebox boilers, and are the most commonly used type. They are usually shipped in one piece, ready for piping connections. Refractory furnaces are usually installed in refractory lined furnace boilers after they are set in place.

Capacities of steel boilers range from those required for small residences up to about 50,000 sq ft EDR (steam).

Boilers for Special Applications

One of these is known as the *magazine-feed boiler* developed for the burning of small sizes of anthracite and coke, and has a large fuel carrying capacity, which results in longer firing periods than would be the case with the standard types burning coal of buckwheat size. Special attention must be given to proper chimney sizes and connections in order to insure adequate draft.

Boilers for *hot water supply* are classified as direct, if the water heated passes through the boiler, and as indirect, if

the water heated does not come in contact with the water or steam in the boiler.

Direct heaters are built to operate at the pressures found in city supply mains, and are tested at pressures from 200 to 300 psig. The life of direct heaters depends almost entirely on the scale-forming properties of the water supplied and the temperatures maintained. If low water temperatures are maintained, the life of the heater will be much longer due to decreased scale formation and minimized corrosion. Direct water heaters in some cases are designed to burn refuse and garbage.

Indirect heaters generally consist of steam boilers in connection with heat exchangers of the coil or tube types which transmit the heat from the steam to the water. This type of installation has the following advantages:

1. The boiler operates at low pressure.
2. The boiler is protected from scale and corrosion.
3. The scale is formed in the heat exchanger in which the parts to which the scale is attached can be cleaned or replaced. The accumulation of scale does not affect efficiency, although it will affect the capacity of the heat exchanger.
4. Discoloration of water may be prevented if the water supply comes in contact with only nonferrous metal.

Where a steam or a forced circulation hot water heating system is installed, the domestic hot water may be heated by an indirect heater attached to the boiler. For most satisfactory performance in the steam system, this heater is placed just below the water line of the boiler. In a forced circulation hot water system, it should be located as high as practicable with respect to the boiler.

BOILER DESIGN CONSIDERATIONS

Furnace Design

Good efficiency and proper boiler performance are dependent on correct furnace design. There must be sufficient volume for burning the particular fuel which is used, and means to obtain a thorough mixing of air and gases at a high temperature and at a velocity low enough to permit complete combustion of all the volatiles. For hand-fired boilers, the furnace volume should be large enough to hold sufficient fuel for reasonably long firing periods. (See Chapters 33 and 34.)

Heating Surface

Boiler heating surface is that portion of the surface of the heat transfer apparatus in contact with the fluid being heated on one side and the gas or refractory being cooled on the other side. Heating surface on which the fire shines, is known as *direct* or radiant surface, and that in contact with hot gases only, as *indirect* or convection surface. The amount of heating surface, its distribution, and the temperatures on either side thereof, influence the capacity of any boiler.

Direct heating surface is more valuable than indirect per square foot because it is subjected to a higher temperature and also, in the case of solid fuel, because it is in position to receive the full radiant energy of the fuel bed.

The effectiveness of the heating surface depends on its cleanliness, its location in the boiler, and the shape of the gas passages. The area of the gas passages must not be so small as to cause excessive resistance to the flow of gases, where natural draft is employed. Inserting baffles so that the heating surface is arranged in series with respect to the gas flow, increases boiler efficiency and reduces stack temperature, but increases the draft loss through the boiler.

Heat-Transfer Rate

Practical average overall heat transfer rates, expressed in Btu absorbed per square foot of surface per hour, will average about 3300 for hand-fired boilers, and 4000 for mechanically-fired boilers when operating at *design load*. When mechanically-fired boilers are operating at *maximum load*, as defined in this chapter under heading Selection of Boilers, these values will run between 5000 and 6000. Boilers operating under favorable conditions at these heat transfer rates, will give exit gas temperatures that are considered consistent with good practice, although there are boilers which have high efficiencies and also operate at higher transmission rates.

RATING AND TESTING CODES

Heating boilers are usually rated according to codes developed by the Steel Boiler Institute, the Institute of Boiler and Radiator Manufacturers, the American Gas Association, and the Mechanical Contractors Association of America, whose test codes have been prepared specifically for the purpose of obtaining information required for establishing acceptable ratings. The various current rating and testing codes will be discussed in following paragraphs in which limitations, methods of application, and resulting ratings will be described.

The Steel Boiler Institute has adopted a rating code for boilers designated *Table 1 Steel Boilers*, *Table 2 Steel Boilers*, and *Table 3 Steel Boilers*, and a testing code for *Oil-fired Table 2* and *Table 3 Steel Boilers* (*SBI Rating Code*, Eighth Edition, February 1958). Tables 1, 2, and 3 of this chapter show the SBI Gross Outputs and Net Ratings of these three classes of boilers.

The *Table 1* boilers (defined as those having 129 to 3571 sq ft of heating surface and formerly designated as *Commercial* boilers) are rated in square feet EDR design load (steam) on the basis of heating surface with limitations set for grate area, furnace volume, and furnace height. The *Table 2* boilers (defined as those having not more than 294 sq ft of heating surface and formerly designated as *Residential* boilers) are rated on the basis of heating surface with ratings confirmed by test. The *Table 3* boilers (defined as having no limits of minimum heating surface or furnace volume, and having Gross Outputs and Net Ratings listed in Table 3) are rated on the basis of performance under the provisions of Section III, Part 2, of the *SBI Rating Code*.

The minimum stack area dimensions to be cataloged for *Table 3* boilers are shown in Table 4. Required stack heights are found in the catalogs of the manufacturers.

Stoker-fired and gas-fired *Table 2* boilers are rated (SBI Net Rating) not in excess of the oil-fired rating. Hand-fired *Table 2* boilers are rated (SBI Net Rating) not greater than fourteen times the heating surface.

The Institute of Boiler and Radiator Manufacturers has adopted a code[1] for rating cast-iron heating boilers, based upon performance obtained under controlled test conditions. This code applies to all sectional cast-iron heating boilers except those of magazine-feed type.

The *Gross I = B = R Output* is obtained by test, and is subject to certain limiting factors. For hand-fired boilers, the number of boilers of a series to be tested, the minimum overall efficiency, the minimum time limit (the time an *Available Fuel Charge* will last when burned at a rate which will produce the *Gross I = B = R Output*), the chimney area and

(a)* The return tapping sizes shown for boilers having 129 to 600 sq ft heating surface, inclusive, are adequate for forced hot water.

(b) Bituminous Stoker-Fired. Does not apply to Scotch-Type Boilers.

(c) Oil, gas or bituminous stoker-fired coal. Minimum furnace volumes for anthracite, stoker-fired, are not specified in this code.

(d) Does not apply to Scotch-Type Boilers.

(e) Does not apply to high-pressure boilers.

Note: Scotch-Type Boilers may be cataloged in sizes having 60 sq ft minimum heating surface with 7.2 cu ft minimum furnace volume, and 70 sq ft minimum heating surface with 11.9 cu ft minimum furnace volume.

26.0	20 × 24	16¾ × 20¾	19.0	18

height, and the draft in the stack are all subject to the limits established in the code. Tests are run using anthracite coal of standard specification. Bituminous coal and coke ratings are the same as for anthracite.

For automatically-fired boilers, the number of boilers of a series to be tested, the flue gas temperature and analysis, the minimum overall efficiency, the draft loss through the boiler, and the heat release in the combustion chamber are subjected to limitation by the code.[1] Oil-fired boiler ratings are established by tests using gun-type oil burners and commercial grade No. 2 fuel oil. Stoker-fired ratings are based on the *Gross I = B = R Output* obtained by oil-fired tests. Gas-fired ratings for boilers having gross outputs greater than 300,000 Btu per hour, where no *A.G.A. Rating* is published, are based on the *Gross I = B = R Output* obtained by oil-fired tests. Gas-fired ratings for boilers having gross outputs less than 300,000 Btu per hour, where no *A.G.A. Rating* is published, are established by gas-fired tests with atmospheric, single-port-type burners using natural or manufactured gas or a mixture of these two gases. The *A.G.A. Output Rating* of a gas-designed boiler may be used in determining the *Net I = B = R Rating*.

The *Net I = B = R Rating* is determined from the *Gross I = B = R Output* by applying specified *Piping and Pickup Factors* which range from 2.36 to 1.40 for hand-fired boilers, and from 1.56 to 1.288 for automatically-fired steam boilers, and from 1.333 to 1.288 for automatically-fired hot water boilers. In all cases, the factor decreases as the boiler size increases. Table 5 is abstracted from the 1951 I = B = R Boiler Rating Tables in the code and illustrates the relationship between *Net I = B = R Rating* and *Gross I = B = R Output*.

The American Gas Association rates gas designed boilers at 80 percent of the A.G.A. *Input Rating*. These ratings are determined by *performance tests* described in the *A.G.A. Approval Requirements for Central Heating Appliances*.

The Mechanical Contractors Association of America has adopted a method, based on their physical characteristics, for rating boilers that are not rated in accordance with the SBI or I = B = R Codes. Ratings are expressed on a Net Load basis in square feet of steam radiation.

The MCAA has also adopted a *Testing and Rating Code for Boiler-Burner Units*.[2] The purpose of this Code is to provide a basis of rating commercial sizes of steel heating boiler-burner units fired with oil or gas fuel. This code allows a higher rating than is permissible under the SBI Code. A gross output is established with certain limiting factors applying to flue gas temperature, carbon dioxide, efficiency, and quality of steam. This output is divided by 1.5 to determine the *net rating*.

BOILER EFFICIENCY

The term efficiency, as used for guarantee of boiler performance, is usually construed as follows:

1. *Solid Fuels.* The efficiency of the *boiler* alone is the ratio of the heat absorbed by the water and steam in the boiler per pound of combustible burned on the grate, to the calorific value of 1 lb of combustible as fired. The *combined* efficiency of *boiler, furnace, and grate* is the ratio of the heat absorbed by the water and steam in the boiler per pound of fuel as fired, to the calorific value of 1 lb of fuel as fired.

2. *Liquid and Gaseous Fuels.* The *combined* efficiency of boiler, furnace, and burner is the ratio of the heat absorbed by the water and steam in the boiler per pound or cubic foot of fuel, to the calorific value of 1 lb or cubic foot of fuel, respectively.

The following efficiencies apply to current designs of boilers operated under favorable conditions at their gross output ratings. Some older boilers, designed primarily for hand firing, may have lower efficiencies when automatically-fired.

Anthracite, hand-fired	60 to 75 percent
Bituminous coal, hand-fired	50 to 65 percent
Stoker-fired	60 to 75 percent
Oil- and gas-fired	70 to 80 percent

Higher efficiencies for hand-fired bituminous coal may be obtained by careful firing of either a regular or a smokeless boiler.

RATING OF BOILERS

In referring to boiler rating, it is necessary to know the basis on which the rating has been established in order to understand the exact meaning of the term. The following example will illustrate the meaning of three ratings which might be established for the same boiler.

Assume that an installation has the following loads determined in accordance with the section Selection of Boilers:

Net Load	1000 sq ft of steam radiation
Piping Tax	200 sq ft of steam radiation
Design Load	1200 sq ft of steam radiation
Pickup Allowance	240 sq ft of steam radiation
Maximum or Gross Load	1440 sq ft of steam radiation

[a] Extracted from Rating Table in 1951 edition of *I = B = R Testing and Rating Code for Low Pressure Cast Iron Heating Boilers.*
[b] To be specified in catalog. [c] Maximum stack height which may be shown in catalog.

A boiler that is just large enough to carry this system might be said to have a *net load* rating of 1000 sq ft, a *design load* rating of 1200 sq ft, or a *gross load* rating of 1440 sq ft, depending on the basis on which the boiler is rated.

On a *net load* basis the boiler would be rated 1000 sq ft of steam radiation and would have sufficient excess capacity to supply the *normal piping* and *pickup load*. Net I = B = R Ratings, SBI Net Ratings, and Net Load Ratings of the Mechanical Contractors Association of America are established on this basis.

On a *design load* basis the boiler would be rated 1200 sq ft of steam radiation and would have sufficient excess capacity to supply the *pickup load*. It would be of adequate size for a system in which the *sum* of the *net load* and the *piping heat loss* did not exceed 1200 sq ft of steam radiation. The SBI Ratings shown in columns 1, 2, 3, 10, 11, and 12 of Table 1 (not to be confused with SBI Net Rating) are established on a *design load* basis.

On a *gross output* basis of rating, the boiler would be rated 1440 sq ft of steam radiation and would be of adequate size for a system in which the sum of the *net load*, *piping load*, and *pickup load* did not exceed 1440 sq ft of steam radiation. Gross I = B = R Output and A.G.A. Ratings are established on a *gross output* basis.

In the determination of boiler ratings, the *Gross Output* is the quantity of heat available at the boiler nozzle, with the boiler normally insulated and when operating under limitations stipulated in the code or method by which the boiler is rated. The boiler may be capable of producing a greater nozzle output, but in doing so would exceed some of these limitations.

SELECTION OF BOILERS

General Factors

The *Maximum Load* or *Gross Load* on the boiler is the sum of the four following items.

The *Design Load* is the sum of items 1, 2, and 3.

The *Net Load* is the sum of items 1 and 2.

1. *Radiation Load*. The estimated heat emission in Btu per hour of the connected radiation (direct, indirect, or forced convection coils) to be installed.

The connected radiation is determined by calculating the heat losses for each room in accordance with data given in Chapters 9, 11, and 12. The sum of the calculated heat losses for all the rooms represents the total required heat emission of the connected radiation, expressed in Btu per hour. As practically all boilers are now rated on a Btu basis, it is unnecessary to convert the radiation load to square feet of equivalent direct radiation.

2. *Hot Water Supply Load*. The estimated maximum heat in Btu per hour required to heat water for domestic use.

I = B = R recommends that allowance for hot water supply load be made only for bathrooms in excess of two, as follows: Instantaneous Coil 12,000 Btu per hour, and for Storage Tank installation 120 Btu per (hour) (gallon of tank capacity). For instantaneous coil installations the boiler capacity should not be less than required to heat 2 to 3 gal of water, 100 deg per min. See also Chapter 56.

3. *Piping Tax*. The estimated heat emission in Btu per hour of the piping connecting the radiation and other apparatus to the boiler.

As the heating industry as a whole is not entirely agreed upon piping tax allowances for different sizes of installations, it is better to compute the heat emission from both bare and covered pipe surface in accordance with data in Chapter 32. In average house heating systems, it is common practice to consider the piping tax to be equal to 25 percent of the Net Load. In determining Net I = B = R Ratings from Gross I = B = R Output, the piping factor allowed varies from 30 percent for small boilers to 12 percent for larger boilers.

4. *Warming-Up or Pickup Allowance*. The estimated increase in the normal load in Btu per hour caused by the heating up of the cold system.

The warming-up allowance represents the load due to heating the boiler and contents to operating temperature, and heating up cold radiators and piping.

Other items to be considered in boiler selection are as follows:

a. Efficiency with hard or soft coal, gas, or oil firing, as the case may be.

b. Grate area with hand-fired coal, or fuel-burning rate with stokers, oil, or gas.

c. Combustion space in the furnace.

d. Type of heat liberation, whether continuous or intermittent, or a combination of both.

e. Convenience in firing and cleaning.

f. Adaptability to changes in fuel and kind of attention.

g. Height of water line.

h. Miscellaneous items such as draft available, possibility of future extension, possibility of breakdown, and head room in the boiler room.

i. The most economical size of boiler is usually one that is just the right size for the load. Either larger or smaller boilers may be less economical.

Cast-Iron Boilers

Net load ratings of cast-iron boilers are usually available from manufacturers' catalogs. They may also be obtained conveniently from published tables of I = B = R ratings,[3] or from recommendations of the Mechanical Contractors Association of America,[4] and can be used in selection of boilers, unless the heating system contains an unusual amount of bare pipe, or the nature of the connected load is such that the normal allowances for pipe loss and pickup do not apply. In such a case, the selection must be based on the gross output.

Steel Heating Boilers

SBI catalog ratings, in accordance with the previously mentioned Steel Boiler Institute code, are intended to correspond with the estimated *design load*. When the heat emission of the piping is not known, the net load to be considered for the boiler may be determined from Tables 1 and 2. The difference between design load and net load represents an amount which is considered normal for piping loss of the ordinary heating system.

Boilers with less than 294 sq ft of heating surface and having SBI net ratings (steam) of not more than 5000 sq ft if mechanically-fired and 4120 sq ft if hand-fired, are classified as *Table 2 Steel Boilers*, formerly Residential boilers. An insulated *Table 2 boiler* for oil, gas, or stoker firing may carry a *net load* expressed in square feet of steam radiation of not more than seventeen times the square feet of heating surface in the boiler, provided the boiler has been tested in accordance with the SBI Code for testing oil-fired steel boilers at output rates of 125, 150, and 175 percent of the steam SBI net rating. The SBI net rating for a water boiler, automatically-fired, expressed in Btu per hour, is 270 times the steam SBI net rating in square feet. The net water rating is 12½ percent greater than the steam rating because a lower piping and pickup factor is generally required in a water system. The SBI net rating (sq ft steam) for hand-fired *Table 2 boilers* is not greater than fourteen times the heating surface. If the heat loss from the piping system exceeds 20 percent of the installed radiation, the excess is to be considered as part of the *net load*.

Gross Output ratings for *Table 1* and *Table 2*, as well as for *Table 3* (a new designation) *Steel Boilers* are shown in the seventh edition of the *SBI Rating Code*.

Heating Surface and Grate Area Basis

Where neither the *net load* nor *gross output* ratings based upon performance tests are available, a good general rule for conventionally designed boilers is to provide 1 sq ft of boiler heating surface for each 14 sq ft of equivalent radiation (240 Btu per sq ft) (hr) represented by the design load. This is equivalent to allowing 10 sq ft of boiler heating surface per boiler horsepower. In this case it is assumed that the *maximum load* including the warming-up allowance will be provided for by operating the boiler in excess of the *design load*, that is, in excess of the 100 percent rating on a boiler-horsepower basis. SBI ratings for hand firing are based on 10 sq ft of heating surface per boiler horsepower.

Table 6 .... Practical Combustion Rates for Coal-Fired Heating Boilers Operating at Maximum Load on Natural Draft of From ⅛ In. to ½ In. Water*

Kind of Coal	Sq Ft Grate	Lb of Coal per (Sq Ft Grate) (Hr)
No. 1 Buckwheat Anthracite	Up to 4	3
	5 to 9	3½
	10 to 14	4
	15 to 19	4½
	20 to 25	5
Anthracite Pea	Up to 9	5
	10 to 19	5½
	20 to 25	6
Anthracite Nut and Larger	Up to 4	8
	5 to 9	9
	10 to 14	10
	15 to 19	11
	20 to 25	13
Bituminous	Up to 4	9.5
	5 to 14	12
	15 and above	15.5

* Steel boilers usually have higher combustion rates for grate areas exceeding 15 sq ft than those indicated in this table.

Due to the wide variation which may be encountered in manufacturers' ratings for boilers of approximately the same capacity, it is advisable to check the grate area required for heating boilers burning solid fuel by means of the following formula:

$$G = \frac{H}{C \times F \times E} \qquad (1)$$

where

G = grate area, square feet.
H = required *gross output* of the boiler, Btu per hour (see Selection of Boilers).
C = desirable combustion rate for fuel selected, pounds of dry coal per (square foot of grate) (hour). (See Table 6.)
F = calorific value of fuel, Btu per pound.
E = efficiency of boiler, usually taken as 0.60.

Example 1: Determine the grate area for a required *gross output* of the boiler of 500,000 Btu per hour, a combustion rate of 6 lb per hour, a calorific value of 13,000 Btu per pound, and an efficiency of 60 percent.

$$G = \frac{500{,}000}{6 \times 13{,}000 \times 0.60} = 10.7 \text{ sq ft}$$

The boiler selected should have a grate area not less than that determined by Equation 1. With small boilers, where it is desired to provide sufficient coal capacity for approximately an eight-hour firing period plus a 20 percent reserve for igniting a new charge, more grate area may be required depending upon the depth of the fuel pot.

Gas-Fired Boilers

After determining the *net load* for the installation, gas-designed boilers can usually be selected from manufacturers' tables of *net load ratings* which are based on piping and pickup allowances varying from 56 percent for small steam boilers and 33.3 percent for small hot water boilers to 28.8 percent for very large boilers. If the piping and pickup load or other factors create an unusual load, a boiler should be selected which has an *A.G.A. output rating* equal to the maximum output required. Detailed recommendations for selection of gas designed boilers are given in the A.G.A. publication, *Comfort Heating*.[5]

SPACE LIMITATIONS

Boiler rooms should, if possible, be situated at a central point with respect to the building, and should be designed for a maximum of natural light. The space in front of the boilers should be sufficient for firing, stoking, ash removal, and cleaning or renewal of flue tubes, and should be at least 3 ft greater than the length of the tubes.

A space of at least 3 ft should be allowed on at least one side of every boiler for convenience of erection and for accessibility to the various dampers, cleanouts, and trimmings. The space at the rear of the boiler should be ample for the chimney connection and for cleanouts. With large boilers the rear clearance should be at least 3 ft in width.

The boiler room height should be sufficient for the location of boiler accessories, and for proper installation of piping. In general, the ceiling height for small steam boilers should be at least 3 ft above the normal boiler water line. With vapor heating, especially, the height above the boiler water line is of vital importance.

CONNECTIONS AND FITTINGS

Steam outlet connections should be the full size of the manufacturers' tappings, in order to keep the velocity of flow through the outlet reasonably low, and to avoid fluctuation of the water line and undue entrainment of moisture, and should extend vertically to the maximum height available above the boiler. A steam velocity in boiler outlets not exceeding 25 to 30 fps at maximum load is recommended, unless data are available to show that a higher velocity is satisfactory. See further data on pipe connections to boilers in Chapters 26 and 28 and in the *ASME Boiler Construction Code for Low Pressure Heating Boilers*.

Where a *return header* is used on a cast-iron sectional boiler to distribute the condensate to both rear tappings, it is advisable to provide full size plugged tees instead of elbows where the branch connections enter the return tappings. This aids in cleaning of sludge from the bottom of the boiler sections through the large plugged openings. An equiva-

lent cleanout plug should be provided in the case of a single return connection.

Blowoff or drain connections should be made near the boiler, and so arranged that the entire system may be drained of water by opening the drain cock. In the case of two or more boilers separate blowoff connections must be provided for each boiler, on the boiler side of the stop valve on the main return connection.

Water service connections must be provided for both steam and water boilers, for refilling and for the addition of make-up water to boilers. This connection is usually of galvanized steel pipe, and is made to the return main near the boiler or boilers.

Fitting connections for pressure gage piping, water gage connections, and safety valves, should be made in accordance with the *ASME Boiler Construction Code for Low Pressure Heating Boilers*.

Smoke Breeching and Chimney Connections. The breeching or smoke pipe from the boiler outlet to the chimney should be airtight and as short and direct as possible, preference being given to long-radius and 45-deg instead of 90-deg bends. The breeching entering a brick chimney should not project beyond the flue lining, and where practicable it should be grouted from the inside of the chimney. A thimble or sleeve usually is provided where the breeching enters a brick chimney.

Where a battery of boilers is connected into a breeching, each boiler should be provided with a tight damper. The breeching for a battery of boilers should not be reduced in size as it goes to the more remote boilers. Good connections made to a good chimney will usually result in a rapid response by the boilers to demands for heat.

ERECTION, OPERATION, AND MAINTENANCE

The directions of the boiler manufacturer should always be read before the assembly or installation of any boiler is started, even though the contractor may be familiar with the boiler. All joints requiring boiler putty or cement, which cannot be reached after assembly is complete, must be finished as the assembly progresses.

Five precautions that should be taken in all installations to prevent damage to the boiler are:

1. There should be provided proper and convenient drainage connections for use if the boiler is not in operation during freezing weather.
2. Strains on the boiler, due to movement of piping during expansion, should be prevented by suitable anchoring of piping, and by proper provision for pipe expansion and contraction.
3. Direct impingement of too intense local heat upon any part of the boiler surface, as with oil burners, should be avoided by protecting the surface with firebrick or other refractory material.
4. Condensation in steam systems must flow back to the boiler as rapidly and uniformly as possible. Return connections should prevent the water from backing out of the boiler.
5. Automatic boiler feeders and low water cut-off devices, which shut off the source of heat if the water in the boiler falls below a safe level, are recommended for mechanically-fired boilers.

Boiler Troubles

A complaint regarding boiler operation generally will be found to be due to one of the following:

1. *The boiler fails to deliver enough heat.* The cause of this condition may be: (*a*) poor draft; (*b*) poor fuel; (*c*) inferior attention or firing; (*d*) boiler too small; (*e*) improper piping; (*f*) improper arrangement of sections; (*g*) heating surfaces covered with soot; (*h*) insufficient radiation installed; or (*i*) with mechanical firing, fuel-burning equipment too small.
2. *The water line is unsteady.* The cause of this condition may be: (*a*) grease and dirt in boiler; (*b*) water column connected to a very active section and, therefore, not showing actual water level in boiler; or (*c*) boiler operating at excessive rate of output.
3. *Water disappears from the gage glass.* This may be caused by: (*a*) priming due to grease and dirt in boiler; (*b*) too great pressure difference between supply and return piping preventing return of condensate; (*c*) valve closed in return line; (*d*) connection of bottom of water column to a very active section or thin waterway; or (*e*) improper connections between boilers in battery permitting boiler with excess pressure to push returning condensate into boiler with lower pressure.
4. *Water is carried over into steam main.* This may be caused by: (*a*) grease and dirt in boiler; (*b*) insufficient steam dome or too small steam liberating area; (*c*) outlet connections of too small area; (*d*) excessive rate of output; (*e*) water level carried higher than specified.
5. *Boiler is slow in response to operation of dampers.* This may be due to: (*a*) poor draft resulting from air leaks into chimney or breeching; (*b*) inferior fuel; (*c*) inferior attention; (*d*) accumulation of clinker on grate; or (*e*) boiler too small for the load.
6. *Boiler requires too frequent cleaning of flues.* This may be due to: (*a*) poor draft; (*b*) smoky combustion; (*c*) too low a rate of combustion; or (*d*) too much excess air in firebox causing chilling of gases.
7. *Boiler smokes through fire door.* This may be due to: (*a*) defective draft in chimney or incorrect setting of dampers; (*b*) air leaks into boiler or breeching; (*c*) gas outlet from firebox plugged with fuel; (*d*) dirty or clogged flues; or (*e*) improper reduction in breeching size.
8. *Low carbon dioxide.* This may be due in oil burning boilers to: (*a*) improper adjustment of the burner; (*b*) leakage through the boiler setting; (*c*) improper fire caused by a fouled nozzle; or (*d*) to an insufficient quantity of oil being burned.

Cleaning Boilers

All boilers are provided with flue cleanout openings through which the heating surface can be reached by means of brushes or scrapers. Flues of solid fuel boilers should be cleaned often to keep the surfaces free of soot or ash. Gas boiler flues and burners should be cleaned at least once a year. Oil-burning boiler flues should be examined periodically to determine when cleaning is necessary.

The grease used to lubricate the cutting tools during erection of new piping systems serves as a carrier for sand and dirt, with the result that a scum of fine particles and grease accumulates on the surface of the water in all new boilers, while heavier particles may settle to the bottom of the boiler and form sludge. These impurities tend to cause foaming, preventing the generation of steam and causing an unsteady water line.

This unavoidable accumulation of oil and grease should be removed by blowing off the boiler as follows: If not already provided, install a surface blow connection of at least 1¼-in. nominal pipe size with outlet extended to within 18 in. of the floor or to sewer, inserting a valve in this line close to boiler. Bring the water line to center of outlet, raise steam pressure, and while fire is burning briskly open valve in blowoff line. When pressure drops, close valve and repeat process adding water at intervals to maintain proper level. As a final operation bring the pressure in the boiler to about 10 psi, close blowoff, draw the fire or stop burner, and open drain valve. After boiler has cooled partly, fill and flush out several times before filling it to proper water level for normal service.

Where the outlined blowing-off procedure does not remove the grease and dirt and obtain clear boiler water, it may be necessary to use a detergent type of cleaner in which case the boiler manufacturer as well as cleaner manufacturer should be consulted regarding procedure to be followed.

When addition of water to a system becomes necessary it is advisable to operate the boiler or at least to raise the water temperature to the boiling point in order to permit escape of oxygen and other dissolved gases that would be corrosive if the boiler is out of operation.

Treatment of Boiler Water

Corrosion on the water side of a boiler can be prevented by proper treatment of the boiler water. Generally, treatment which will remove the dissolved oxygen and carbon dioxide and maintain a minimum pH of 11 (slightly alkaline water) will effectively prevent corrosion. A pH higher than 11 may be used although the boiler water is more likely to foam and cause wet steam with the greater concentration of alkali. A number of compounds are being marketed for this purpose. The Steel Boiler Institute adopted a conditioning compound for use with steel boilers after an extensive cooperative study and many members of the Institute either supply this compound with their boilers or have it available.

It should be emphasized that when the character of the water is such that treatment is required, the treatment should be administered immediately after the boiler and system have been cleaned. It is not good practice to fill a boiler with fresh water and allow it to stand idle as the dissolved gases in fresh water available in many localities can start corrosive action in a very short time. After refilling a system it is advisable to elevate the temperature close to the boiling point to drive off the dissolved gases immediately.

Care of Idle Heating Boilers

Heating boilers are often seriously damaged during summer months due chiefly to corrosion resulting from the combination of sulfur in the soot with the moisture in the cellar air. At the end of the heating season the following precautions should be taken:

1. All heating surfaces should be cleaned thoroughly of soot, ash, and residue, and the heating surfaces of steel boilers should be given a coating of lubricating oil on the fire side.
2. All machined surfaces should be coated with oil or grease.
3. Connections to the chimney should be cleaned, and in case of small boilers, the pipe should be placed in a dry place after cleaning.
4. If there is much moisture in the boiler room, it is desirable to drain the boiler to prevent atmospheric condensation on the heating surfaces of the boiler when they are below the dew-point temperature. Due to the hazard that someone may inadvertently build a fire in a dry boiler, however, it is safer to keep the boiler filled with water, particularly in residential installations. Air can be excluded from a steam boiler by raising the water level into the steam outlets. A hot water system usually is left filled to the expansion tank.
5. The grates and ashpit should be cleaned.
6. Clean and repack the gage glass if necessary.
7. Remove any rust or other deposit from exposed surfaces by scraping with a wire brush or sandpaper. After boiler is thoroughly cleaned, apply a coat of preservative paint where required to external parts normally painted.
8. Inspect all accessories of the boiler carefully to see that they are in good working order. In this connection, oil all door hinges, damper bearings, and regulator parts.
9. If a system has been drained and refilled with fresh water, the boiler should be fired long enough to elevate the water temperature close to the boiling point to drive off dissolved oxygen and carbon dioxide. These gases can be responsible for excessive corrosion if allowed to remain in the system.

WARM AIR FURNACES

Warm air heating furnaces of a number of types and a wide range of sizes are listed and illustrated in the Catalog Data Section.

Warm air furnaces may be classified in several different ways:

1. According to method of heat distribution—these are either gravity or mechanical (blower) furnaces.
2. According to fuels for which the furnaces are designed—these are coal hand-fired or stoker-fired, oil, gas, or wood.
3. According to materials of construction—they are cast iron, low carbon steel, and occasionally high temperature steel alloys.
4. According to design or construction, such as drum and radiator, tubular, horizontal, etc.

Gravity Warm Air Furnaces

A gravity furnace is one in which the motive head producing air flow depends upon the difference in density between the heated air leaving the top of the casing and cooled air entering the bottom of the casing. Since this gravity head is relatively low, the furnace must have low internal resistance to the flow of air, and relatively large areas must be available for free circulation within the furnace casing. It is common practice to provide approximately 50 percent free-air area through gravity-type furnaces.

Furnaces for gravity-type systems are available in designs suitable for central heating, pipeless furnace, or unit floor-furnace installations. Booster fans are sometimes used, in conjunction with gravity systems, to increase air circulation. Where a fan is to be used with a furnace casing sized for gravity air flow, some form of baffling must be employed to restrict the free area within the casing and to force impingement of the air against the heating surfaces. Where square casings are used, the corners must be baffled.

Mechanical Warm Air Furnaces

Mechanical or forced warm air furnaces include fans or blowers as integral parts, for the purpose of circulating the air, and usually include air filters.

Centrifugal fans with either backward- or forward-curved blades are the type most commonly used. Motors may be mounted on the fan shaft or connected to the fan by a belt drive. Adjustable pulleys are desirable to provide means of regulating the quantity of air distributed to the heated spaces. Either the motor load or the noise considerations may limit the maximum operating fan speed. Two-speed motors have given successful operating results. Motors and mountings must be carefully selected for quiet operation. Electrical conduit and water piping must not be fastened to, nor make contact with, the fan housing.

Filters

Several types of filters are available for mechanical warm air furnace applications, and are discussed in Chapter 24. For maximum efficiency and life under operating conditions, filters should not be subjected to a temperature in excess of 150 F. Filters should have at least 80 percent average efficiency on an 8-hr test at a maximum resistance of 0.25 in. of water. Filter resistance rises rapidly with the accumulation of dirt, and may reduce the air circulation over heating surfaces. In domestic furnaces, the maximum velocity, based on nominal filter area, should not exceed 300 fpm.

Fuel Utilization

A combustion rate of from 5 to 8 lb of coal per (square foot of grate) (hour) is recommended for residential furnaces. A higher combustion rate is permissible with larger furnaces for buildings other than residences, depending upon the ratio of grate surface to heating surface, firing period, and available draft.

In residential furnaces for coal burning, the ratio of heating surface to grate area will average about 20 to 1; in commercial sizes the ratio may be as high as 50 to 1, depending on fuel and draft. Furnaces may be installed singly, each furnace with its own fan, or in batteries of a number of furnaces, using one or more fans.

Where oil fuel is used, care must be exercised in selecting the proper size and type of burner for the particular size and type of furnace used. Furnaces for burning oil fuel are usually designed for blow-through installations so that the pressure in the air space is higher than that in the combustion chamber or flues. The National Warm Air Heating and Air Conditioning Association has prepared a *Tentative Code for Testing and Rating of Oil-Fired Furnaces*. Compact fan-furnace-burner units are available, suitable for basement, closet, or attic installations.

Gas-fired forced air furnaces should conform in construction and performance to A.G.A. Approval Requirements.

Heavy Duty Fan Furnaces

Fan furnaces for large commercial and industrial buildings, churches, schools, etc., are available in sizes ranging from 300,000 to 6,000,000 Btu per (hour) (unit). Heavy duty furnace heaters may be arranged in battery combinations of one or more units.

Most manufacturers of heavy duty furnaces rate their furnaces in Btu per hour, and also indicate the number of square feet of heating surface. Limitations on temperature of flue gases, heat exchanger, and casing as well as carbon monoxide and air temperature rise are also factors in establishing ratings for these units. These limits are shown in the *ASHAE Code for Testing and Rating Heavy Duty Furnaces and Direct-fired Unit Heaters*.

Control of temperature is secured through (1) controlling the quantity of heated air entering the room, (2) using mixing dampers, or (3) regulating the fuel supply.

The design of heavy duty fan furnace heating systems is in many respects similar to that of the central fan heating systems described in Chapter 19. Ducts are designed by the method outlined in Chapter 21.

MATERIALS AND CONSTRUCTION

Both cast-iron and steel furnaces are made in capacities ranging from those for small insulated residence application with inputs of 40,000 Btu per hour or less, to capacities as large as 600,000 Btu per hour.

Cast-iron furnaces are usually constructed with a minimum sectional thickness of ¼ in., and effectively resist high temperatures and corrosion. They usually have a fairly large heat capacity because of their mass, which provides a distinct *fly wheel* or carry-over heating effect.

In steel furnaces welding, riveting, or both are used to join the formed metal. The use of steel castings, however, is rare, because of the cost, and because high stresses are not encountered in normal furnace construction. Steel furnaces have low heat capacities as a result of their relatively low mass and, therefore, deliver heat rapidly on demand.

FURNACE RATING

Rating Equations for Gravity Warm Air Furnaces[6]

Until a method of testing and rating gravity warm air furnaces has been developed, the following empirical rating equations are recommended by the National Warm Air Heating and Air Conditioning Association.

Gravity warm air furnaces of conventional design, having ratios (of heating surface to grate area) of 15 to 1 or greater, and having a ratio of casing area to face area not less than 0.4, are rated by the following equations:

1. *Hand-fired furnaces converted to Stoker, Gas, or Oil Firing.*

Bonnet Capacity in Btu per hour $= 1785 \times S \times 1.333$ (2)

2. *Hand-fired furnaces, with ratios of heating surface to grate area greater than 15 to 1 and less than 25 to 1.*

Bonnet Capacity in Btu per hour $= 1785 \times S \times 1.333$ (3)

3. *Hand-fired furnaces with ratios of heating surface to grate area in excess of 25 to 1.*

Bonnet Capacity in Btu per hour $= 1785 \times 25 \times G \times 1.333$ (4)

where

S = heating surface, in square feet.
G = actual grate area, in square feet.

The *Register Delivery Rating* is equal to 0.75 × (*Bonnet Capacity*). The *Leader Pipe Rating* in square inches, formerly used as a rating unit, may be found by dividing the *Register Delivery Rating* by 136.

Heating Surface of Furnace

Prime heating surface is defined[6] as surface above the top of the grate having *hot gases or live fuel on one side and circulating air over the other*, and in all cases is measured on the exterior or air side. The areas of the outer casing, the inner liner, and any radiation shields shall not be considered as heating surface.

In determining the amount of heating surface, extended surfaces are considered to be prime heating surface subject to the following limitations:

1. Extended heating surface may consist of fins, ribs, webs, lugs, or other projections from the prime heating surface. Projections less than ¼ in. thick at the base, and extending more than 1 in. from the prime surface are classified as fins.

2. Integral fins are continuously welded to, or cast as a part of, the prime heating surface. Both sides are included as heating surface, subject to the following allowances:

Distance from prime surface	1st in.	2nd in.	3rd in.	Over 3 in.
Ratio of effective area to total area	0.40	0.30	0.20	None

3. Non-integral fins are spot welded to, or otherwise held in line contact with, the prime heating surface. Both sides are included as heating surface, subject to the following allowances:

Distance from prime surface	1st in.	2nd in.	3rd in.	Over 3 in.
Ratio of effective area to total area	0.30	0.20	0.15	None

4. In the case of ribs, webs, or lugs more than ¼ in. thick at the base and extending less than 1 in. from the prime surface, the entire surface in contact with circulating air is included as heating surface.

5. In the case of ribs, webs, or lugs more than ¼ in. thick at the base and extending more than 1 in. from the prime heating surface, the areas of both sides of the first inch are included as prime heating surface. The portions projecting beyond 1 in. are treated as integral fins.

Grate Area

Grate area is defined[6] and treated for purpose of rating as follows:

1. The *nominal grate area* is defined as the total cross-sectional area of the bottom of the firepot. In steel furnaces the nominal grate area is the cross-sectional area inside the firebrick lining.

2. The *actual grate area*, used for calculating the ratios of heating surface to grate area, is the nominal grate area minus certain areas that cannot be considered as part of the grate itself. The following rules govern these deductions: (1) If a solid, continuous ledge extends around the grate and inside the firepot, any area of this ledge extending inside of a circle, the diameter of which is 1 in. less than the diameter of the bottom of the firepot, shall be deducted. (2) If separate, solid projections extend from the firepot towards the grate, the areas of any portions of these projections extending inside of a circle, the diameter of which is 3 in. less than the diameter of the bottom of the firepot, shall be deducted. (3) In the case of grates which are inclined, or are conical, the projected area is the same as the nominal grate area. The latter should, therefore, be used after making any necessary deductions.

Ratings for Forced Air Furnaces

For solid-fuel-burning, forced air furnaces having bonnet capacities between 80,000 and 250,000 Btu per hour, no standard method of test has been accepted, although eventually such codes will be developed. The National Warm Air Heating and Air Conditioning Association recommends the following empirical equations for use in rating solid fuel forced air furnaces:

1. *Hand-fired furnaces converted to Stoker, Gas, or Oil Firing.*

Bonnet Capacity in Btu per hour $= 2265 \times S \times 1.177$ (5)

2. *Hand-fired furnaces, with ratios of heating surface to grate area greater than 15 to 1 and less than 25 to 1.*

Bonnet Capacity in Btu per hour $= 2265 \times S \times 1.177$ (6)

3. *Hand-fired furnaces with ratios of heating surface to grate area in excess of 25 to 1.*

Bonnet Capacity in Btu per hour $= 2265 \times 25 \times G \times 1.177$ (7)

where

S = heating surface, in square feet.
G = actual grate area, in square feet.

The *Register Delivery Rating* is equal to 0.85 × (*Bonnet Capacity*).

The following testing and rating codes have been generally accepted in the industry:

Commercial Standard CS-109-44 for rating solid-fuel-burning, forced air furnaces having bonnet outputs of 80,000 Btu per hour or less. This provides a method of rating small coal-fired forced air furnaces by test.

A Tentative Code for Testing Oil-Fired Furnaces. This code has been adopted by the National Warm Air Heating and Air Conditioning Association for rating oil-fired furnaces by test.

The American Gas Association method of rating gas-fired furnaces on performance under tests. This is described in the *Approval Requirements for Central Heating Gas Appliances —Vol. II, Gravity and Forced Air Central Furnaces*, Z21.13.2.

Commercial Standard 113-51 is a method of rating oil-burning floor furnaces by test.

Commercial Standard CS 104-49 is a method of rating warm air furnaces equipped with pot-type oil burners by test.

Various codes covering the construction and performance of appliances as related to fire hazards have been developed by Underwriter Laboratories, Inc. In addition, there are many municipal codes[7] which regulate construction and installation of furnace equipment.

The yardstick of the National Warm Air Heating and Air Conditioning Association provides criteria for evaluating a furnace design and installation against industry accepted standards.

FURNACE EFFICIENCY

Rating formulas of the National Warm Air Heating and Air Conditioning Association are based on 55 percent efficiency for gravity coal furnaces and 65 percent efficiency for forced air coal furnaces. In the tentative *Oil Testing Code* the contemplated minimum efficiency is 70 percent for oil-fired forced air furnaces. Gravity gas furnaces approved by the American Gas Association are assigned a rating based on 75 percent efficiency. All *forced-air gas-fired furnaces* approved by American Gas Association are assigned a rating based on 80 percent efficiency.

DESIGN CONSIDERATIONS

Considerations of prime importance in the design of warm air furnaces and some general suggestions to be observed in connection with each, are as follows:

1. *Adequate heat transfer surface.*
   a. Heat transfer rates of 2000 to 4500 Btu per (hour) (square foot) of heating surface may be obtained without unduly high metal temperatures. With some types of design somewhat higher rates are acceptable.
   b. Fins, pins, and bosses are frequently used to add surface and to break down superficial gas films, both on gas-to-metal and metal-to-air surfaces.
   c. Surface and stack (flue gas) temperatures are good indications of the amount and effectiveness of the heating surfaces.
2. *Safe and efficient combustion of fuel.*
   a. Proper mixture of fuel and air is necessary for efficient combustion. This necessitates careful attention to the design of grates, nozzles, burners, air inlet areas and location, and combustion chamber baffling.
   b. Regulation of the quantity and the distribution of the air for combustion should be provided by use of check dampers, draft regulators, draft hoods, air shutters, and air orifices.
   c. Total draft loss through appliances should not exceed that available from chimneys which would normally be obtainable in the size of building which the appliance will supply with heat.
   d. The use of ignition safety devices such as safety pilots, hold-fire controls, and the like is recommended.
3. *Fuel capacity of appliance.*
   a. With solid fuels adequate coal capacity should be provided for at least 5 hr of operation at the maximum rated combustion rate.
4. *Adequate circulation of air over heating surface.*
   a. In gravity furnaces, free air space between casing and heat exchanger should be great enough to permit free flow over all surfaces.
   b. Forced air furnace design must include fans having proper capacity and suitable performance characteristics. Internal static pressures must be minimized without losing the advantages of high-velocity circulation over the heat exchanger surfaces.
   c. The air flow over the heating surface must be directed to obtain maximum efficiency and to eliminate hot spots and air noises.

d. Air velocities at bonnet should not be much in excess of 1000 fpm, and air temperature distribution at the furnace outlet should be uniform within approximately ± 30 deg.

5. *Durability.*

a. A minimum metal weight for gas-fired heat exchangers is established as No. 20 U.S. Gage for plain carbon steel by the *A.G.A. Approval Requirements for Central Heating Gas Appliances*, with some municipal codes specifying 18 gage. Cast-iron sectional thicknesses of ¼ in. to ⅜ in. are recommended.

b. Added strength and reinforced designs may be required to preclude damage in shipment, burning out from overfiring, or corrosion from condensation.

c. Maximum heat exchanger surface temperatures which may be used vary with the metal. The *American Gas Association Approval Requirements for Central Heating Gas Appliances* specify a maximum of 875 F for cast-iron or steel gas furnaces, and the *National Bureau of Standards* CS 109-44 *Code for Forced Air Solid Fuel-Burning Furnaces* specifies 1000 F as a maximum surface temperature. These temperatures define the range in which oxidation of non-alloy ferrous metal begins. The use of proper alloy additions increases the temperature resistance properties of metals.

d. Casing temperatures should be controlled so that they do not become hazards by burning those who touch them, or by creating fires.

6. *Serviceability.*

a. Those parts of the furnace which may be subject to soot, fly-ash, or condensation deposits should be accessible for cleaning.

b. Parts which may require adjustments or replacements, such as grates, baffles, liners, controls, should be removable.

c. Furnaces should be so designed that they can be installed with a minimum of difficulty.

7. *Control.*

a. Thermostatic controls of various types should be used to correlate space temperatures with unit operation.

b. Controls should be provided wherever possible, to prevent the occurrence of excessive temperatures or other conditions which might cause unsafe operation in any part of the unit.

8. *General design considerations.*

a. Furnace casings are normally constructed of formed and painted sheet steel or of galvanized iron. The casing should be protection from excessive radiation losses and temperatures by use of insulation or sheet steel air space liners. Liners should extend from the grate level to the top of the furnace and should be spaced from 1 in. to 1½ in. from the outer casing.

b. The hood or bonnet of the casing above the furnace should be as high as basement conditions will allow, to form a plenum chamber over the top of the furnace. This tends to equalize the pressure and temperature of the air leaving the bonnet through the various openings. It is generally considered advisable to take off the warm air pipes from the side of the bonnet near the top, as this method of take-off allows the use of a higher bonnet and thus provides a larger plenum chamber.

c. Warm air outlet and return air connections should be designed so that the ductwork may be easily attached. A ⅞ in. flange is normally used for this purpose.

d. Suitable provision should be made in appliances so that the controls and humidifiers may be installed in the proper location. When these auxiliary units are installed in the ductwork, detailed instructions should be provided to insure their proper location.

e. The flue connection should be of integral flue pipe size, and provision should be made to attach the flue pipe to the flue outlet of the furnace.

HUMIDIFICATION EQUIPMENT

Evaporating pans are usually located in the outlet air. There is a present trend toward heating the water. Equipment for doing this may make use of sprays, or it may take the form of water circulating coils placed within the combustion chamber, and connected by pipes to the humidifier pans where a constant water level is maintained by some separate float device. All humidifiers require provision for removal of dirt and lime.

SPACE HEATERS

Space heaters may be classified in several ways, such as:

1. By the type of fuel used as coal, wood, gas, and fuel oil.

2. According to the method of heat distribution as circulators or radiant types. A radiant heater is one in which the heat exchanger surface is exposed directly to the room atmosphere, and the generated heat is dissipated primarily by radiation. A circulating heater is essentially a jacketed radiant heater from which circulation of room air is promoted by the chimney effect caused by the movement of air passing upward between the jacket and heat exchanger surface.

3. According to method of design for particular fuel types, such as: (a) surface-fired and magazine-feed for solid fuels, (b) vaporizing pot-type and blue-flame heater for oil, and (c) vented and unvented heaters for gas. (The type of gas burner design, such as injection, yellow flame, power, and pressure, may also be mentioned.)

SOLID FUEL-FIRED HEATERS

Surface-fired heaters normally have a front firing door and are operated with relatively shallow fuel beds. A magazine-feed heater includes a deep reservoir of fuel to lengthen the attention intervals. In a true magazine-feed heater the rate of fuel ignition would be equal to the rate of burning; and self-feeding should operate to move the unburned fuel by gravity flow from the magazine section into the hearth area. However, the ideal balance between rate of ignition and rate of burning is virtually impossible to attain for any solid fuel under normal usage, although self-feeding may be obtained with wood and some free burning coals. Thus, a magazine-type space heater is essentially a deep surface-fired heater, its principal difference from other heaters being increased fuel capacity.

Materials and Construction

There is no accepted code governing the construction of solid-fuel-burning space heaters. In past years cast iron was used predominantly in the construction of coal and wood heaters, with the exception of the so-called *airtight* heaters designed as low-cost wood-burning units with little consideration for long life, and stoves were priced on a poundage basis. The present trend is toward fabricated steel parts and welded assemblies, although cast iron is still used for grates, firebox liners, and parts subject to high temperatures. Refractory firebox liners are also used quite extensively.

Formed sheet steel is used predominantly for the outer jacket of circulator heaters, although heaters with outer casings formed from cast iron are still readily available. Circulator cabinets normally have surfaces finished with a porcelain enamel, while the casing of a radiant heater is finished with an air-dried japan or a baked enamel.

Both welding and stove bolts are used in unit assembly, and stove cement is used on section joints to prevent air leakage. This latter is extremely important to obtain a low rate of combustion when desired.

Testing and Rating

There is no accepted code governing the method of testing and rating solid fuel space heaters. A tentative procedure, TS-3443, has been issued by the Division of Trade Standards, National Bureau of Standards, but is based on use of anthracite as a rating fuel, although bituminous coals are used predominantly as heating fuels. This procedure, which has been the basis of published ratings, consists of determining the heater output, expressed in Btu per hour, by the indirect method. The measurable heat losses: (1) loss due to moisture in the fuel, (2) loss due to heat in the dry flue gases, (3) loss due to unburned carbon monoxide, and (4) loss due to unburned combustible in the ash and refuse, are measured by test. The total of these four measurable losses, plus an assumed value for unaccounted for losses, are then subtracted from the heat input. The difference multiplied by the burning rate in pounds per hour is the heater output.

When using anthracite as the rating fuel, the unaccounted for loss has been assumed to be zero. It has been accepted practice to use a 20 percent allowance for the unaccounted for losses when burning a bituminous coal. The value of this factor has been under study and, although test work is incomplete, a value of 12 percent of the heat input has been determined as representing the losses due to smoke and unburned hydrocarbons for a surface-fired heater, when burning a high volatile bituminous coal.

No allowance is made for a radiation loss, as this is useful heat.

Design Considerations

Some important considerations in the design of solid-fuel space heaters are:

1. Suitable protection by baffling or insulation against overheating of floors and walls. Although there are no industry-accepted standards by which floor and wall temperatures may be determined, some indication of heater performance, with regard to overheating, may be found by the use of the corner booth test arrangement described in *National Bureau of Standards Commercial Standard* CS 103-43 and *Underwriters Laboratories Standard*, Subject 896, mentioned in following section on Oil Heaters.

2. Tight heater construction to prevent air leakage, and to enable maintenance of a suitably low minimum burning rate. This includes a ground, paper tight joint between the ashpit door and door frame.

3. Sufficient free air space, between the casing and heat exchanger of circulating heaters, to permit free air flow over all surfaces and maintain a suitably low casing temperature.

4. Protection of all metal parts from deterioration due to high temperature. This may be accomplished by: (a) fabrication of certain parts from cast iron or an alloy iron, (b) protection by a refractory liner, (c) use of high temperature enamel coatings, (d) directing air against hot spots.

5. Proper admission of secondary air to complete the combustion process. Care should be taken to prevent this air from also functioning as primary air.

6. Strength in assembly to prevent transportation and use damage.

Considerable work has been directed toward improvement of the performance of bituminous coal-fired space heaters, with particular reference to smokeless operation under conditions of normal operation such as obtained in homes. A smokeless coal heater has been developed by Bituminous Coal Research, Inc., wherein smokeless combustion is obtained by admitting secondary air through a narrow slot, extending from side to side, above the edge of the fuel bed where the gas leaves to enter a vertical gas passage.[4] Complete mixing of the volatile material, released from the coal in the magazine, with the secondary air supplied is obtained as both streams pass under the bottom of the arch. Complete combustion results from this intimate mixing in a region which maintains itself at high temperatures even during banking periods.

OIL HEATERS

Vaporizing pot-type oil heaters consist of: (1) a metal pot in the bottom of which the oil is vaporized, the vapors burning at or near the top of the pot and (2) a secondary combustion chamber, or heat exchanger, in which combustion is completed. The flue connection is made to this chamber or through a second heat exchanger which may be of the diving-flue type installed to increase efficiency. The burner may be designed for operation both with and without mechanical draft.

Blue-flame oil burners differ from the pot-type variety in that removable perforated sleeves are provided above an oil pan instead of a metal pot, and lighting rings or kindlers are used for easy lighting.

Both types of oil burners operate by the burning of the oil vapor rather than the oil itself, the oil being first fed to a chamber in which the oil is entirely vaporized, then mixed with air introduced through suitably located ports and burning at the top of the pot or perforated sleeves. Such heaters are designed to burn No. 1 oil (See Table 4, Chapter 33) or kerosine (coal oil). At no time should oil heavier than that for which the burner is designed be used, as heavier oils may cause excessive carbonization in the burner or fuel feed line.

Materials and Construction

Formed sheet steel and welded assemblies are used primarily in oil heater construction. Standards governing construction which have been generally accepted are:

1. *Commercial Standard for Flue-Connected Oil-Burning Space Heaters Equipped with Vaporizing Pot-Type Burners*, CS101-43 (National Bureau of Standards).

2. *Standard for Oil-burning Stoves*, Subject 896 (Underwriters' Laboratories, Inc.).

3. *Standard for Construction and Performance of Oil Burners for Installation in Stoves and Ranges*, Subject 865 (Underwriters' Laboratories, Inc.).

Some states or municipalities have codes which apply locally, but these usually apply primarily to installation, and the Underwriters' Laboratories label of approval is sufficient to cover acceptance of the unit.

Testing and Rating

Commercial Standard CS101-43 is intended to provide a uniform standard method for ascertaining the maximum practical heat output in Btu per hour of flue-connected oil-burning space heaters under approximately normal service conditions. This method is based upon the following equations:

$$H_r = A - B \qquad (8)$$

and

$$E = H_r/A \qquad (9)$$

where

A = total heat of fuel used.
B = heat lost in flue gases.
H_r = net heat delivered to the room.
E = unit efficiency.

The following minimum performance requirements are stipulated:

1. Adequate provision for ease of lighting and insurance against loss of ignition prior to heating of burner.
2. Ease of operation of controls.
3. Proper operation of burner without excessive carbonization with grades of oil recommended by the manufacturer.
4. The heater shall be capable of passing the 6 percent ICHAM smoke test.
5. The heater shall be capable of operating with an overall efficiency of not less than 70 percent under conditions of test, or at a lower stack draft recommended by the manufacturer.

Design Considerations

Some factors important in the design of oil-burning heaters are:

1. Proper pitch of oil lines from the sump to the burner, thus preventing vapor and air lock.
2. Proper positioning of the oil sump or constant-level valve to maintain the proper oil level in the burners, if factory assembled.
3. Tight construction, not only of oil lines, but of oil tank, sump, and burner to prevent a hazardous condition due to oil leakage.
4. Provision for leveling and aligning the entire heater for maintenance of proper operation. If a separate fuel tank is used, the heater should have provision for secure fastening to the floor to prevent excessive strain on oil supply line, and the consequent danger of leakage of oil.
5. Provision of a draft regulator to prevent abnormal draft fluctuations.
6. Proper shielding of an attached fuel oil supply tank to prevent excessive oil temperatures.
7. All metal parts subjected to the corrosive action of the oil shall be made of noncorrodible metal, or of metal suitably coated to resist corrosion.
8. The heater should have suitable baffling or insulation to prevent overheating of floors and walls.
9. Strength in assembly to prevent transportation and use damage.

GAS HEATERS

Vented gas heaters are defined as those capable of removing 90 percent of the flue gases through a single flue outlet. All heaters having a gas input rating in excess of 50,000 Btu per hour must be of the vented type in order to meet *ASA Approval Requirements for Gas-Fired Room Heaters*.[9]

Space heaters may be classified by burner type as follows:

1. *Injection Burner* type which employs the energy of a jet of gas to inject air for combustion into the burner and mix it with the gas.
2. *Yellow Flame Burner* type in which secondary air only is depended on for the combustion of the gas.

Materials and Construction

Standards covering materials and accessories used in the construction of gas heaters are described in *ASA Approval Requirements for Gas-Fired Room Heaters*[9] and in applicable Listing Requirements.[10]

Efficiency Requirement

Vented space heaters having input ratings in excess of 20,000 Btu per hour are required to have a heating efficiency of not less than 70 percent,[9] based on the total heating value of the gas. Vented space heaters having input ratings of 20,000 Btu per hour or less are required to have a heating efficiency of not less than 65 percent.[9] These efficiencies are based upon the following equation:

$$e_t = 100 - \frac{H_f}{q} \times 100 \qquad (10)$$

where

e_t = heating efficiency, percent.
H_f = heat above room temperature carried away by the flue products, Btu per hour.
q = hourly gas heat input, Btu per hour.

Radiant heaters are required to have a radiant efficiency of not less than 28 percent.

Design Considerations

Some factors important in the design of gas heaters are:

1. Proper design of the burner head, port sizes, and locations so that the flame will not lift, float, or flash back, and be excessively noisy in operation.
2. Proper venting of combustion chamber for relief of forces resulting from ignition of an explosive mixture of gas and air.
3. Protection of valve handles to prevent excessive temperature rise during operation.
4. Insulation and baffling of heater to prevent overheating of walls and floor.

INSTALLATION OF SPACE HEATERS

The two most important considerations involved in the installation of a space heater are safety and chimney draft. The items of chimney details and flue connections which should have special attention are outlined in Chapter 36, Chimneys and Draft Calculations. In all cases, it is recommended that installation be made in accordance with the current *National Building Code*.

CHAPTER 36

CHIMNEYS AND DRAFT CALCULATIONS

Draft Definitions, Theoretical Natural Draft, Factors Affecting Natural Draft, Available Draft, Required Draft; Industrial Chimneys, Available Draft for the Industrial Chimney, Determining Industrial Chimney Sizes; Residential Chimneys, Available Draft for Residential Chimneys, Short Chimneys, Determining Residential Chimney Sizes, Draft Requirements of Appliances, Chimneys for Gas Appliances; Recommendations of the National Board of Fire Underwriters, General Considerations

DRAFT is the pressure difference associated with the movement of flue gases through a flue or chimney. Natural draft is caused and measured by the difference in weight of a column of flue gas within the flue and a corresponding column of air of equal dimension outside the flue. Natural draft is always negative and is expressed in inches of water gage.

When the movement of air is supplied by a fan, the draft is said to be forced or induced. When the fan is located so as to push the flue gases through the flue, the draft is forced. When the fan is located so as to draw the flue gases through the flue, the draft is induced.

THEORETICAL NATURAL DRAFT

Theoretical natural draft is produced solely by the difference in weight of the column of flue gases within the flue and that of a corresponding column of air of equal dimensions outside the flue. In the determination of theoretical natural draft, no allowance is made for friction or other positive or negative effects. Theoretical natural draft is expressed by the following formula:

$$D_t = 2.96\, HB_a \left(\frac{\rho_a}{T_a} - \frac{\rho_s}{T_s} \right) \qquad (1)$$

where

D_t = theoretical draft, inches of water.
H = height of flue or chimney, feet.
B_a = barometric pressure, inches of mercury.
ρ_a = density of air at 0 F and 1 atmosphere pressure, pounds per cubic foot.
ρ_s = density of flue gas at 0 F and 1 atmosphere pressure, pounds per cubic foot.
T_a = temperature of air surrounding the chimney, Fahrenheit absolute.
T_s = temperature of the gases, average or effective, in the chimney, Fahrenheit absolute.

Theoretical natural draft may also be expressed by the following simplified formula in which it is assumed that the densities of the flue gas and of the air are equal at the same temperature and pressure:

$$D_t = \frac{\rho H (T_s - T_a)}{5.2 T_a} \qquad (2)$$

where

ρ = mean density of atmospheric air, pounds per cubic foot.

FACTORS AFFECTING NATURAL DRAFT

As indicated in both Equations 1 and 2, the theoretical natural draft is directly proportional to the height of the flue and is dependent upon the absolute mean temperature of the gases within the flue. It is also directly proportional to the density of the air outside the flue although the effect of this factor is minor.

The formulas for theoretical natural draft are based on mean or average temperature which is one half of the sum of the entering and exit temperature. Since the difference in exit and entering temperatures, or the temperature gradient in the flue, is due to the escape of heat through the walls of the flue and chimney, the heat transfer characteristics of the chimney construction affect draft. Heat transfer is also affected by the rate of flow of the flue gases through the flue so that draft is also affected directly.

The flow of flue gases through the flue is retarded by friction which varies directly with the friction coefficient of the flue surface, and with the rate of flue-gas flow. The friction loss may be estimated by means of one of the formulas for ducts such as the Fanning equation or it may be estimated with sufficient accuracy by the method used for air ducts. (See Chapter 21.)

The height of the flue is measured from the point of entrance of the flue gases to the top of the flue. With no wind to produce an aspirating effect and with no obstruction such as a rain cap at the top of the flue, the column of flue gases may extend upward above the top of the flue for several feet. The effect of this column may be sufficient to overcome the negative or retarding effect of friction and to cause the observed draft to exceed the theoretical draft. This added effect has been measured in some test work. A wind blowing across the top of the flue may also produce an aspirating effect sufficient to overcome the effect of friction and to cause the observed draft to exceed the theoretical. Both of these effects are transient and unreliable and should not be considered in determining the proper design of a chimney.

AVAILABLE DRAFT

The available draft produced by any chimney is equal to the theoretical natural draft minus the friction loss. Given the height, the heat transfer characteristics of the chimney construction, the entering temperature of the flue gases and their volume, and the friction coefficient of the flue and its dimensions, the available draft is readily calculable.

The efficiency of a chimney is defined as the ratio of the observed draft or available draft, produced by the chimney

for a given inlet temperature and flow rate, to the ideal draft that would be observed if the same quantity of flue gases traversed the chimney without cooling and without friction. The chimney efficiency may be calculated as follows:

$$\text{Efficiency} = \frac{\text{final measured draft}}{\text{ideal draft calculated from the inlet temperature}}$$

REQUIRED DRAFT

Before the proper chimney for a particular installation can be selected or designed, the required draft of the combustion unit must be known. The required draft is equal to the sum of all of the resistances to gas flow from the point at which combustion air enters the unit to and including the chimney connection. This is based on the assumption that air for combustion is available without restriction (such as would be caused by tightly enclosed building construction) at that

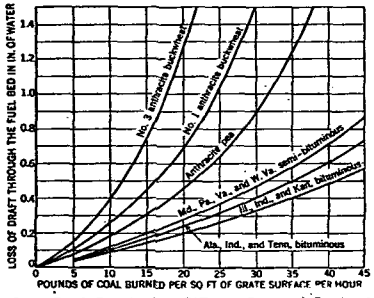

Fig. 1 .... Draft Required at Different Rates of Combustion for Various Kinds of Coal

point of entrance to the unit. Particularly in residences, unrestricted supply of combustion air must be assured.

Fig. 1 presents information on the fuel-bed draft loss for various kinds of coal burned at different rates. Rough generalizations can be given for the losses in the flue passages of boiler or furnace but, on account of the great differences in such devices, more reliable data on their flue-gas volume, temperature, and flue resistance should be obtained for design purposes from their respective manufacturers.

Flue gases encounter resistance to flow in breechings or smoke pipes, and this can probably be treated with sufficient accuracy by means of the method used for air ducts. (See Chapter 21.) The friction in straight ducts can be estimated by means of the last term of Equations 3 and 4.

Also, the temperature of flue gases falls during passage through breechings or flue pipes. For uninsulated surfaces this probably can be adequately estimated by assuming a loss of heat from the flue gas of 3 Btu per (hr) (sq ft) (Fahrenheit deg temperature difference between the gases and surrounding air).

INDUSTRIAL CHIMNEYS

Chimneys can be classified as residential and industrial, the chief difference being their sizes and the types of draft. Chimneys over approximately 1½ ft in diameter are in the industrial chimney class, and their requirements should be treated accordingly. The majority of industrial chimneys operate under induced or forced draft, resorting to natural draft operation only in the case of emergencies. They are built of brick, concrete, or steel, depending upon economy and the type of installation needed. Proper height is of importance because of removal of waste products, inasmuch as the products of combustion are often deflected downward around the chimney and, with the large amount of gases that are exhausted to the atmosphere through the industrial chimney, downwash can be very objectionable.[1]

AVAILABLE DRAFT FOR THE INDUSTRIAL CHIMNEY

The available draft, D_a, *for large chimneys and stacks* has been estimated with apparent satisfaction in the past by means of formulas which in effect deduct an estimated friction loss from a theoretical draft determined as in Equation 1. The friction loss can be estimated by means of one of the formulas available for ducts, such as the Fanning equation. This procedure results in formulas for the available draft as follows:

For a *cylindrical* stack:

$$D_a = 2.96\,HB_a\left(\frac{\rho_a}{T_a} - \frac{\rho_c}{T_c}\right) - \frac{0.00126W^2T_cfL}{d^5B_a\rho_c} \qquad (3)$$

and for a *rectangular* stack:

$$D_a = 2.96\,HB_a\left(\frac{\rho_a}{T_a} - \frac{\rho_c}{T_c}\right) - \frac{0.000388W^2T_cfL(x+y)}{(xy)^2B_a\rho_c} \qquad (4)$$

where

D_a = available draft, inches water gage.
H = height of chimney above inlet, feet.
B_a = existing barometric pressure, inches of mercury.
ρ_a = density of air at 0 F, 1 atmosphere pressure.
ρ_c = density of flue gas at 0 F, 1 atmosphere pressure.
T_a = temperature of atmosphere, Fahrenheit, absolute.
T_c = temperature of flue gas, Fahrenheit, absolute.
W = flue gas flow rate, pounds per second.
f = coefficient of friction.
L = length of friction duct (approximately equal to H), feet.
d = minimum diameter of round chimney, feet.
x and y = length and width of cross-section of rectangular chimney, feet.

The following notes facilitate the use of Equations 3 and 4.

1. The *barometric pressure*, represented by B_a, is the actual pressure at the site of the chimney and not the pressure reduced to sea level datum.

In general, the barometric pressure decreases approximately 0.1 in. Hg per 100 ft increase in elevation.

2. The *unit weight of a cubic foot of chimney gases* at 0 F and sea level barometric pressure is given by the equation:

$$\rho_c = 0.131CO_2 + 0.095O_2 + 0.083N_2 \qquad (5)$$

In this equation CO_2, O_2, and N_2 represent the percentages of the parts by volume of the carbon dioxide, oxygen, and nitrogen content, respectively, of the gas analysis. For ordinary operating conditions, the value of ρ_c may be assumed at 0.09.

The effect on the chimney gas density, of superheated water vapor resulting from moisture and hydrogen in the fuel, or of any air infiltration in the chimney proper, is disregarded. Although water vapor content is not disclosed by Orsat analysis,

its presence tends to reduce the actual weight per cubic foot of chimney gases.

3. The *atmospheric temperature* is the actual observed temperature of the outdoor air at the time the analysis of the operating chimney is made. The mean atmospheric temperature in the temperate zone is approximately 62 F.

4. The *chimney gas temperature* decreases from the breeching connection to the top of the stack. This drop in temperature depends upon the material and construction of the stack, its tightness or freedom from leaks, its area, its height, and the velocity of the gases through it. The same chimney will suffer different temperature losses depending upon the capacity under which it is working, and the variable atmospheric conditions. No general equation covering all these variables has been suggested, but from observations on chimneys varying in diameter from 3 to 16 ft, and in height from 100 to 250 ft, Equation 6 was deduced:[2]

$$T_c = \frac{3.13T_t\left[\left(\frac{H_b}{3}\right)^{0.86} - 1\right]}{H_b - 3} \qquad (6)$$

where

T_t = temperature at the center of the connection from the breeching, Fahrenheit, absolute.
H_b = height of the stack above center line connection to breeching, feet.

5. The *coefficient of friction* between the chimney gases and a sooted surface has been taken by many workers in this field as a constant value of 0.016 for the conditions involved. This value, of course, would be less for a new unlined steel stack than for a brick or brick-lined chimney, but in time the inside surface of all chimneys, regardless of the materials of construction, becomes covered with a layer of soot, and thus the coefficient of friction has been taken the same for all types of chimneys and generally constant for all conditions of operation. For reasons of simplicity and convenience to the reader, this constant value of 0.016 has been employed in the development of the various special equations and charts shown in this chapter.

In important large chimney design, especially when the construction or the materials are unusual, it is recommended that use be made of the Reynolds number[3] in determining the friction factor, f.

The following problem illustrates the use of Equation 3:

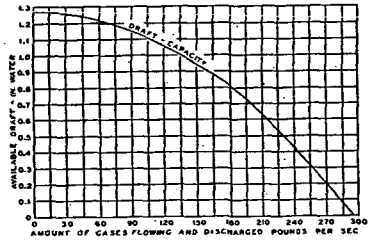
Example 1: Determine the available draft of a natural draft chimney 200 ft in height and 10 ft in diameter, operating under the following conditions: atmospheric temperature, 62 F; chimney gas temperature, 500 F; sea level atmospheric pressure, B_a = 29.92 in. Hg; atmospheric and chimney gas density, 0.0863 and 0.09, respectively; coefficient of friction, 0.016; length of friction duct, 200 ft. The chimney discharges 100 lb of gases per second.

Solution: Substituting these values in Equation 3 and reducing,

$$D_a = 2.96 \times 200 \times 29.92 \times \left(\frac{0.0863}{522} - \frac{0.09}{960}\right) - \frac{0.00126 \times 100^2 \times 960 \times 0.016 \times 200}{10^5 \times 29.92 \times 0.09}$$

$$= 1.27 - 0.14 = 1.13 \text{ in.}$$

Fig. 2 shows the variation in the available draft of a typical 200 ft by 10 ft chimney operating under the general conditions noted in *Example 1*. When the chimney is under static conditions and no gases are flowing, the available draft is equal to 1.27 in. of water, the theoretical intensity. As the amount of gases flowing increases, the available draft decreases until it becomes zero at a gas flow of 297 lb per second, at which point the draft loss, due to friction, is equal to the theoretical intensity. The point of maximum draft and



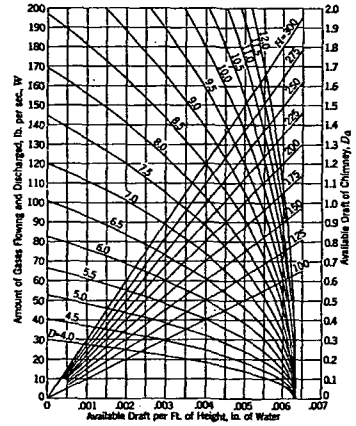


Fig. 2 .... Typical Set of Operating Characteristics of a Natural-Draft Chimney

zero capacity is called shut-off draft, or point of impending delivery, and corresponds to the point of shut-off head of a centrifugal pump. The point of zero draft and maximum capacity is called the wide open point, and corresponds to the wide open point of a centrifugal pump. A set of operating characteristics may be developed for any size chimney operating under any set of conditions by substituting the proper values in Equation 3, and then plotting the results in the manner shown in Fig. 2.

Fig. 3 is a typical chimney performance chart giving the available draft for various gas flow rates and sizes of chimney. This chart is based on an atmospheric temperature of 62 F, a chimney gas temperature of 500 F, a unit chimney gas

To solve a typical example: Proceed horizontally from a Weight Flow Rate point to intersection with diameter line; from this intersection follow vertically to chimney height line; from this intersection follow horizontally to the right to Available Draft scale. Starting from a point of Available Draft, take steps in reverse order.

Fig. 3 .... Chimney Performance Chart

weight of 0.09 lb per cu ft, sea level atmospheric pressure, a coefficient of friction of 0.016, and a friction duct length equal to the height of the chimney above the grate level. These curves may be used for general operating conditions. For specific conditions, a new chart may be prepared from Equation 4.

DETERMINING INDUSTRIAL CHIMNEY SIZES

If the required performance for a proposed chimney is known, and *if a chimney-gas velocity is assumed*, Equation 3 can be transposed to yield the necessary height, and an equation can be developed for the required diameter. These operations result in the following equations:

$$H = \frac{D_r}{2.96B_a\left(\frac{\rho_a}{T_a} - \frac{\rho_c}{T_c}\right) - \frac{0.184 f \rho_c B_a V^2}{T_c d}} \qquad (7)$$

The weight of gas per second, $W = 12.075\ (dVB_a\rho_c/T_c)$

$$d = 0.288\sqrt{\frac{WT_c}{B_a\rho_c V}} \qquad (8)$$

where

H = required height of chimney above inlet, feet.
d = required minimum diameter of chimney, feet.
V = chimney gas velocity, feet per second.
D_r = total required draft, inches of water.

For large chimneys, it is usual to assume that total construction cost is least when the product Hd (height × diameter) is minimum. On this assumption, the product of Equations 7 and 8 can be differentiated, and the differential set equal to zero to find the minimum. Solution for velocity then yields the following equation:

$$V_e = \left(\frac{0.772T_c\left(\frac{\rho_a}{T_a} - \frac{\rho_c}{T_c}\right)\sqrt{\frac{WT_c}{B_a\rho_c}}}{f\rho_c}\right)^{2/5} \qquad (9)$$

where

V_e = economical chimney gas velocity, feet per second.

Equations 7, 8, and 9 can of course be simplified if values are assumed for some of the factors in it. Some typical values for boiler plants are:

Average chimney gas temperature 500 F ..... T_c = 960 F absolute
Average atmospheric temperature 62 F ..... T_a = 522 F absolute
Average coefficient of friction 0.016 ..... f = 0.016
Average chimney gas density, 0 F, 1 atmosphere ..... ρ_c = 0.09 lb per cu ft
Barometer reading, sea level ..... B_a = 29.92 in. Hg

When these values are substituted in Equations 7, 8, and 9, respectively, the results are:

$$H = 190D_r \qquad (10)$$

$$d = 1.5W^{2/5} \qquad (11)$$

$$V_e = 13.7W^{2/5} \qquad (12)$$

These equations should be used for general operating conditions only, or where the required data necessary for an exact determination are difficult or impossible to secure. Whenever it is possible to obtain accurate data, or the anticipated operating conditions are fairly well known, the required size should be determined from Equations 7, 8, and 9.

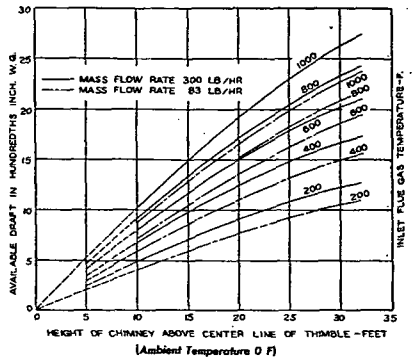

Fig. 4 .... Available Draft for 9″ x 9″ and 9″ x 13″ Masonry Chimneys

Additional construction data for large industrial chimneys, whether brick, concrete, or steel may be found in *Kent's Mechanical Engineers' Handbook*[4] or the *Handbook of Building Construction*.[5]

RESIDENTIAL CHIMNEYS

Since residential heating appliances depend to a large extent on the natural draft of residential chimneys for satisfactory performance, the chimneys must be of adequate height and of optimum cross-sectional area, reasonably gas tight, and as smooth as practicable internally. They must be of such construction as to create no fire hazard to the building. The height and location of a residential chimney are usually limited by architectural and structural considerations, and therefore the draft produced will sometimes be inadequate for satisfactory and efficient operation of the fuel-burning equipment. The basementless house, the one-story ranch or rambler type, and the flat-roofed structure are usually restrictive, particularly with regard to adequate chimney height. The limitations of chimney height should be carefully considered to determine whether or not the type of heating equipment specified will operate properly. If the available draft of the chimney is less than the draft required for the particular heating equipment specified, auxiliary means such as forced or induced draft should be included.

Until recently most chimneys for residences were constructed of masonry. The *National Building Code* of the National Board of Fire Underwriters specifies a minimum of 4 in. of masonry enclosing a fire clay flue liner. Within the past several years, however, the Underwriters' Laboratories have tested and listed as approved *Type A* flues, several chimneys of prefabricated construction. Their advantages, compared with masonry chimneys, are ease of installation, and usually lower cost and a greater degree of safety under abnormal firing conditions. Through the use of insulation or other means to reduce heat transfer through the chimney walls, these *Type A* flues usually operate at a higher mean

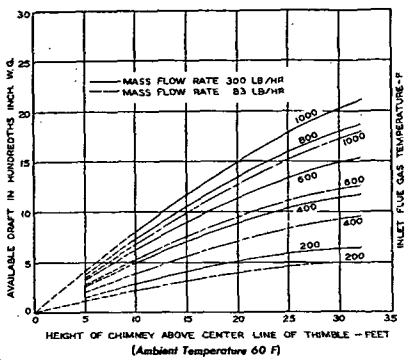

Fig. 5 .... Available Draft for 9″ x 9″ and 9″ x 13″ Masonry Chimneys

temperature for a given entering temperature and therefore produce slightly higher drafts.

AVAILABLE DRAFT FOR THE RESIDENTIAL CHIMNEY

Equations 3 and 4 cannot readily be used for computing the available draft for residential chimneys because of the relatively greater importance of friction losses, cooling of the gases, and soot deposits in small chimneys. Eddy currents and simultaneous flow both upward and downward can occur in a residential chimney for very low flue-gas velocities.

At present, it is best to rely on actual test data for determining the available draft of residential chimneys. Fig. 4 shows the available draft of nominal 9 x 9-in. and 9 x 13-in. masonry chimneys with an ambient temperature of 0 F for a range of effective heights from 5 to 32 ft, a range of entering flue-gas temperatures from 200 to 1000 F, and for mass flow rates of 83 and 300 lb per hr. Fig. 5 shows the same information for an ambient temperature of 60 F. The available drafts produced by 9 x 9-in. and 9 x 13-in. masonry chimneys are equal for practical purposes over the range of mass flow from 83 to 300 lb per hr.[6] In tests of these chimneys the smaller chimney produced slightly greater drafts in the lower end of the range of mass flow rates whereas the larger chimney produced slightly higher drafts in the upper end of the range.

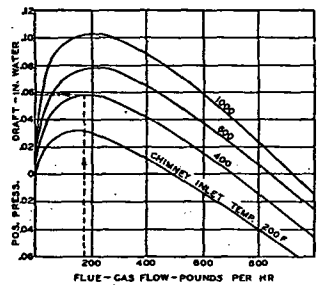
The chimney height for heating plants that operate on an *on-off* or *high-fire low-fire* cycle should be selected to produce the desired draft from Fig. 5 since this class of heating system is required to operate at rated input for short periods when the outdoor temperature is 60 F. Heating plants whose fuel-burning rate is gradually increased as the outdoor temperature decreases are not required to operate at rated input except when outdoor temperatures approach design conditions. For such systems, the chimney height should be selected from Fig. 4 which shows the available draft for an outdoor temperature of 0 F since this is likely to be the more critical condition with respect to chimney draft. The available draft for outdoor temperatures between 0 F and 60 F can be obtained by interpolation from Figs. 4 and 5 with only slight error.

Fig. 6 is a graphical representation of the available draft for a 13-ft brick chimney with a nominal 8 x 8-in. flue liner[7] over a wide range of mass flow rates and for inlet flue-gas temperatures ranging from 200 to 1000 F. This family of curves is a typical group of performance curves showing that there is a certain mass flow rate that produces a maximum available draft for any flue-gas temperature.

The following approximate method may alternately be used to determine the available draft for small residential chimneys, from 10 to 25 ft in height and with internal cross-section areas from 35 to 55 sq in., with a maximum probable error of ±15 percent at the same flow and temperature conditions. This method is based on the chimney efficiencies[8] shown in Fig. 7 and the ideal draft computed from the chimney inlet temperature. The available draft may be expressed as:

$$D_a = \eta_c D_i \qquad (13)$$

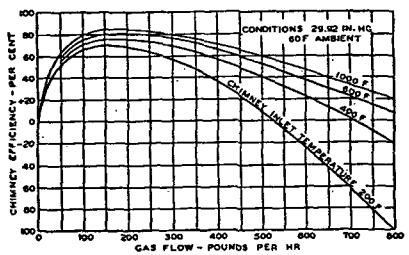
where



η_c = chimney efficiency taken from Fig. 7 at the desired conditions of temperature and flow.
D_i = ideal draft, calculated from Equation 14, assuming that the barometric pressure is 29.92 in. Hg, and the ambient temperature is 60 F.

$$D_i = 0.2554B_aH\left(\frac{1}{T_a} - \frac{1}{T_i}\right) \qquad (14)$$

where



B_a = barometric pressure, inches of mercury.
H = chimney height, feet.
T_i = chimney inlet temperature, Fahrenheit, absolute.
T_a = ambient air temperature, Fahrenheit, absolute.

The clay-lined brick chimney is the most commonly used chimney, but recently other building materials have been used for reasons of economy or convenience. Investigations have established that the results shown in Figs. 4 and 5 for brick

[a] Square Flue Liner 6¾ x 6¾ in. inside.

Fig. 7.... Effect of Gas Flow on Chimney Efficiency[a]

chimneys can be used, with slight error, for chimneys made of shale tile, concrete block, or cinder block.[6]

SHORT CHIMNEYS

The application of heating systems to one-story houses without basements requires special consideration because the chimneys in such houses are often made so low in height for architectural reasons that they produce insufficient draft for some kinds of heating systems. Gas-burning devices do not necessarily require a chimney for proper combustion of the gas, but the chimney must be of adequate size and height to carry the flue gases out of the building since it is undesirable and contrary to American Standards to have the products of combustion discharged in the living space. If a natural-draft oil-burning device is operated with insufficient draft because of a short chimney, smoky combustion usually occurs, pulsations are possible in the combustion chamber, the chimney or smokepipe may become blocked with soot, and the capacity of the heating equipment may be reduced to the point of inadequacy. Insufficient draft is not ordinarily the cause of smoky combustion in coal-burning heaters, but too short a chimney can cause slow pickup of the fire and insufficient heating capacity of the device.

Based on the amount of draft usually required for present-day heating systems at rated output, any chimney with an effective height of less than 15 ft above the center line of the thimble should be regarded as a short chimney. In short chimneys every precaution should be taken to attain the highest possible average temperature in the chimney and the lowest practicable friction loss. Short chimneys of conventional construction are likely to produce from 60 to 90 percent of the ideal draft and, therefore, the draft would only be increased from 10 to 40 percent if all friction and cooling could be eliminated.

The available draft for short chimneys can perhaps be determined most readily by using Equation 13, Fig. 8, and Table 1. Fig. 8 shows the relationship between effective chimney height, inlet flue-gas temperature, and the ideal draft that would be produced for two values of outdoor temperature if there were neither friction nor cooling of the gases as they traversed the chimney. After obtaining the ideal draft for a given chimney height and entering flue-gas temperature from Fig. 8 and selecting the appropriate efficiency value from Table 1, the available draft can be computed from Equation 13. Fig. 8 can be used in reverse in conjunction with

Table 1.... Efficiency of Short Chimneys

A. Masonry Chimneys

Height h ft	Flue Gas Flow Rate lb/hr	Internal Liner Size, in.		
		7 (dia)	7 x 7	7 x 11 and 10 (dia)
		Efficiency, Percent		
5 to 15	90	75–82	65–76	65–80
	200	83–84	67–85	82–88
	315	75–89	67–86	81–89
		(Inlet Flue Gas Temp. 200 to 1000 F)		

B. Uninsulated Metal Chimneys

Height h ft	Flue Gas Flow Rate lb/hr	Internal Diameter, in.	
		6	8
		Efficiency, Percent	
4 to 8	90	90–100	85–95

[b] Internal dia 8-in.; flue gas flow rate 50 to 125 lb/hr; inlet flue gas temp. 200 to 1000 F.

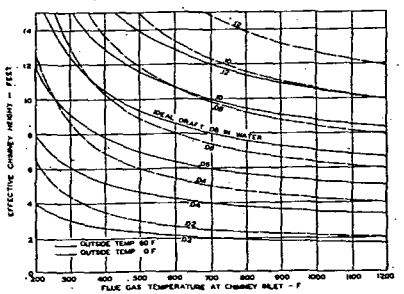

Fig. 8.... Ideal Draft for Short Chimneys at Outside Temperatures of 0 F and 60 F

efficiency values from Table 1 to determine what chimney height is required to produce the required draft at rated output for a given heating appliance.

Fig. 7 shows that the efficiency of a given chimney varies with the mass flow rate of gases and with the entering flue-gas temperature. The efficiency also varies with the height for a given construction and depends somewhat on the method used to connect the smokepipe to the chimney and the amount of exposure to the outdoor air. Experimental data are not sufficiently complete to tabulate efficiencies that take into account all of these variables. However, recommended values of efficiency for several sizes of domestic chimneys of masonry materials and of metal have been selected from the literature[4, 7, 8, 9] and summarized in Table 1 for use with Fig. 8 in determining the available draft produced by short chimneys of 15 ft in height or lower. In parts A and B of Table 1 the value of efficiency chosen from the range cited should be increased as the chimney inlet temperature increases over the applicable range. In part C of Table 1 the efficiency values listed will yield the available draft for the range of mass flows, inlet flue gas temperatures, and chimney height shown within 10 percent.

In the application of short chimneys, observance of the following precautions will assist in obtaining the highest practicable draft and may cure unsatisfactory operation of the chimney and heating plant in certain instances:

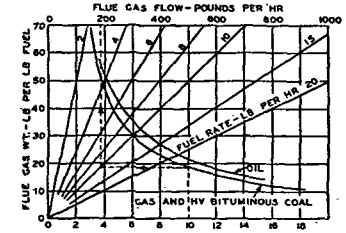
1. Use a minimum length of horizontal smokepipe between the heater and chimney.
2. Insulate the smokepipe and the chimney itself, if made of metal. Insulation of the chimney liner in masonry chimneys reduces the heat loss from the flue gases and the infiltration of cold air.
3. Do not use an oversized chimney because larger chimneys produce greater cooling of the flue gases.
4. Avoid downdrafts by proper construction above the roof or by the use of a suitable chimney cap.
5. Avoid the use of barometric dampers in the smokepipe of natural-draft heaters since most barometric dampers permit enough cold air to leak into the chimney to reduce the draft appreciably.
6. Avoid air leaks in the smokepipe and chimney.
7. Avoid connecting more than one heating device to a single chimney.
8. Use construction materials of low heat capacity if the chimney draft must increase quickly for an intermittently-fired heating device.
9. Do not operate a kitchen exhaust fan unless an air intake of ample area is used to prevent lowering the house pressure.
10. Avoid tight utility closets so the chimney draft will not be required to do the added work of drawing combustion air into the closet from the surroundings.

DETERMINING RESIDENTIAL CHIMNEY SIZES

The flue sizes for small residential chimneys are governed by the *National Building Code* of the National Board of Fire Underwriters for gas-burning appliances. Chimney areas for liquid- and solid-fuel-burning devices are selected primarily to meet the requirements of local building codes, but these requirements are not determined by any rigorous formula based on physical principles.

By calculating the available draft for the chimney in question, and comparing it with the performance values of the heating unit (either natural or forced draft type) at the desired output, it is possible to determine whether the chimney is adequate in height for the particular heating unit it serves.

For calculations where the fuel rate and the percentage CO_2 are the only known factors, the flue gas rate can easily be determined for coal, oil, and gas from Fig. 9. By entering Fig. 9 at the percentage CO_2, moving vertically to the curve for the type of fuel, and then moving horizontally to the fuel rate, the flue gas rate in pounds per hour may be determined for any fuel.[7]



Any of the described methods of determining available draft may be used, but a graphical solution to the problem may be had for the 8 x 8-in. chimney from Figs. 6, 7, and 9. This solution can be best explained by a numerical example.

Example 5: Determine whether a 13-ft, 8 x 8-in. nominal-size flue is sufficient for a coal-heating unit rated at 0.03 in. of water draft at 400 F inlet temperature, fuel rate being 10 lb per hr of bituminous coal, with 10 percent CO_2.

Solution: From Fig. 9, a flue gas rate of approximately 180 lb per hr is obtained. The available draft for a 180 lb per hr fuel rate, and an inlet temperature of 400 F, obtained from Fig. 6, is 0.056 in. of water. This indicates that the chimney is adequate.

The selection of chimney areas for liquid- and solid-fuel-burning devices is difficult because of the variability in efficiency of different models, the possibility that soot on the lining will restrict the chimney area, and the variation in combustion air requirements of different solid fuels. Figs. 6 and 7 show that a given chimney produces a maximum available draft and a maximum efficiency for some intermediate mass flow rate for any selected inlet flue gas temperature. For mass flow rates lower than the optimum the greater cooling of the gases in the chimney causes lower available draft, whereas for mass flow rates above the optimum the greater friction losses reduce the available draft. A chimney for a given heating system should probably be designed to operate at its point of maximum efficiency and maximum available draft for its full rated output. A chimney would have an accelerating effect[10] on the combustion rate of a solid-fuel burning device if it were operating to the left of the optimum point in Fig. 6 because an additional increment in mass flow rate would increase the available draft a small amount and tend to increase the mass flow still more. On the other hand, a chimney operating to the right of the optimum point in Fig. 6 would tend to decelerate the combustion rate for any small increase in mass flow rate.

Data are not complete for the selection of proper chimney areas for heating plants of different capacities, but some information on the effect of cross-section area on the capacity of masonry chimneys is provided by tests[8, 11] on several chimneys with liners having nominal outside dimensions: 9-in.

[a] Average density gas 0.0845 lb per cu ft, 62 F. Average weight oil 7.08 lb per gal, 60 F.

Fig. 9.... Graphical Evaluation of Rate of Flue Gas Flow from Percent CO_2 and Fuel Rate[a]

Table 2 .... Approximate Flue Gas Flow Rates for Maximum Available Draft in Masonry Chimneys

Nominal External Liner Dimensions, In.	Internal Area of Liner Sq. In.	Flue Gas Temperature at Chimney Inlet, F: Mass Flow Rate, Lb/Hr — 200	600	1000	Flue Gas Velocity at Chimney Inlet, Fpm — 200	600	1000
9 (dia)	38.5	170	150	130	175	250	300
9 x 9	49	215	306	334	175	400	600
12 (dia)	78.5	290	Above 320	Above 320	150	—	—
9 x 13	77	295	Above 320	Above 320	150	—	—

diameter, 12-in. diameter, 9 x 9-in., and 9 x 13-in. These tests showed that for flue gas rates up to 200 lb per hr, and entering flue gas temperatures from 200 to 1000 F, the 9-in. round liner provided an available draft equal to, or greater than, that produced by the other three larger liners. When the flue gas rate was increased to 320 lb per hr, the three larger liners produced a little more draft than the smallest one for entering flue gas temperatures above 600 F. Other data[8] show that metal chimneys with an internal diameter of 6 in. should not be used for mass flow rates greater than 130 lb per hr.

Table 2 shows approximate values of the mass flow rates and flue-gas velocities at the chimney inlet that produce the maximum available draft for masonry chimneys[8] of several conventional sizes and with an effective height of 15 ft. This table shows that a 9-in. round chimney is best suited to mass flow rates from 130 to 170 lb per hr, a 9 x 9-in. chimney performs best for flow rates from about 200 to 300 lb per hr, and 9 x 13-in. and 12-in. round chimneys are best suited to flow rates above 300 lb per hr. These results were obtained with clean chimneys, so that conclusions about chimney areas require some modification if soot deposits are taken into consideration.

Soot deposits in chimneys reduce the effective area of the liner and may in some cases entirely close the passage. Soot deposits are likely to be greater in the horizontal passages in the heating plant, the breeching, and the smokepipe, than in the vertical chimney liner. An increase in the liner diameter of one inch above that required for a clean chimney will probably make adequate allowance for soot deposits in all but the worst cases. Where smoky combustion is likely to occur and the mass flow rates on a clean chimney basis approach those listed in Table 2, the next larger commercial size liner should be used. Smoky combustion with oil-burning devices, particularly with vaporizing oil burners, is likely to be caused by inadequate draft which is often due to insufficient chimney height. For coal, inadequate chimney height or chimney area may be a contributing cause, but smoky combustion with coal is related to fuel characteristics and firing methods. Therefore, an increase in chimney area will usually not cure smoky combustion of a coal-burning device, but can be expected to lengthen the interval between cleanings.

New standard sizes of clay flue linings were recently developed by the industry and approved by the American Standards Association, in order to effect economies that can be derived from coordination of the dimensions of building materials. These linings are known as modular clay flue linings, and the dimensions and tolerances are summarized in *ASA Standard* A62.4-47. As the effective areas of these liners are somewhat smaller than those of the corresponding linings used previously, they cannot be used in certain municipalities where building codes specify minimum areas based on the older dimensions.

DRAFT REQUIREMENTS OF APPLIANCES

Typical flue-gas temperatures and drafts required at rated output for several kinds of domestic heating appliances[28] are contained in Table 3. Chimney height and chimney area for cast-iron boilers are specified in the *I = B = R Testing and Rating Code* of the Institute of Boiler and Radiator Manufacturers.

Mechanically-fired devices such as oil burners and stokers are equipped with blowers, and therefore, the chimney is not required to overcome the resistance of the fuel bed or burner. Nevertheless, a draft in the firebox, of about 0.03 in. of water, is desirable so that leakage, if any, will be into the firebox rather than outward from it.

Insufficient draft for natural-draft appliances is likely with installations in attics or in one-story basementless houses. Automatic oil-burning space heaters, floor furnaces, and warm air furnaces employing natural-draft vaporizing burners require a draft of 0.06 to 0.08 in. water for outdoor temperatures of 60 F. Coal-burning heaters and furnaces which attain design rating at 0 F outdoor temperature would require about the same draft. For such requirements, data from Figure 8 and Table 1 show that an effective chimney height, above chimney inlet, should be a minimum of 8 to 12 ft. Because temperature drop and friction loss in the flue pipe cannot be calculated accurately,[7] and the resistance of various chimney connections is uncertain, the minimum calculated heights should have a generous factor of safety applied to allow for these and other uncertainties. Where ample height cannot be provided, forced or induced draft should be provided. Extreme care should be used in the application of forced draft to avoid producing a pressure in combustion

Table 3 .... Drafts Required by Typical Residential Heating Devices or Appliances

Device	Draft, In. Water	Stack Temperature[a] F
Space Heater, Oil-Burning, Pot Burner	0.06 to 0.08	1000
Warm Air Furnace, Oil-Burning, Pot Burner	0.06	860
Warm Air Furnace, Hand-Fired	0.06[b]	900
Floor Furnace, Oil-Burning, Pot Burner	0.06	860
Mechanical Oil Burner, Less than 5 gph	0.03[a]	—
Mechanical Oil Burner, More than 5 gph	0.05[a] or less	—
Cooking Stove, Solid-Fuel	0.04[b]	400
Space Heater, Coal-Burning	0.06[b]	900

[a] 18 in. from heater.

chambers, because they are not usually designed to prevent the outward leakage of toxic gases which might result.

Induced draft by means of motor-driven fans or blowers will solve low-draft problems, but would usually be employed for residential systems only as a last resort. Operation of a blower entails some cost, introduces maintenance requirements, and may be dangerous in event of power failure unless suitable protective devices are used. Induced draft fans designed to resist effects of high temperature and corrosion are available. Fans not carefully designed or modified to meet these conditions should not be applied to this service.

CHIMNEYS FOR GAS APPLIANCES

The Approval Requirements of the American Gas Association are such that a gas-fired appliance must be able to operate at its rated input (plus 10 or 15 percent) without a chimney connection, and without producing carbon monoxide. The primary functions of the chimney for the gas-fired appliance are to remove the products of combustion from the living space and to assure safety to the building. The chimney therefore becomes essentially a vent and, in fact, the vents tested and listed by Underwriters' Laboratories for use only with gas appliances were for some time designated as *Type B* Gas Appliance Vents. Their use is limited to appliances approved by the American Gas Association and operating with flue-gas temperatures not in excess of 550 F at the outlet of the draft hood. A draft hood is always required in connection with a *Type B* flue. The *Type B-W* gas flue is further limited to the venting of wall heaters having an input of not more than 50,000 Btu per hr.

Because of the low temperatures to which gas flues are limited care should be taken to ascertain that the appliance

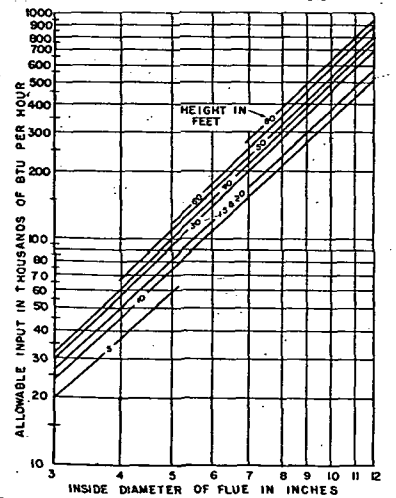

Fig. 10 .... Capacity in Btu per Hour for Gas Appliance Flues or Vents

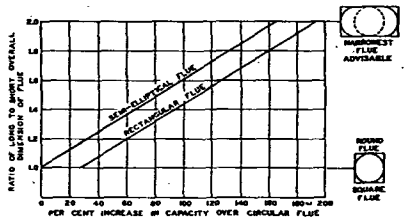

Fig. 11 .... Capacity of a Rectangular Flue or a Semi-Elliptical Flue, with Semi-Circular Ends Having Its Minimum Width Equal to the Diameter of a Circular Flue, Compared with the Capacity of the Circular Flue

is not convertible to fuels other than gas and that the appliance is approved by the American Gas Association. It is well also to be certain that gas fuel will continue to be available to the building.

Chimneys for venting appliances designed for burning gas, can therefore be low in height, but must have adequate area. The height is usually established by the building height. Chimney sizes are usually selected on the basis of heat input of the appliance. The minimum flue or vent sizes adopted by the American Standards Association and the National Board of Fire Underwriters in 1950 for gas appliances[29] are shown in Fig. 10.

Additional provisions of *ASA Standard* 221.30-1950 relating to chimney size are:

1. In no case shall the vent area be less than the area of a 3-in. diameter pipe.
2. When more than one appliance vents into a flue or vent, the flue or vent area shall be not less than the area of the largest flue or vent connector plus 50 percent of the areas of the additional flue or vent connectors.
3. Any-shaped flue or vent may be used provided its flue gas venting capacity is equal to the capacity of the round pipe for which it is substituted.

Since Fig. 10 has been prepared for circular flues, relative capacities for rectangular and semi-elliptical flues[14] are shown in Fig. 11.

Heating appliances designed to burn gas, as well as appliances converted to gas burning, except those equipped with power-type burners and excepting conversion burner installations in excess of 400,000 Btu per hour input in large steel boilers, are always equipped with a draft hood attached to the flue outlet of the appliance. This draft hood is required if the appliance is to meet the approval requirements of the American Gas Association and the American Standards Association, and is essential for safe operation. It is designed to prevent excessive chimney draft which would lower appliance efficiency, to prevent a blocked flue or a downdraft in the chimney from impairing combustion, to provide a relief opening for the products of combustion during downdraft or blocked-flue conditions, and to prevent spillage of the products of combustion to the space surrounding the appliance, if there is a chimney draft equivalent to that provided by a 3-ft chimney. As the draft hood is designed without moving parts, the relief opening is always open, and consequently some air is drawn into the chimney. This air lowers

the gas temperature in the chimney, but it also lowers the dew point of the gases and tends to prevent condensation.

The installation of conversion burner equipment in large boilers is usually made in accordance with regulations of the local gas company. In such installations a definite chimney draft may be required for proper combustion, and consequently the foregoing reference to the use of draft hoods would not apply.

The products of complete combustion of gas are water vapor and carbon dioxide. In the case of manufactured gas, the presence of organic sulfur compounds, generally between 3 and 15 grains per hundred cubic feet, gives rise to minute percentages of sulfur dioxide and sulfur trioxide. The volume of water vapor in the flue products from natural or coke oven gas is about twice the volume of carbon dioxide. It is extremely important that the chimney be tight and resistant to corrosion, not only from moisture, but also from dilute sulfur trioxide.

Clay linings with joints which prevent retention of moisture, and linings made of noncorrosive materials, are advantageous. The interior protection of unlined chimneys by applying an asphalt-chromate emulsion has been investigated by some gas companies but the material is not of current interest because insurance companies do not favor potentially combustible coatings.[14]

Table 4 .... Results of Field Survey on Chimney Damage

Type of Construction	Number of Chimneys	Number Reported Damaged	Percent Damaged
Chimneys without liners	4720	562	11.9
Chimneys with sewer tile construction	8410	104	1.2
Wilder metal coated with asphalt chromate emulsion	5185	291	5.6
Steel coated with plastic	9200	1928	21.0
Vitreous enamel on steel	614	No record	—
Aluminum	50,000	228	0.45

An investigation of damage occurring in 78,129 chimneys used for venting gas appliances in a severe climate has been made by the Minneapolis Gas Company with the results shown in Table 4 taken from Reference 15.

Advice regarding recommended practice and materials for flue connections and chimney linings can usually be obtained from the local gas company, and should be given careful consideration.

RECOMMENDATIONS OF THE NATIONAL BOARD OF FIRE UNDERWRITERS

For general data on the construction of chimneys, reference should be made to the *National Building Code*, recommended by the National Board of Fire Underwriters, Article X, Section 1001 to 1006, in which the following are some of the important provisions listed in the 1951 edition:

1. *Flue Connections Required.* Every heating apparatus or heat producing appliance requiring a flue connection shall be connected with a flue conforming to the provisions of this article. This shall not include electric appliances; gas appliances, except as specifically required in this article; or oil fired appliances especially designed for use without flue connection.

2. *Use of Nonconforming Flues.* Flues not conforming to the requirements of this article for chimneys, metal smokestacks or vents for gas appliances, shall not be used unless listed by Underwriters' Laboratories, Inc., installed in full compliance with the listing and the manufacturer's instructions, and approved for such use by the building official.

3. *Smoke Pipe Connections.*

a. No flue shall have smoke pipe connections in more than one story of a building, unless provision is made for effectively closing smoke pipe openings with devices made of noncombustible materials whenever their use is discontinued temporarily, and completely closing them with masonry when discontinued permanently.

b. Two or more smoke pipes shall not be joined for a single connection, unless the smoke pipes and flue are of sufficient size to serve all the appliances thus connected.

c. The smoke pipe of a heating appliance shall not be connected into the flue of an incinerator which has the rubbish chute identical with the smoke flue.

4. *Construction of Chimneys.*

a. Chimneys hereafter erected within or attached to a structure shall be constructed in compliance with the provisions of this section.

b. Chimneys shall extend at least 3 ft above the highest point where they pass through the roof of the building, and at least 2 ft higher than any ridge within 10 ft of such chimney.

c. Chimneys shall be wholly supported on masonry or self-supporting fireproof construction.

d. No chimney shall be corbeled from a wall more than 6 in.; nor shall a chimney be corbeled from a wall which is less than 12 in. in thickness, unless it projects equally on each side of the wall; provided that in the second story of 2-story dwellings corbeling of chimneys on the exterior of the enclosing walls may equal the wall thickness. In every case the corbeling shall not exceed 1 in. projection for each course of brick projected.

e. No change in the size or shape of a chimney, where the chimney passes through the roof, shall be made within a distance of 6 in. above or below the roof joists or rafters.

5. *Chimneys for Heating Appliances, Low Heat Industrial Appliances and Portable Type Incinerators.*

a. Chimneys for stoves, cooking ranges, warm air, hot water and low pressure steam heating furnaces, fireplaces, and low heat industrial appliances, other than chimneys for incinerators of nonportable type, shall be constructed of solid masonry units or of reinforced concrete. The walls shall be properly bonded or tied with corrosion-resistant metal anchors. In dwellings and buildings of like heating requirements, the thickness of the chimney shall be not less than 4 in. In other buildings the thickness shall be not less than 8 in., except that rubble stone masonry shall be not less than 12 in. thick.

b. Every such chimney hereafter erected or altered shall be lined with a flue lining conforming to the requirements below.

c. Flue linings shall be made of fire clay or other refractory clay which will withstand the action of flue gases and resist, without softening or cracking, the temperatures to which they will be subjected, but not less than 2000 F. Flue linings may be of cast iron of approved quality, form and construction.

d. Required clay flue linings shall be not less than ⅝ in. thick for the smaller flues, and shall increase in thickness for the larger flues.

e. Flue linings shall be installed ahead of the construction of the chimney as it is carried up, carefully bedded one on the other in Type A, Type B, or fire clay mortar with close fitting joints left smooth on the inside.

f. Flue linings shall start from a point not less than 8 in. below the intake, or, in the case of fireplaces, from the throat of the fireplace. They shall extend, as nearly vertically as possible, for the entire height of the chimney, and be extended 4 in. above the top of cap of the chimney.

g. Cleanouts for flues or fireplaces shall be equipped with cast-iron doors and frames arranged to remain tightly closed when not in use.

h. When two or more flues are contained in the same chimney, at least every third flue shall be separated by masonry at least 4 in. thick bonded into the masonry wall of the chimney. Where flue linings are not so separated, the joints of adjacent flue linings shall be staggered at least 7 in.

6. *Sizes of Flues.*

a. The cross-sectional area of smoke flues shall be designed and proportioned to meet the conditions of temperature, within and without flue, thickness of masonry, exposure, shape and material of flue, and other influences.

The *National Building Code* specifies lined chimneys and metal smoke stacks for all gas appliances which may be converted readily to the use of solid or liquid fuel, and also for all boilers and furnaces, except those having a flue-gas temperature not exceeding 550 F at the outlet of the draft hood when burning gas at the manufacturer's rating and which may, therefore, be connected to *Type B* vent piping. Approved *Type B* vent piping is noncombustible, corrosion-resistant piping of adequate strength and heat-insulating value, and having bell and spigot or other acceptable joints. Fig. 10 may be used for selection of vent-pipe size.

Important points to be considered in the use of *Type B* vent piping are:

1. *Type B flues* must be plainly and permanently marked at the point where the vent connection enters the flue: *For Use on Gas Appliances Only.*

2. *Type B* gas vents shall be installed with a clearance to combustible material or construction, whether plastered or unplastered, of not less than one inch, provided that for vents of floor furnaces, such clearance shall be not less than 3 ft from the outlet of the draft hood, measured along the center line of the vent piping.

Other important points that should be considered for flues and vents for gas appliances are as follows:

1. Clearances from combustible material to gas appliance vent piping other than approved *Type B* gas vents shall be in accordance with the *Building Code Standards* of the National Board of Fire Underwriters for the Installation of Heat Producing Appliances, Heating, Ventilating, Air-Conditioning, Blower, and Exhaust Systems.

2. Every flue-connected appliance, except an incinerator, unless its construction serves the same purpose, shall be equipped with an effective draft hood which either (*a*) has been approved as part of the appliance or (*b*) complies with nationally recognized standards for draft hoods. The draft hood shall be attached to the flue collar of the appliance as conditions permit, and in a position for which it is designed with reference to horizontal and vertical planes. The draft hood shall be so located that the relief opening is not obstructed by any part of the appliance or adjacent construction.

3. No vent pipe from a gas appliance shall be interconnected with any other vent pipe, smoke pipe, or flue, unless such gas appliance is equipped with an automatic device to prevent the escape of unburned gas at the main burner or burners. Where a gas appliance vent pipe is joined with a smoke pipe from an appliance burning some other type of fuel, for connection into a single flue opening, they shall be joined by a Y fitting located as close as practicable to the chimney. With liquefied petroleum gases, the automatic device to prevent the escape of unburned gas shall shut off the pilot light, as well as the main burner or burners.

Recent tests of masonry chimneys[16] made of a variety of materials have developed additional recommendations regarding the construction of masonry chimneys that will decrease the hazard to surrounding combustible materials.

GENERAL CONSIDERATIONS FOR CHIMNEYS

The draft of domestic chimneys may be subject to a variety of influences not usually encountered in power chimneys[17] because of the low available draft often supplied by a short chimney. Horizontal winds have an aspirating effect as they cross the chimney and are an aid to draft. However, surrounding objects, such as trees or other buildings, may affect the direction of the wind at the chimney top, and may even direct it down the chimney, tending to reduce the draft or even to cause it to change to a positive pressure.

It is not to be assumed that increasing the cross-sectional area of a chimney will always effect a cure for poor draft. The opposite result may occur because of the cooling effect of the larger area, and the effect of recirculation of the flue gases. The flow of gases into the chimney top has been observed at low rates, and recirculation in small residential chimneys has been noted throughout the entire length of a chimney and smoke pipe, with the greater amount of recirculation occurring at the thimble. The effect of recirculation decreases with chimney height and the increase in flue-gas velocity.

It is also important to consider the course of the air supply for proper combustion. The boiler or furnace is usually located in the basement. In the majority of cases, the furnace room has windows and doors opening to the outdoors on two or more sides of the house. Usually enough air leaks into the furnace room through these openings to sustain combustion. In some cases, however, windows and doors are so tight as to restrict the flow of combustion air, and thereby affect the correct operation of the chimney. If the boiler room is fairly tight and is open to the outdoors on only one side of the house, the draft will be affected in windy weather even with windows or doors open. If the wind is blowing toward the boiler room, the draft will be increased, but if blowing in the opposite direction, the draft may be decreased.

The surrounding of a heating appliance with a restrictive enclosure that will limit entrance of combustion air is more likely to occur in a small utility closet installation on the first floor than in a basement installation. An opening with a free area approximately twice the area of the smokepipe should therefore, be provided between the utility closet and the living space or the outdoors. If the utility closet is connected to the outdoors, greater difficulty with wind pressures will be encountered. Where a draft regulator is used it should have ample communication with the same space from which the combustion air is taken. Where forced warm air furnaces are enclosed in utility closets, care should be used to make the return air connection inside the utility closet airtight so that the blower cannot reduce the pressure in the closet and cause a downdraft in the chimney.

Two or more chimneys, either large or small, should never be connected. If connected at the bottom, hot gases in the U-tube thus formed would be in unstable equilibrium. Cold air from the top would descend through one such chimney and drive the hot gases out of the other, thus annulling the draft.

More than one device can be served by one chimney. Batteries of boilers are commonly connected to a single chimney in power plants. However, if two or more chimneys are used, each chimney should be used separately for part of the boilers, and not connected in manifold with another chimney, in order to avoid the difficulty described previously.

In domestic installations it is sometimes necessary to serve a space heater or cooking stove and a water heater with the same chimney flue. This is not desirable, especially for low chimneys, since doors left open on one device, while it is unfired, will tend to annul the draft on another device. Gas-burning devices, with their draft hoods and lack of draft dampers, are especially bad in this respect. The traditional method of avoiding this with brick chimneys has been to construct multiple-flue chimneys, so that each fuel-burning device could be served by a separate opening. If two devices must be served by one flue-opening in a chimney, their connections to the chimney should not be located opposite each

other. The connection from the larger device should be reasonably low, and that from the smaller should be up near the ceiling, so that each device can be serviced as well as possible, regardless of the treatment of the other.

Even where such precautions are taken, there is, under unusual conditions, some possibility of flow of combustible gases from one appliance into another. Reverse flow of cooled gases has been demonstrated in a chimney at very low rates of flow.[7] Under certain similar quiescent conditions, accidental discharge of combustible gases from a defective device into a chimney could result in flow of these gases counter current into the combustion chamber of another device attached to the same chimney. If ignition occurred in this second device, an explosion could result.

Excessive height in a chimney does no harm, but means for controlling the draft are more than ordinarily essential if the chimney is too tall. Coal-burning devices often have air leaks around the firebox, and the draft doors sometimes fit so poorly that the fire cannot be controlled at a low rate. The simplest remedy for such cases is the barometric damper which admits air into the flue pipe and thus reduces draft.

Where a chimney serves a fireplace, it is important that no other heating device be connected to it unless the fireplace is effectively sealed.

CHAPTER 37

ESTIMATING FUEL CONSUMPTION FOR SPACE HEATING

Bases of Fuel Estimates; Efficiency of Utilization; Calculated Heat Loss Method: Computation and Application, Short Methods for Estimating Heat Loss; Degree-Day Method: Computation and Application, Unit Fuel Consumption per Degree Day, Estimating Consumption for Various Fuels, Degree Day as an Operating Unit; Industrial Degree Days; Maximum Demand and Load Factors

IT IS often necessary to estimate the anticipated heat requirements and fuel consumptions of heating plants for either short or long terms of operation. These quantities can be much more difficult to calculate than design heat loss or required system capacity, since they involve essentially the summing up of the net result over the period in question of the influence of many factors which may vary greatly with time. It will seldom be possible to predict with any great accuracy the way in which all the factors involved will vary throughout the prediction period. In addition to this, the calculations required to take all such variations into account become very involved. For these and other reasons records of past operating experience, when these are available, provide the most reliable and usually the most accurate basis for the prediction of future requirements.

Records of past heat requirements or of fuel consumption of a particular building are a better basis for estimates than are averages of records from similar buildings. In the absence of past records for a particular building the data from similar plants in the same locality may have to be used. Averages of consumption figures taken from many types of plants in many types of buildings in various localities can only produce an average estimate which may prove to be inaccurate when applied to a particular building.

Where unusual operating conditions exist due to factors such as excessive ventilation, abnormal inside temperatures, and heat gains from external sources, or where, in the case of proposed buildings of unusual design, no information is available regarding former consumption, it is necessary to estimate fuel consumption from the computed heat losses.

In preparing fuel consumption estimates it is well to realize that any estimating method used will produce a more reliable result over a long period operation than over a short period. Nearly all of the methods in common use will give trustworthy results over a full *annual* heating season, and in some cases such estimates will prove consistent within themselves for monthly periods. As the period of the estimate is shortened, there is more chance that some factor not taken into account directly in the estimating method will deviate from its long-time average value, and thus lead to serious error in the predicted heat requirement.

EFFICIENCY OF UTILIZATION

Any method of estimating fuel requirements based primarily on calculation of heat losses must, of necessity, also take into account considerations of the efficiency with which the heat in the fuel is used. Efficiency can be defined in a variety of ways for various purposes, and the values in any given case can vary widely depending on the conditions. For estimating purposes, as will be shown later, it is the *efficiency of utilization* of the fuel over the calculation period which is wanted. This is distinct from *furnace efficiency* which expresses the heat delivered by a furnace unit as a percentage of the heat provided in the fuel and which is the efficiency normally used in describing the performance of a unit under rated, or stated, load conditions. It has been shown, at the University of Illinois for example,[1] that in the case of a dwelling with an inside chimney, as much as 35 percent of the heat delivered to the chimney which is normally considered to be a loss so far as efficiency of the furnace is concerned may be delivered to the house through the heated chimney walls. This recovered heat amounted to as much as 12 percent of the heat required by a house. Much of this recovered heat may be available for heating. It has been said in connection with the same study that at times only about 50 percent of the heat utilized by a house was supplied by radiators, while the other 50 percent of the heat utilized was supplied from such sources as chimney, piping, boiler jacket and smoke pipe, people, lights, etc. A summary[2, 3] of many tests in two research residences at the University of Illinois using many fuels and systems give values of 67 to 90 percent for overall house efficiency (the ratio of the heat loss from the structure to the heat input to the unit for an average day).

The efficiency of utilization of the fuel burned can at times be relatively very high for houses. It can also vary quite widely from one house to another because of variations in chimney location and design, in the utilization of heat lost to the basement from the heating unit and smoke pipe, and for other reasons. The efficiency of utilization may also vary with time of year as the average load on the furnace varies. Some of the reasons for this in the case of intermittently-fired oil furnaces have been demonstrated.[4]

In buildings other than houses the efficiency of utilization of the heat supplied in the fuel may also vary widely. There will, in general, be less tendency in many larger buildings toward effective use for heating purposes of the heat which is normally lost from chimney, furnace, and piping surfaces, and efficiency is seldom likely to be as high as in the case of many houses.

The average fuel consumption of various types of approved gas-fired equipment has been obtained from a large number of heating systems.[5] Corresponding efficiencies of

utilization over the heating season can be calculated from these data. They show a variation from approximately 72 to 88 percent depending upon the type and size of system. Laboratory tests on a gas conversion burner in a heating boiler operated with *on* and *off* cycles gave about 72 percent efficiency.[4] Other tests on coal-fired room heaters indicated, for the heating season, efficiencies of 65 to 75 percent, when the heat from the flue pipe was included.[7] A survey of 30 residences in one locality showed a variation of 45 to 75 percent in utilization efficiency, depending upon the condition of the equipment and the fuel used.[8]

Experience at the University of Illinois was used in establishing overall efficiencies for a tabulation of the comparative costs of heating the same building with various fuels to be found in a publication of the Small Homes Council.[9]

The efficiencies of utilization over the heating season shown in Table 1 are suggested as a guide. Considerable judgment may have to be exercised in selection of appropriate values for any given case of fuel consumption calculations.

Table 1 . . . . Efficiency of Utilization Over the Heating Season

Type of Fuel-Burning Unit	Efficiency, Percent
Gas, designed unit	75–80
Gas, conversion unit	60–80
Oil, designed unit	65–80
Oil, conversion unit	60–80
Bituminous coal, hand-fired with controls	50–65
Bituminous coal, hand-fired without controls	40–60
Bituminous coal, stoker-fired	50–70
Anthracite, hand-fired with controls	60–80
Anthracite, hand-fired without controls	50–65
Anthracite, stoker-fired	60–80
Coke, hand-fired with controls	60–80
Coke, hand-fired without controls	50–65
Direct electric heating	100

CALCULATED HEAT LOSS METHOD

The quantity of fuel or energy required for heating may be found by the Calculated Heat Loss Method from the equation

$$F = \frac{XN}{EC} \tag{1}$$

where

F = quantity of fuel or energy required (in the units in which C is expressed).
X = average heat requirement for the period under consideration, Btu per hour.
N = number of heating hours in estimate period (for an Oct. 1–May 1 heating season, 212 days × 24 hr = 5088).
E = efficiency of utilization of the fuel over the period, expressed as a decimal; not the efficiency at peak or rated load condition.
C = heating value of one unit of fuel or energy.

The value of X is usually found from the equation

$$X = \frac{H(t - t_o)}{t_i - t_o} \tag{2}$$

where

H = calculated heat loss including infiltration loss, Btu per hour, based on t_o and t_i.
t = average inside temperature maintained during heating period, Fahrenheit.
t_o = average outside temperature through estimate period, Fahrenheit (for U. S. cities with an Oct. 1–May 1 heating season—see Table 2).
t_i = *indoor design* temperature, Fahrenheit (usually 70 F).
t_o = outdoor design temperature, Fahrenheit (see Table 2).

so that the value of F becomes

$$F = \frac{H(t - t_o)N}{E(t_i - t_o)C} \tag{3}$$

The calculation of X, the average heat requirement, Btu per hour, over the period under consideration is given only approximately by Equation 2, when the value of H used is the calculated maximum load, or design heating load for the building, as computed by the methods outlined in Chapters 9, 11, and 12. This value is commonly used since it is usually available from the heating system design calculations. This procedure will usually lead to values of X which are too high. In the first place, the design wind speed on which such calculations are based is usually higher than the average wind speed for the period so that infiltration losses may be overestimated. In addition there will usually be many sources of heat not taken into account in the estimation of maximum heat demand which may actually contribute to the heating and thus may decrease the fuel or energy required for heating without necessarily affecting the maximum heat demand. The more important sources are solar radiation, people, lights, and equipment.

Improved estimates of fuel requirements will result if H can be recalculated so as to be more representative of *average* conditions over the heating period rather than the *maximum* conditions used in maximum heating load estimation. Further improvement may be obtained at the expense of more involved calculations by making estimates of the average heat gains, and deducting these from the calculated heat losses. There is a practical limit to the refinement in calculations which should be attempted since there will always be some factors which are only approximately known. The weather, for example, very largely determines the heat losses, but will normally be described only approximately in terms of average values of a limited number of weather elements. Wind speed, and sunshine will not necessarily be distributed uniformly over periods of different outdoor temperatures. In addition there is a limit to the accuracy of prediction of the weather elements over the period of interest which is always in the future. For these and other reasons, including such unpredictable factors as the way in which windows and doors will be opened and closed, the determination of H or of X must always be in the nature of an estimate only.

Values of the average outdoor temperature, t_o, are required for the calculation of X by means of Equation 2. Such values for the period October 1 to May 1 are given for U. S. cities in Table 2. The assumption of an Oct. 1–May 1 heating season is reasonably accurate in the well-populated New York-Chicago zone but heating may be required over a longer period for points as far north as Minneapolis, and over a shorter period south of Washington, D. C. Consequently values taken from Table 2 may have to be adjusted

[a] Data for United States cities from a publication of the United States Weather Bureau, *Monthly Normal Temperatures, Precipitation and Degree Days*, 1954, are for the period 1921 to 1950 inclusive. Those United States cities for which years are given in Column 3 are not listed in the above publication and the data are those which were computed by the United States Weather Bureau in 1946 and 1947 in accordance with the requirements of the National Joint Committee on Weather Statistics.

[b] Data for airport stations, A, and city stations, C, are both given where available.

[c] Data for Canadian cities were computed by the Meteorological Division, Department of Transport from normal monthly mean temperatures, adjusted for the summer months by a method described by H. C. S. Thom, The Rational Relationship between Heating Degree Days and Temperature, *Monthly Weather Review* Vol. 82, No. 1, January 1954.

[d] For period October to April, inclusive.

appropriately. When data on degree days are available these may be used in the calculation of average outdoor temperature for use in Equation 2 or 3. (See definition of degree day, Chapter 4.)

It may be noted that a portion of Equation 3, $(t - t_o)N$ will, when divided by 24, correspond exactly to the degree days for the period, provided that $t = 65$ F, the usual basis for calculating degree days (see discussion of degree days in following sections). Some engineers substitute degree days for the period, multiplied by 24, for the value of $(t - t_o)N$ in Equation 3. Since this amounts to the basis for degree-day calculations, assuming that $t = 65$ F, some allowance is thus made for the fact that F will frequently be overestimated, when H is taken as the maximum, or design, heat load.

Example 1: A residence building is to be heated to 70 F from 6 a.m. to 10 p.m. and 65 F from 10 p.m. to 6 a.m. The calculated hourly heat loss is 120,000 Btu per hour based on 70 F inside at −10 F outdoors. If the building is to be heated by metered steam, how many pounds would be required during an average heating season?

Solution: The heating value of steam may be taken as 1000 Btu per lb, and since it is purchased steam, the efficiency can be assumed as 100 percent. Assume average outdoor temperature as 36.4 F. The average inside temperature is:

$$\frac{(16 \times 70) + (8 \times 65)}{24} = 68.3 \text{ F.}$$

Substituting in Equation 1

$$F = \frac{120{,}000(68.3 - 36.4)5088}{1.00[70 - (-10)]1000} = 243{,}000 \text{ lb.}$$

Example 2: What would be the fuel cost to heat the building in *Example 1* during an average heating season, using stoker-fired bituminous coal at $14.00 per ton having a calorific value of 13,000 Btu per lb, assuming that the seasonal efficiency of the system is 65 percent?

Solution: Substituting in Equation 1

$$F = \frac{120{,}000(68.3 - 36.4)5088}{0.65[70 - (-10)]13{,}000} = 28{,}800 \text{ lb.}$$

The fuel cost is then $(28{,}800 \div 2000)\ (14) = \$201.00$

Example 3: What will be the estimated fuel cost per year of heating a building with gas, assuming that the calculated hourly heat loss is 92,000 Btu based on 0 F, which includes 26,000 Btu for infiltration? The design temperatures are 0 F and 72 F. The normal heating season is 210 days, and the average outdoor temperature during the heating season is 36.4 F. The seasonal efficiency will be 80 percent. The heating plant will be thermostatically controlled, and a temperature of 65 F will be maintained from 11 p.m. to 7 a.m. Assume that the price of gas is 7.5 cents per 100,000 Btu of fuel consumption, and disregard the loss of heat through open windows and doors.

Solution: The average hourly temperature is

$$t_o = \frac{(72 \times 16) + (65 \times 8)}{24} = 69.7 \text{ F.}$$

The maximum hourly heat loss is

$$H = 92{,}000 \text{ Btu.}$$

The seasonal heat loss is

$$M = \frac{92{,}000(69.7 - 36.4) \times 24 \times 210}{100{,}000 \times 0.80 \times (72 - 0)}$$

$$= 2697 \text{ hundred thousand Btu.}$$

The estimated seasonal fuel cost will be

$$2697 \times \$0.075 = \$202.00$$

It should be noted that savings from night setback may not result as calculated. Room temperature may not decrease and combustion efficiency may be poor during morning pickup.[10]

Several time-saving procedures have been devised for quickly estimating the hourly Btu loss of one- and two-story residences in order that fuel estimates can be predicted more quickly from Equation 1. A graphical method of calculating heat losses has been developed[11] which makes possible a quick solution if the gross wall, ceiling, or floor areas and respective transmission coefficients are known.

The Federal Housing Administration has originated a short-cut formula for residential heat loss determinations which makes use of the floor area and three selected *transmission coefficients*. The formula was developed to apply to detached houses approximately rectangular in shape with total exterior door and window areas equal to about 25 percent of the floor area, and with a floor area not greater than about 1500 sq ft. Equation 4 is for a one-story residence, and Equation 5 is intended for two-story structures.

$$H_1 = A(G + U_w + U_c + U_f)(t_i - t_o) \quad (4)$$

$$H_2 = A(G + 1.2U_w + 0.5U_c + 0.5U_f)(t_i - t_o) \quad (5)$$

where

H_1 = heat loss from one-story residence, Btu per hour.
H_2 = heat loss from two-story residence, Btu per hour.
A = floor area, square feet, measured to the inside faces of enclosing walls and is the sum of the following areas: (1) all the area on each principal floor level; (2) the area of all finished habitable attic rooms, including bathrooms, toilet compartments, closets, and halls; (3) all other areas intended to be heated and not located in the basement.
G = glass and infiltration factor for ordinary construction: (0.45 for no weatherstripping or storm windows), (0.40 for weatherstripping), (0.30 for storm windows with or without weatherstripping).
U_w = coefficient of transmission for outside wall.
U_c = coefficient of *transmission for ceiling.*
U_f = coefficient of transmission for floor.
t_i = indoor design temperature, Fahrenheit degrees.
t_o = outdoor design temperature, Fahrenheit degrees.

Notes for application of Equations 4 and 5.

1. The calculation of heat loss from heated spaces into adjacent spaces such as attics, basementless areas, and heated or unheated garages shall be based on the assumption that the temperature of such adjacent spaces is the same as the outdoor design temperature.

2. For all floors over basements or other warmed spaces assume $U_f = 0$.

3. For structures having concrete slab floors laid on the ground a modified application of the formula may be made. Assume $U_f = 0$ and calculate the heat loss in accordance with the check formula. Then add the slab loss determined in accordance with the procedure developed by the National Bureau of Standards and described in *Building Materials and Standards Report* 103.

4. No basement area is to be included in the formula calculation. If finished habitable rooms in the basement are to be heated, the additional heat loss should be calculated separately and added to the amount obtained by the formula.

Both the graphical method[11] and FHA formulas, when used within the limitations established, have been found to give reasonably accurate results for the average residence, but if precise estimates are required, the heat loss should be calculated as outlined in Chapter 12.

In the case of gravity warm air heating installations, the load was formerly expressed in square inches of leader pipe which can be converted into Btu per hour by multiplying the square inches of leader area by 111, 167, and 200 for first, second, and third floors, respectively.

DEGREE-DAY METHOD

This method is based on consumption data which have been taken from buildings in operation, and the results have been computed on a degree-day basis. While this method may not be as theoretically precise as the Calculated Heat Loss Method, it is considered by many to be of more value for practical use.

The amount of heat required in a building depends upon the outdoor temperature, if other variables are eliminated. Theoretically it is proportional to the difference between the outdoor and indoor temperatures. The American Gas Association[12] determined from records in the heating of residences that the gas consumption varied directly as the degree days, or as the difference between 65 F and the mean outdoor temperature. In other words, on a day when the mean temperature was 20 deg below 65 F, twice as much gas was consumed as on a day when the temperature was 10 deg below 65 F. For any one day, when the mean temperature is less than 65 F, there are as many degree days as there are degrees difference in temperature between the mean temperature for the day and 65 F. Degree days may be calculated on other than the 65 F base for use mainly for warehouse and other industrial spaces in which temperatures to be maintained are considerably below the 68 to 72 F range. They are listed in a later section of this chapter.

Studies made by the National District Heating Association[13] of the metered steam consumption of 163 buildings located in 22 different cities, and served with steam from a district heating company, substantiate the approximate correctness of the 65 F base chosen by the gas industry.

Table 2 lists the average number of degree days that have occurred over a long period of years, by months, and the yearly totals for various cities in the United States and Canada. The number of degree days for United States cities were calculated by taking the difference between 65 F and the daily mean temperature computed as half the total of the daily maximum and the daily minimum temperatures. The monthly averages were obtained by adding daily degree days for each month each year and dividing by the number of days in the month; then totaling the respective calendar monthly averages for the number of years indicated and dividing by the number of years. *The total or long term yearly* average degree-day value is the summation of the 12 monthly averages. Degree days for Canadian cities were supplied by the Canadian Meteorological Division of the Department of Transport, and were computed from the mean temperature normals on record for the various stations. (See Note c, Table 2.)

Any attempt to apply the degree-day method of estimating fuel consumption for less than one month would be of very little value. It should be noted that this method of calculation is based on a long term average and cannot be expected to coincide with any single year in calculating fuel requirement. Individual yearly degree-day calculations may vary as much as 20 percent above and below the long term average.

If the degree days occurring each day are totaled for a reasonably long period, the fuel consumption during that period as compared with another period may be assumed to be in direct proportion to the number of degree days in the two periods. Consequently, for a given installation, the fuel consumption can be calculated in terms of fuel used per degree day for any sufficiently long period, and compared with similar ratios for other periods to determine the relative operating efficiencies with the outdoor temperature variable eliminated.

Such results should be used with some reservation since it is possible to have wide variations, for example, as between early and late winter periods.[14]

Computation and Application

The general equation for calculating the probable fuel consumption by the degree-day method is:

$$F = U \times N \times D \times C_f \quad (6)$$

where

F = fuel consumption for the estimate period.
U = unit fuel consumption, or quantity of fuel used per (degree day) (*building load unit*).
N = number of *building load units* (when available, use calculated hourly heat loss instead of actual amount of radiation installed).
D = number of degree days for the estimate period.
C_f = temperature-correction factor from Table 3.

Table 3 .... Correction Factors for Outdoor Design Temperatures[a]

Outdoor Design Temp F....	−20	−10	0	+10	+20
Correction factor.....	0.778	0.875	1.000	1.167	1.400

[a] The multipliers in Table 3, which are high for mild climates and low for cold regions, are not in error as might appear. The unit figures in Tables 4, 5, and 6 are per square foot of radiator or thousand Btu heat loss per degree day. For equivalent buildings and heating seasons, those in warm climates have lower design heat losses and smaller radiator quantities than those in cold cities. Consequently, the unit figure in quantity of fuel per (square foot of radiator) (degree day), is larger for warm localities than for colder regions. Since the northern cities have more radiator surface per given building and a higher seasonal degree-day total than cities in the south, the total fuel per season will be larger for the northern city.

Values of N depend on the particular building for which the estimate is being prepared and must be found by surveying plans, by observation, or by measurement of the building. Values of U for use in this equation are the unit fuel consumptions per degree day, obtained as a result of the collection of operating information and listed in Tables 4, 5, and 6. Attention is directed to the nature of these units in the next following sections.

Unit Fuel Consumptions per Degree Day

The quantity of fuel used per degree day in a given heating plant can be reduced to a unit basis in terms of quantity of fuel or steam per degree day per thousand Btu hourly heat loss at design conditions. A less frequently used basis is quantity of fuel per (degree day) (square foot of floor area). In fact any convenient unit can be used to relate the consumption *to the degree day and to the building.*

The choice of these units requires explanation, and some discrimination and judgment. If the volume basis is used, the net heated space is preferable to the gross building cubage, since gross cubage includes outer walls and certain portions of attic and basement space that are usually unheated. In the absence of data on net heated volume, a value of 80 percent of the gross volume may be used to obtain the estimated net heated volume. The volume basis has been rather widely used primarily because it is simple to apply. In industrial buildings it is usually easier to obtain the correct

Table 4 .... Unit Fuel Consumption Constants (U) for Gas[a]

Based on 0 F Outdoor Temperature, 70 F Indoor Temperature

Heating Value of Gas Btu per Cu Ft	Hot Water			Steam			Warm Air

[a] Abstracted from *Comfort Heating*, American Gas Association, 1938, and 5 percent added for operation without night reduction of temperature.

volume of a given building than to measure and evaluate the heating capacity of its heating system, or calculate its maximum hourly Btu loss. The comparison of buildings on a straight volume basis does not allow for variation in exposure, type of construction, ratio of exposed area to cubical contents, and type of occupancy. It is inaccurate for estimating purposes unless the buildings are of very similar nature.

The calculated heat loss or the heating capacity of the installed radiation may be used as the unit. The use of the heating capacity of the installed radiation is of questionable value when referring to heat-transfer surfaces used in warm air furnace or central air-conditioning systems. Where steam or hot water radiation is already installed, care should be exercised when using the installed radiation as the basis for estimating, since actual installed radiation may differ considerably from the exact radiation requirements. In view of all these considerations, it is believed that the unit based on *thousands of Btu of hourly calculated heat loss for the design hour* is probably the most desirable.

Estimating Gas Consumption

Values of the Unit Fuel Consumption Constant U for gas are given in Table 4 for various gas heating values, and different types and sizes of heating systems. They are based on an indoor design temperature of 70 F and an outdoor design temperature of 0 F, and apply only to these conditions. For other outdoor design conditions corrections must be made by applying factors given in Table 3.

The factors in Table 4, as corrected if necessary, are satisfactory for regions having 3500 to 6500 degree days per heating season. In regions with less than 3500 degree days the unit gas consumption is higher than given; where over 6500, the unit is less than given. Ten percent addition or deduction in these cases is recommended by A.G.A. publications. This table cannot be used for making estimates for industrial buildings where low inside temperatures are maintained.

For gas heat values other than those given in Table 4, simply interpolate or extrapolate. It will also be noted that Table 4 applies only to small installations. Since the unit gas consumption becomes smaller as the installation becomes larger, the values in the table should be used with care, if at all, for large gas-burning installations.

Example 4: Estimate the gas required to heat a building located in Chicago, Ill., where the heating season has 6310 degree days and the gas heating value is 800 Btu per cu ft. The calculated heating requirements are 1000 sq ft of hot water radiation based on design temperature of −10 F and 70 F.

Solution: From Table 4, the fuel consumption for a design temperature of 0 F with 800 Btu gas is found to be 0.087 cu ft of gas per (degree day) (square foot of hot water radiation).

Table 5 .... Unit Fuel Consumption[a] Constants (U) for Oil[b]

Based on 0 F Outside Temperature, 70 F Inside Temperature

Unit[c]	Efficiency in Percent	
	70	80
Gal oil per sq ft steam radiator	0.00105	0.00092
Gal oil per sq ft hot water radiator	0.00066	0.00058
Gal oil per 1000 Btuh heat loss	0.00437	0.00383

[a] Based on a heating value of 141,000 Btu per gallon.

[b] Abstracted by permission from *Degree-Day Handbook* (Second Edition, 1937), by C. Strock and C. H. B. Hotchkiss. Seven percent added for operation without night reduction of temperature and change to heating value of 141,000 Btu per gallon.

[c] Per degree day.

Table 6 .... Unit Fuel Consumption[a] Constants (U) for Coal[b]

Based on 0 F Outdoor Temperature, 70 F Inside Temperature

Unit[c]	Efficiency in Percent				
	40	50	60	70	80
Lb coal per sq ft steam radiator	0.0216	0.0172	0.0143	0.0123	0.0108
Lb coal per sq ft hot water radiator	0.0135	0.0108	0.0091	0.0078	0.0068
Lb coal per 1000 Btuh heat loss	0.0889	0.0717	0.0592	0.0507	0.0444

[a] Based on a heating value of 12,000 Btu per pound.

[b] Abstracted by permission from *Degree-Day Handbook* (Second Edition, 1937), by C. Strock and C. H. B. Hotchkiss. Eight percent added for operation without night reduction of temperature.

[c] Per degree day.

From Table 3, the correction factor is 0.875 for −10 F outdoor design temperature, hence, $0.875 \times 0.087 = 0.076$. By Equation 4,

$$F = 0.076 \times 1000 \times 6310 = 480{,}000 \text{ cu ft.}$$

Estimating Oil Consumption

Table 5 gives unit fuel consumption factors for oil, similar to those given for gas in Table 4.

The factors in Table 5 apply only to an indoor design temperature of 70 F and an outdoor design temperature of 0 F. For other outdoor design temperatures, the constants in Table 5 must be multiplied by the values in Table 3 as explained under Estimating Gas Consumption.

Values given in Table 5 are based on use of oil with a heating value of *141,000 Btu per gallon*. For other heating values, multiply the values in Table 5 by the ratio of 141,000 divided by the heating value per gallon of fuel being used.

Example 5: Estimate the seasonal oil consumption of a boiler, designed for oil firing, in a building located in Toledo, Ohio. The building has a calculated heat loss of 240,000 Btu per hr. The oil heat value is 144,000 Btu per gal, and the assumed seasonal efficiency is 80 percent. The outdoor design temperature for Toledo is −10 F, and the indoor design temperature is 70 F.

Solution: From Table 5, under 80 percent efficiency and in the bottom line, the value of U is found to be 0.00383 gal per 1000 Btu hourly heat loss for 0 F outdoor temperature. The correction factor for −10 F outdoor design temperature from Table 3 is 0.875 which makes the correction $0.875 \times 0.00383 = 0.00335$. Making a further correction for the heating value, $0.00335 \times (141{,}000/144{,}000) = 0.00328$ gal per 1000 Btu per hr calculated heat loss per degree day.

From Table 2, *the total normal degree days for Toledo are* 6394. Since U is expressed in 1000 Btu, N is equal to 240. Substituting in Equation 4

$$F = 0.00328 \times 6394 \times 240 = 5030 \text{ gal.}$$

Estimating Coal or Coke Consumption

Coal or coke consumption estimates are made by following *exactly the same procedure as for oil*. Values of U are given in Table 6 which only apply to an indoor design temperature of 70 F and an outdoor design temperature of 0 F. A correction must be made for other conditions by use of the multiplying factors in Table 3. Data in Table 6 are based on 12,000 Btu per lb coal, and for other heating values of coal they must be multiplied by the ratio of 12,000 divided by the heating value of fuel used.

Example 6: A building in Scranton, Pa. has a calculated heat loss of 240,000 Btu per hr based on an indoor design temperature of 70 F and an outdoor design temperature of −10 F. What will be the estimated normal seasonal anthracite or coke consumption for heating if 13,000 Btu per lb fuel is burned in a hand-fired boiler, with automatic control, at a seasonal efficiency of 80 percent, and what part of the total will be used during November, December, and January?

Solution: From Table 6, U is 0.0444 of coal or coke per 1000 Btu per hr heat loss per degree day. Correcting for the outdoor design temperature of −10 F from Table 3, the value of U is $0.875 \times 0.0444 = 0.0389$. From Table 2, D is 6218 and from the problem, N is 240.

Substituting in Equation 4,

$$F = 0.0389 \times 240 \times 6047 = 56{,}500 \text{ lb.}$$

Fuel used over any period is, according to the theory of the degree day, proportional to the number of degree days during the period. From Table 2, the average numbers of degree days for November, December, and January in Scranton are 693, 1057, and 1141 respectively, a total of 2891. The yearly total is 6047, so that during these three months the estimated consumption is

$$\frac{2891}{6047} \times 56{,}500 = 27{,}000 \text{ lb.}$$

Estimating Steam Consumption

In estimating steam consumption the efficiency is generally assumed at 100 percent. If for low-pressure steam an average heating value of 1000 Btu per pound of steam is used, no correction is necessary. In comparing values from different cities, correction should be made for design temperature (see Table 3) when the unit figures are in terms of heat loss but not when the values are in terms of building volume or floor space.

Where the heat loss is calculated in Btu per (hour) (*degree difference in temperature*) the simple Equation 7 may be used:

$$F = \frac{H \times 24 \times D}{1000} \tag{7}$$

F = pounds of steam required for estimate period.
H = calculated heat loss, Btu per (hour) (degree difference).
24 = hours in one day.
D = number of degree days for the period of estimation.
1000 = Btu delivered per pound of steam condensed.

In this method the number of degree days automatically takes care of average indoor and outdoor temperature difference. *When degree days are taken from* Table 2, an av-

* From *Degree-Day Handbook*, by C. Strock and C. H. B. Hotchkiss (The Industrial Press, 1937, pp. 123-134). Values are not coordinated with Table 2 which is from a later source.

erage indoor temperature of approximately 70 F is assumed throughout the period. If an average indoor temperature other than approximately 70 F is to be used, the number of degree days should be obtained for the new base.

Example 7: An eight-story building in Pittsburgh is operated with a daytime temperature of 70 F. The calculated heat loss is 10,500 Btu per (hr) (*degree temperature difference*). What is the estimated average yearly steam consumption for building heating?

Solution: Since the average indoor temperature is approximately 70 F, the degree days from Table 2, based on 70 F may be used. Therefore, from Table 2, Pittsburgh has 5048 degree days per normal season. Inserting in Equation 5:

$$F = \frac{10{,}500 \times 24 \times 5048}{1000} = 1{,}272{,}000 \text{ lb of steam.}$$

Consideration has been given to the difference in steam utilization of different types of buildings, and Table 7 shows actual average units for these various types. These figures were obtained from operating results in 896 buildings located in all sections of the United States. Being averages, and for small groups in each type, the figures may need considerable modification to allow for local variations. It should be especially noted that the steam used for heating water for service is not included in the values given in Table 7.

Additional figures are to be found in a paper presented before the Society.[18]

Example 8: A store in Philadelphia with a heating system designed to maintain 70 F indoors in 0 F weather has 250,000 cu ft of heated space. What would be the estimated average yearly steam consumption of purchased steam for heating?

Solution: According to Table 7, a store would use 0.624 lb of steam per degree day per 1000 cu ft heated space. From Table 2, Philadelphia has 4523 degree days per normal year. Inserting in Equation 4:

$$F = 0.624 \times 250 \times 4523 = 706{,}000 \text{ lb of steam.}$$

Degree Day as an Operating Unit

The degree day is also widely used as a means of comparing the efficiency of the fuel consumption of one period with another *for the same building*. Since the fuel consumption is approximately proportional to the weather (degree days), and since the periods to be compared may not have the same weather conditions, the comparison can be made only after the fuel consumptions have been computed on a comparable weather basis, that is, upon the actual number of degree days occurring for a given month and year in the city under consideration. Since fuel consumption is proportional to the number of degree days, plant operators frequently compute each month the fuel burned per degree day by the heating plant. The resulting unit value, by eliminating the outdoor temperature variable, indicates whether the operating efficiency of the plant is above or below the previous month or year.

INDUSTRIAL DEGREE DAYS

When estimating the heating requirements of warehouses, factories, and other buildings where the indoor temperature to be maintained differs greatly from the usual indoor temperature range of 68 to 72 F, it is common to use degree days based on temperatures of 55 to 45 F. These are generally referred to as industrial degree days, and are listed in Table 8 for a number of cities using both 55 F and 45 F as the base. In general, the degree days (55 F base) are used when the temperature of the heated space is to be maintained at approximately 60 F. For an inside temperature of about 50 F, the degree days calculated on a 45 F base should be used.

The industrial degree days are useful for estimating fuel consumption by comparison between localities in which the difference in degree days is not too great, and where the known fuel consumption of one building may be used to determine unit consumption per degree day.

MAXIMUM DEMANDS AND LOAD FACTORS

In one form of district heating rates, a portion of the charge is based upon the maximum demand of the building. The maximum demand may be measured in several different ways. It may be taken as the instantaneous peak or as the rate of use during any specified interval. One method is to take the average of the three highest hours during the winter. These figures ar shown for a number of buildings in Detroit in Table 9.[18]

Table 9 .... Building Load Factors and Demands of Some Detroit Buildings

Building Classification	Load Factor	Lb of Demand per (Hour) (Sq Ft EDR)
Clubs and Lodges	0.318	0.184
Hotels	0.316	0.207
Printing	0.287	0.217
Offices	0.263	0.209
Apartments	0.255	0.225
Retail Stores	0.238	0.182
Auto Sales and Service	0.223	0.248
Banks	0.203	0.158
Churches	0.158	0.152
Department Stores	0.138	0.145
Theaters	0.126	0.151

These maximum demands were measured by an attachment on the condensate meter, and therefore represent the amounts of condensate passed through the meter in the highest hours, rather than the true rate at which steam is supplied. There might be slight differences in these two quantities due to time lag and to storage of condensate in the system, but wherever this has been investigated it has been found to be negligible.

The load factor of a building is the ratio of the average load to the maximum load and is an index of the utilization. Thus, in Table 9, the theaters, operating for short hours, have a load factor of 0.126 as compared with the figure of 0.318 for clubs and lodges.

CHAPTER 38

REFRIGERATION

Refrigeration Theory: Definitions and Basic Concepts, Refrigerants, Vapor Compression Refrigeration Cycles, Suction and Discharge Pressure Effect, Complex Refrigeration Cycles, Air Cycle, Steam Jet, Absorption System; Basic Refrigeration Equipment: Compression Machines and Controls, Condensers, Evaporators and Coolers, Refrigeration Control, Piping and Accessories, Equipment Characteristics and Selection

WITH the increasing use of all-year comfort air-conditioning installations, the importance of refrigeration to the air-conditioning engineer has been greatly magnified. The details of equipment operation, maintenance, and design remain problems for the refrigeration engineer, but the air-conditioning engineer does retain a responsibility to the customer which requires on his part some knowledge of the different refrigeration cycles and the relative merits of each. In order to assist in meeting this need, the present chapter has been divided into four parts, the first covering the fundamental technical relationships which govern the selection and analysis of an operating cycle, the next two presenting brief discussions of basic refrigerating equipment and auxiliaries, and the last, information on selection criteria.

REFRIGERATION THEORY

Definitions and Basic Concepts

The *ton of refrigeration* is a quantity unit which originated in the days when harvested ice was the principal source of summer cooling. By definition the *ton* is the cooling effect realized when one ton of 32 F ice melts to water at 32 F. Since the latent heat of fusion of ice is 144 Btu per pound, the *ton* represents a unit cooling effect of $144 \times 2{,}000 = 288{,}000$ Btu. In common practice the ton is usually considered a rate (rather than quantity) unit, and is taken as 288,000 Btu per day (24 hours), or 12,000 Btu per hour, or 200 Btu per minute. Thus for air-conditioning calculations, the size of the requisite refrigeration machine, expressed in tons, can be obtained by dividing the heat gain of the structure, expressed in Btu per hour, by 12,000. In equation form:

$$H_t = (\text{Btu per hour heat gain}) \div 12{,}000 \qquad (1)$$

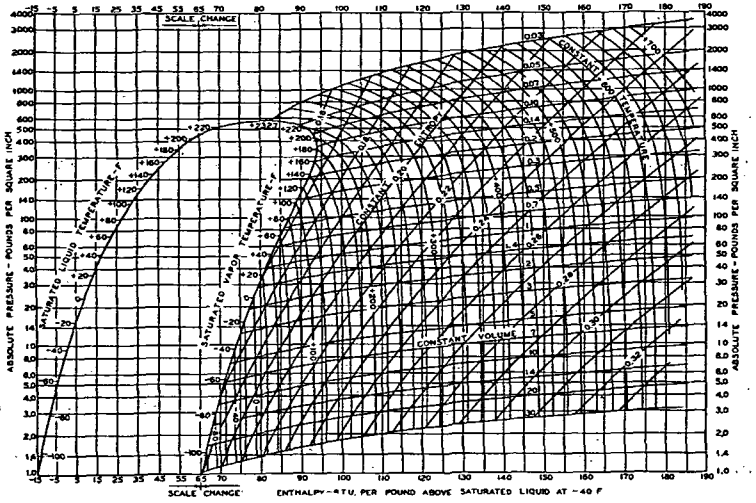
where

H_t = load in tons.

The *working substance*, or *refrigerant*, is the fluid which carries heat through the refrigeration cycle from the evaporator, where heat enters the refrigerant, to the condenser where the heat is discharged to some cooling medium. The great majority of modern refrigeration systems use a liquefiable vapor as the working substance. By altering the pressure of the refrigerant its boiling temperature is changed, allowing the material to *boil* in the evaporator at a temperature sufficiently lower than that of the conditioned space, to insure maintenance of an effective heat transfer rate from the space (or in some cases from a secondary cooling fluid such as brine or cold water) to the refrigerant. The vapor formed in the evaporator is then raised in pressure (by a compressor, or by the absorber-generator combination of the absorption system) until its new boiling temperature exceeds the temperature of the available cooling medium. Under these conditions, heat transfer is established from the refrigerant vapor to the cooling medium with resultant condensation of the refrigerant. When condensed, the high-pressure liquid refrigerant is reduced in pressure and again allowed to *boil* in the evaporator.

In order to permit evaluation of the effectiveness with which any given cycle operates, some term is desirable that would be comparable to the term *efficiency* used for heat engines. In refrigeration the desired effect is heat extraction, and the cost of achieving this extraction is the amount of energy that must be supplied as shaft work. Thus the ratio of refrigerating effect to the heat equivalent of the compressor work is used as a measure of effectiveness, and is defined as the coefficient of performance.

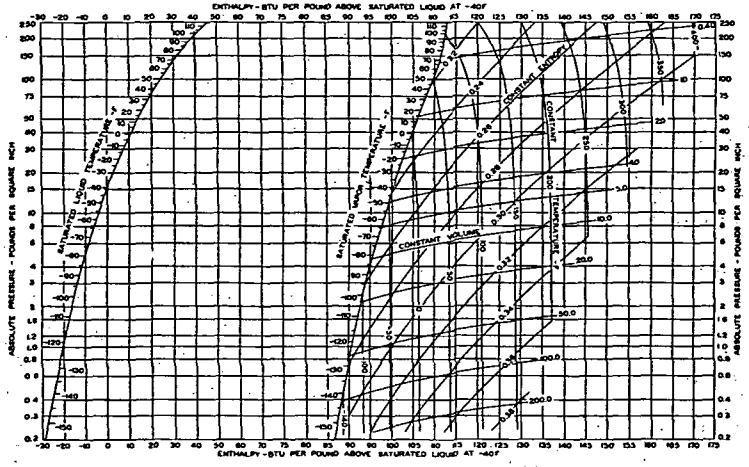
If the desired effect is the rejection of heat through the condenser instead of heat extraction through the evaporator, the refrigeration system is then termed a heat pump. In this case the coefficient of performance is the ratio of the heat rejected from the condenser to the heat equivalent of the compressor work. The coefficient of performance for the heat pump is greater than that for a system operating as a refrigerating machine, because all mechanical shaft work required to operate the compressor is dissipated as useful heat through the condenser.



The Carnot cycle, an ideal, thermodynamically reversible cycle consisting of an adiabatic expansion and an isothermal expansion, followed by an adiabatic compression and an isothermal compression to form a closed cycle, may be shown to be a measure of the maximum possible conversion of heat energy into mechanical energy. In its reversed form it is a measure of the maximum performance possible for any refrigeration cycle operating either as a refrigerator or as a heat pump. Although it cannot be applied in an actual machine because of the impossibility of obtaining complete reversibility, it is, nevertheless, extremely valuable as a criterion of inherent limitations. The coefficient of performance (CP) of a reversed Carnot cycle system operating as a refrigeration system is

$$(\text{CP}) = \frac{T_e}{T_c - T_e} \qquad (2)$$

where



T_e = evaporator temperature, Fahrenheit, absolute.

T_c = condenser temperature, Fahrenheit, absolute.

Temperature—F; Volume—Cu Ft per Lb; Entropy—Btu per (Lb) (F deg).

Fig. 1 .... Pressure-Enthalpy Diagram for Dichlorodifluoromethane (CCl_2F_2) (Refrigerant 12)

Temperature—F; Volume—Cu Ft per Lb; Entropy—Btu per (Lb) (F deg).

Fig. 2 .... Pressure-Enthalpy Diagram for Monochlorodifluoromethane ($CHClF_2$) (Refrigerant 22)

With the ideal Carnot cycle operating as a heat pump, the coefficient of performance is

$$(CP) = \frac{T_c}{T_c - T_e} \tag{3}$$

The Carnot cycle coefficient of performance for both a refrigerating machine and a heat pump increases as the spread between the evaporator and the condenser temperatures decreases. In general, the same is true for an actual system operating as either a refrigerating machine or a heat pump.

Refrigerants

A desirable refrigerant should possess chemical, physical, and thermodynamic properties that permit its efficient application in refrigerating systems. In addition, when the volume of the charge is large, there should be little or no danger to health or to property in case of its escape.

Thermodynamically, a material for use as a refrigerant should have a large latent heat of vaporization since it is this heat quantity—subject to minor variations—that constitutes the working effectiveness of the refrigerant. Further, since the work required to compress a vapor increases rapidly with the pressure ratio, the thermodynamic characteristics of the fluid should be such that the required low-to-high temperature range can be achieved with only a moderate change in ratio. A further consideration, from the standpoint of practical operating effectiveness, is that the suction pressure should not be below atmospheric (to prevent leakage of air into the refrigerant lines) nor should the condenser pressure be excessively high (to prevent need for extra-heavy construction). The specific volume-specific enthalpy relationship is also important because some materials would have such low density, when in vapor form, that impractical compressor displacements would be needed to handle the suction vapor.

Properties of refrigerants are usually given either in tabular or graphic form. In contrast to the temperature-entropy plotting which is used almost exclusively in steam-power work, refrigeration problems are usually referred to a pressure-enthalpy chart. The advantage of pressure-enthalpy plotting in that linear distances on the chart correspond to energy gains or losses, and the two types of processes, constant-pressure and constant-enthalpy, that occur most frequently in refrigeration cycles, can both be represented by straight vertical or horizontal lines. Figs. 1 and 2 present pressure-enthalpy charts for dichlorodifluoromethane, CCl_2F_2, and monochlorodifluoromethane, $CHClF_2$, respectively. Although tabular arrangements of refrigerant properties require interpolation between values, they have the advantage of an accuracy greater than that obtainable from a chart. Tables 1, 2, 3, and 4 give the thermodynamic properties of four of the more common refrigerants used in air-conditioning installations: Refrigerant* 12, dichlorodifluoromethane; Refrigerant 22, monochlorodifluoromethane; Refrigerant 11, trichloromonofluoromethane; and Refrigerant 113, trichlorotrifluoroethane. The first two of these are commonly used in reciprocating compressors while the last two are commonly used in centrifugal machines.

Referring to Table 1, the first column gives the range of saturation temperatures likely to occur in practice. The second column gives the saturation pressure expressed in pounds per square inch absolute corresponding to a given temperature, while the next six columns give the three fundamental specific properties, volume, enthalpy, and entropy, of the saturated liquid and saturated vapor, respectively. The last four columns give values of enthalpy and entropy for gases with 25 deg and with 50 deg of superheat; note particularly that the column heading *50 F superheat* means, not that the gas is at a temperature of 50 F, but that its temperature exceeds by 50 deg the saturation temperature corresponding to its actual pressure. Thus, CCl_2F_2 vapor at 38.0 psig and 91 F possesses 50 deg of superheat, since its saturation temperature corresponding to 52.7 psia is 41 F.

The tabular arrangements of refrigerant properties are literally for saturated or superheated materials only. In many cases, however, the engineer must work with subcooled liquids. With an accuracy sufficient for all practical purposes, the specific volume and the enthalpy of any subcooled refrigerant can be taken as equal to the values read from the tables for a saturated liquid at the same temperature. Thus, if CCl_2F_2 at 121 psia and 40 F is passing through a pipe, its volume and enthalpy can be determined from Table 1 as 0.0116 cu ft per pound and 17.0 Btu per pound.

Frequently it is necessary to determine the properties of a *wet* vapor or of a mixture of liquid with some added vapor, such as is found at the discharge from an expansion valve. This can be done from the tables by noting that the specific enthalpy of the mixture must be equal to that of the saturated liquid, plus a fraction of the latent heat of vaporization equal to the fraction of refrigerant that is present in vapor form. Consider, for example, CCl_2F_2 with a quality (the percent in vapor form) of 30 percent; the enthalpy of this material would be equal to

$$h_m = h_f + 0.30\ (h_v - h_f) \tag{4}$$

where

h_m = specific enthalpy of the mixture.
h_f = specific enthalpy of the liquid.
h_v = specific enthalpy of the saturated vapor.

Values of h_f and h_v for use in Equation 4 can be obtained directly or by calculation from the tables of properties of refrigerants.

By a reversal of this same procedure the tabular data can be used to determine the state of a mixture leaving an expansion valve. Consider a valve to which saturated liquid at pressure p_s is admitted, and a mixture of saturated liquid and vapor at pressure p_d is discharged. The quality of the material at discharge is then determined by making use of the fact that the expansion process is completely irreversible, is a throttling process, and hence, occurs without change in enthalpy. Thus, the enthalpy of the mixture, h_m, is equal to the enthalpy of the saturated liquid at the entrance state, h_{fs}, and can therefore be read from the table. Thus,

$$h_{fs} = h_m = h_{vd} - (1 - x)\ (h_{vd} - h_{fd}) \tag{5}$$

or,

$$x = (h_m - h_{fd}) \div (h_{vd} - h_{fd}) \tag{6}$$

where

h_{fs} = enthalpy of saturated liquid at entrance to expansion valve.
h_m = enthalpy of mixture.
h_{vd} = enthalpy of saturated vapor at discharge.
h_{fd} = enthalpy of liquid at discharge.
x = proportion of liquid in the mixture, decimal.

Vapor Compression Refrigeration Cycle

Simple Cycle. The refrigerant *cycle* is the series of state changes (which occur in the conditioning processes) needed

* ASRE designations for these refrigerants.

[a] ASRE designation—Refrigerant 12.

to restore the refrigerant to a condition in which it will possess the ability to extract heat from the space to be cooled. For all compression-type systems the cycle consists of four processes: heat gain in the evaporator; pressure rise in the compressor; heat loss in the condenser; pressure loss in the expansion valve. The compression process is accomplished at the expense of energy added to the compressor in the form of shaft work, and the expansion process could be carried out, if the economics of the system would permit, in an expanding engine with consequent release of energy as shaft work. In ordinary systems, however, the additional first cost and maintenance cost of an expanding engine so greatly exceed the advantage resulting from the work realized, that such engines are not used, and instead, the pressure reduction is allowed to occur irreversibly in an expansion valve. Basically, then, a refrigeration cycle consists of two heat-transfer processes and two pressure-change processes, no work entering into the heat-transfer processes and—in the simple cycle—no heat transfer occurring during the pressure-change processes.

The most common and least complicated type of refrigeration cycle is called the simple saturation cycle, and is shown diagrammatically in Fig. 3 and plotted upon pressure-enthalpy coordinates in Fig. 4. For this system, saturated vapor flows without gain or loss of heat from the evaporator to the suction of the compressor. During passage through the compressor the energy added as shaft work goes entirely to increase the enthalpy of the refrigerant, and the compression process, which is assumed to occur reversibly and without external heat transfer, is characterized by constant entropy. Thus, the state of the superheated vapor leaving the compressor can be determined from the tables of thermodynamic properties by noting the discharge pressure and fixing, also, the entropy of the saturated vapor at entrance to the compressor.

Superheated vapor from the compressor flows to the condenser where de-superheating and condensation take place. From the condenser the refrigerant flows to the expansion valve, undergoes a constant-enthalpy pressure reduction, and returns to the evaporator where it again removes a quantity of undesired heat. When the evaporator is arranged to permit direct cooling of room air by the refrigerant, the system is said to be of the *direct-expansion* type, while a system in which the evaporating refrigerant cools water or brine, which in turn cools the air, is said to be *indirect*. Although many differences exist between most actual systems and that of the simple saturation cycle, this latter is, nonetheless, of great value in that it provides an extremely simple method of rapidly achieving an approximate analysis of probable power requirements, compressor size, etc. Further, the equations used in analysis of a simple saturation cycle form the basis of the more complex treatments required for compound refrigeration cycles. For these reasons a typical simple saturation problem will be worked in detail.

Example 1: A simple saturation cycle carries a 7-ton load when operating between suction and discharge pressure of

Data from Kinetic Chemicals, Inc., 1945. [a] ASRE designation—Refrigerant 22.

52.7 psia and 121 psia with dichlorodifluoromethane, CCl_2F_2, as the refrigerant. Determine: (*a*) the cooling effect provided by each pound of refrigerant; (*b*) the refrigerant circulating rate; (*c*) the horsepower required; (*d*) the quantity of heat to be dissipated from the condenser; (*e*) the required condenser cooling water, in gallons per minute, if the temperature rise of water passing through the condenser is 8 deg; (*f*) the bore and stroke of a double acting cylinder (neglecting the effect of the piston rod) if speed of compressor is 500 revolutions per minute; (*g*) coefficient of performance.

Solution: (*a*) Saturated liquid CCl_2F_2 at 121 psia leaves the condenser and enters the expansion valve. The enthalpy of this material (from Table 1) is 29.68 Btu per pound, and this must also be its enthalpy at entrance to the evaporator. Leaving the evaporator as a saturated vapor at 52.7 psia, its enthalpy is 82.82, so the refrigerating effect must be 82.82 − 29.68 = 53.14 Btu per pound.

(*b*) The refrigerant circulating rate is equal to the total heat to be picked up in unit time, divided by the pickup per pound of refrigerant or,

$$W_r = (7 \text{ ton} \times 200) + 53.14 = 26.3 \text{ lb per minute.}$$

(*c*) The horsepower required is equal to the increase in energy of the refrigerant passing through the compressor (expressed in Btu per minute) divided by the conversion factor 42.42, which is the number of Btu per minute corresponding to 1 hp,

$$(\text{hp}) = W_r(h_d - h_{ss}) \div 42.42 \qquad (7)$$

where

(hp) = horsepower.
W_r = refrigerant circulating rate in pounds per minute.
h_d = enthalpy of vapor at condition of discharge from compressor.
h_{ss} = enthalpy of saturated vapor entering compressor.

W_r is known from (*b*) and h_{ss} is the enthalpy of refrigerant as it enters the compressor in a saturated vapor state at 52.7 psia; thus h_{ss} = 82.82.

In order to determine h_d, the state of the refrigerant must first be determined at the compressor discharge. At the known suction state the entropy (from Table 1 for saturated vapor at 52.7 psia) is 0.16828 and, since the compression is assumed to occur isentropically, it therefore follows that the discharge stage must have the same entropy at 121 psia. From the table the entropy of vapor superheated 25 deg is 0.17330, so the superheat, t_{sd}, possessed by the actual gas discharged from this compressor can be obtained by interpolation as,

$$\frac{t_{sd}}{25} = \frac{0.16828 - 0.16608}{0.17330 - 0.16608}$$

from which t_{sd} = 7.6 deg.

As the saturation temperature at 121 psia is 94 F the actual temperature, t_d, of the vapor leaving the compressor is, t_d = 94 + t_{sd} = 94 + 7.6 = 101.6 F. By the same kind of interpolation the enthalpy of the discharged vapor can be determined from the enthalpies given for vapor superheated 25 F and for saturated vapor,

$$\frac{(h_d - 88.10)}{(92.16 - 88.10)} = \frac{(0.16828 - 0.16608)}{(0.17330 - 0.16608)}$$

from which, h_d = 89.34 Btu per pound.

Then substituting in Equation 7,

$$(\text{hp}) = 26.3\ (89.34 - 82.82) \div 42.42 = 4.03.$$

(*d*) The rate of heat loss from the condenser, Q_c, must be equal to the sum of the energies picked up by the refrigerant in the evaporator and the compressor, Q_c = 53.14 + (89.34 − 82.82) = 53.14 + 6.52 = 59.66 Btu per pound or 26.3 × 59.66 = 1569 Btu per minute. This same figure can, of course, be determined more directly by subtraction of the enthalpy

[a] ASRE designation—Refrigerant 11.

of liquid leaving the condenser from the enthalpy of superheated vapor going into it, thus,

$$Q_c = 26.3\ (89.34 - 29.68) = 1569 \text{ Btu per minute.}$$

(e) The cooling water rate (based on a gallon as 8.34 lb) is $1569 \div (8 \times 8.34) = 23.5$ gpm.

(f) The compressor size is fixed by the volume of gas which must be drawn into the machine per unit time. Saturated vapor at 52.7 psia has a specific volume, from Table 1, of 0.779 cu ft per pound, hence $26.3 \times 0.779 = 20.49$ cfm of gas must be handled. Assuming a volumetric efficiency of 90 percent, the compressor must then displace $20.49 \div 0.9 = 22.8$ cfm. The speed is given as 500 rpm and, as the unit is known to be double-acting, the displacement is therefore $(22.8 \times 1728) \div (2 \times 500) = 39.4$ cu in. If the unit were designed so that bore d and stroke were the same,

$$(\pi d^3) \div 4 = 39.4 \qquad d = 3.69 \text{ in.}$$

(g) $$\text{(CP)} = (h_{ss} - h_{fc}) + (h_e - h_{se})$$
$$= (82.82 - 29.68) + (89.34 - 82.82) = 8.17$$

where h_{fc} is the specific enthalpy of liquid at discharge from the condenser.

The coefficient of performance of *Example 1* may be compared with that of an ideal system operating on the Carnot cycle between the same temperature limits. Then $T_s = 501$ F (which is 41 F + 460) and $T_c = 554$ F (which is 94 F + 460) and,

$$\text{(CP)} = \frac{501}{554 - 501} = 9.6$$

The actual cycle is therefore $8.17 \div 9.6$ or 85 percent as effective as a Carnot cycle between the same temperature limits.

Influence of Suction Pressure

Brief consideration of the analytical procedure used in discussion of the simple saturation cycle will bring out the need for maintaining the suction pressure on any refrigeration system as high as the load will permit. As the suction pressure increases, for fixed discharge pressure, the enthalpy of refrigerant entering the evaporator remains unchanged, but the leaving enthalpy increases and, hence, the refrigerating effect increases. Further, compressor energy input is reduced not merely because of the greater enthalpy of the gas at suction, but also because of a reduction in the enthalpy of the superheated gas at discharge. Since the refrigerating effect is greater and the work less, it is obvious that there will be a substantial gain in the coefficient of the performance. See Chapter 54, Fig. 1.

The actual value of suction pressure on any system is obviously determined by the required temperature which must be maintained in the conditioned space. For a direct-expansion system the evaporator can be held at a temperature not much less than that of the conditioned enclosure, except in cases where lower temperatures may be needed in order to establish a desired ratio of dehumidifying to cooling load. When dehumidification requirements dictate the use of unusually low evaporator temperatures, the increased operating cost should properly be charged against the dehumidification rather than the sensible cooling.

* Inches of mercury below one atmosphere.
† Standard cycle temperatures.
[a] ASRE designation—Refrigerant 113.

Influence of Discharge Pressure

In contrast to suction pressure, the compressor discharge pressure should be kept as low as operating conditions will allow. This pressure must be high enough to provide a saturation temperature of refrigerant within the condenser that is greater than the exit temperature of the cooling water. The discharge pressure therefore is a direct function of the temperature of the cooling fluid, and will automatically rise whenever the temperature of cooling water (or air) rises; it will also rise when the flow rate of the cooling medium is decreased.

Increase in discharge pressure (for fixed suction pressure) raises the enthalpy of the gas leaving the compressor; hence, increases the work of compression. Further, as the enthalpy of saturated liquid leaving the condenser increases with pressure, the refrigerating effect must decrease. Thus the effect of such a pressure rise is to require more work per pound of refrigerant handled, and at the same time to necessitate an increase in the refrigerant flow rate. (See Chapter 54, Fig. 1.)

Influence of Water Jacket

The preceding discussion has, in every case, assumed isentropic compression. Where exact performance data are not available, this assumption is a desirable one since it leads to a conservatively large determination of the power required. In most actual systems, the compression process departs from isentropic due to irreversible heat transfers which occur between the vapor in the cylinder and the cylinder wall, and also because of intentional heat dissipation from the outside of the cylinder walls to the surroundings, or to a cooling fluid passing through a water jacket around the

cylinder. Compressor cooling is highly desirable as a method of reducing power consumption.

Influence of Superheating and Subcooling

The most common departure from conditions of the simple saturation cycle is that resulting from admission of superheated vapor to the compressor. Thermodynamically, superheat is undesirable because the enthalpy increase required to compress a vapor through a given pressure range increases with superheat. Further, superheated vapor leaving an evaporator is usually an indication that the suction pressure is lower than necessary. Under practical operating conditions, however, superheat is almost universally used as a

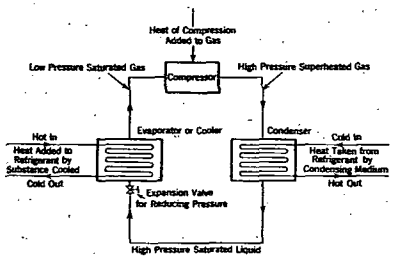

Fig. 3 . . . . Mechanical Refrigeration System

means of assuring complete vaporization of the refrigerant going to the compressor. With modern compressors operating at high speed, and with relatively small clearance space, it is particularly necessary to avoid admission through the suction valves of liquid refrigerant.

Another common departure of actual systems from the simple saturation cycle occurs because of subcooling of refrigerant in the condenser. Thermodynamically, such subcooling is advantageous since it increases the refrigerating effect without affecting the unit energy requirements of the compressor. Further, it can be shown that for a fixed ratio of condenser cooling water to refrigerant circulating rate, the total compressor power requirements will be greater when operating at simple saturation than when operating with maximum subcooling. What is even more surprising is that condenser pressure may be lower for the subcooling cycle than for the saturation cycle. This condition results from the fact that, for the same capacity on a heavily loaded condenser, the refrigerant flow rate is less when there is subcooling.

Because of the advantages attendant upon the use of subcooling, many methods are in use for obtaining some subcooling effect outside of the condenser. One common procedure is to use the cold vapor leaving the evaporator to cool the liquid flowing from condenser to expansion valve.

Another somewhat unusual subcooling cycle allows cold refrigerant from the downstream side of the expansion valve to cool liquid refrigerant from the condenser down to the evaporator temperature. Fig. 5 shows the pressure-enthalpy diagram for a typical refrigeration cycle operating with both subcooling of the refrigerant from the condenser and superheating of the refrigerant leaving the evaporator.

Complex Refrigeration Cycles

The preceding sections have dealt only with refrigeration systems in which there is but one evaporator; compression is accomplished through but a single stage, and expansion proceeds through a single expansion valve. In large systems or in low-temperature systems in which the compression ratio is high, the compression process can be carried out in stages, with the refrigerant passing through several cylinders arranged for operation in series. The thermodynamic advantage of such compound compression arises from the fact that intercoolers can be placed between the stages of compression to extract heat from the vapor, and thereby cause the overall compression process to approach more closely the ideal condition of isothermal compression. Essentially, such intercoolers serve the same purpose as a cooling jacket, but with greater effectiveness because of the more satisfactory heat-transfer conditions.

In the simple saturation cycle the saturated liquid entering the expansion valve commences to vaporize as soon as its pressure starts to drop. The vapor produced during the expansion process has no further use, in terms of refrigerating effect, since it has already picked up its latent heat of vaporization as a result of heat which it has extracted from the unvaporized residue. Thus the instant such vapor forms, its usefulness is at an end, and to allow such material to undergo a further drop in pressure is uneconomical. With compound compression, there is at least one intermediate pressure at which flash vapor can be extracted. In such cases several expansion valves can be utilized with all of the refrigerant from the condenser passed through a first expansion valve to the higher suction pressure, and the flash vapor then extracted and returned to the condenser through the high compression stage. The remaining refrigerant can then pass through a second expansion valve where the pressure is dropped to that corresponding to the low-pressure evaporator. The number of expansion valves is limited by the number of stages of compression.

Further cycle complications may arise if more than one evaporator is to be operated with a single compressor, and particularly, if the pressures in these evaporators are to differ. The most common solution is to operate the compressor at the suction pressure of the lowest pressure evaporator, and to equip all other evaporators with back-pressure regulating valves or throttling devices between the evaporator and the compressor suction.

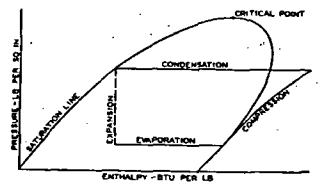

Fig. 4 . . . . Pressure-Enthalpy Diagram for Simple Saturation Cycle

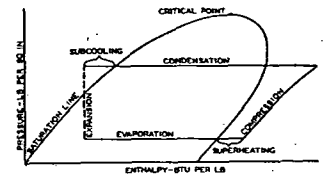

Fig. 5 . . . . Pressure-Enthalpy Diagram for Refrigeration Cycle with Subcooling and Superheating

The Air-Cycle System

Fundamentally, the air cycle[1] is essentially the same as the vapor cycle. Compression is accomplished by a reciprocating or centrifugal compressor, and, since there is no change of phase of the refrigerant upon expansion, an *air cooler* replaces the condenser, and a *refrigerator* replaces the evaporator. Although some cooling would result from the expansion of the gas through an ordinary expansion valve, a much greater drop in air temperature is accomplished if the expansion is controlled to approach the isentropic by replacing the valve with an expansion engine or turbine. Furthermore, the work recovered by such an expansion engine can be utilized to supply part of the work of compression or to drive other devices.

The Steam-Jet System

The *steam-jet system*, under certain circumstances, is desirable for use in air conditioning.[2] Steam supplies directly the power used for compressing the refrigerant, thus eliminating the losses connected with other methods of supplying energy. As the compression ratio between the evaporator and condenser under normal circumstances is large, the mechanical efficiency of the equipment is somewhat lower than that of the positive mechanical type compressor. The condensing water requirements are considerably greater, as both the refrigerant and the impelling steam must be condensed.

The steam-jet system functions on the principle that water under high vacuum will vaporize at low temperatures. Steam-jet boosters or compressors of the type commonly used in power plants for various processes, will produce the necessary low absolute pressure to cause evaporation of the water.

A diagrammatic representation of a typical steam-ejector water-cooling system is shown in Fig. 6. The figures correspond to an average representative system. The water to be cooled enters the evaporator and is cooled to a temperature corresponding to the vacuum maintained. Because of the high vacuum, a small amount of the water introduced in the evaporator is flashed into steam. As this requires heat, and the only source of heat is the rest of the water in the evaporator tank, this other water is almost instantly cooled to a temperature corresponding to the boiling point determined by the vacuum maintained. The amount of water flashed into steam is a small percentage of the total water circulated through the evaporator, amounting to approximately 11 lb per (hr) (ton of refrigeration developed). The remainder of the water at the desired low temperature is pumped out of the evaporator and used at the point where it is required.

The ejector compresses the vapor which has been flashed in the evaporator, plus any entrained air taken from the circulated water, to a somewhat higher absolute pressure. The vapor and air mix with the impelling steam on the discharge side of the jet, and the total mixture then passes from the ejector into the condenser.

The slight amount of air which may be entrained in the cooled water is removed by a small secondary ejector that raises the pressure sufficiently so that the air can be discharged to the atmosphere. A secondary condenser is then necessary to condense the steam in the secondary jet.

While a single booster of smaller than 15 tons capacity is difficult to build, steam-jet vacuum-cooling units have been built for as small as 5 to 6 tons capacity. They can readily be built for steam pressures of from 5 to 200 psig, and condenser water temperatures as high as 90 F. The

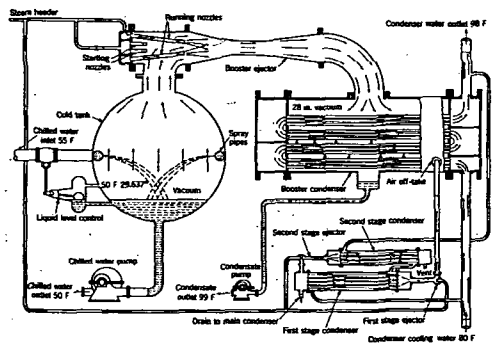

Fig. 6 . . . . Diagrammatic Arrangement of Steam-Jet Vacuum-Cooling Unit

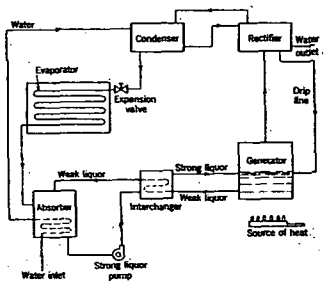

Fig. 7 . . . . Closed Absorption System

steam consumption in pounds per hour per ton of refrigeration increases rapidly as the booster steam pressure is lowered. For example, the lowering of the booster steam pressure from 200 to 90 psig results in an increase in steam consumption of approximately 5 percent, whereas a further decrease in booster steam pressure to 10 psig increases steam consumption by approximately 72 percent over that required at 200 psig.

The capacity of a steam-jet system is usually controlled by controlling the number of boosters in use since the unit usually has several boosters operating on the same evaporator. Usually one booster is automatically controlled, whereas the others are manually operated. The capacity is dependent, as for all compressors, upon the evaporator *temperature*, or in other words, the suction pressure. For example, the capacity is lowered approximately 17 percent if the evaporator or chilled water temperature is lowered from 50 to 45 F. The capacity therefore can be controlled to some extent by regulating the evaporator temperature.

The Absorption System

The absorption and mechanical compression cycles have in common the vaporizing and condensing of a liquid, but differ in that one has a compressor unit and the other an absorber-generator unit for producing the necessary pressure difference between vaporizing and condensing levels. Both cycles require energy for operation: mechanical energy for the compression cycle; heat for generation in the absorption cycle.

Thermodynamic analysis of absorption cycles is relatively complex and requires the use either of tables or graphs showing the equilibrium relationships and thermodynamic properties of the refrigerant-absorbent combination. Data of this kind are given in the first book in the bibliography. A discussion of various absorbents is given in the sixth book. Thermodynamically, the effectiveness of a refrigerant-absorbent combination increases directly with its negative deviation from Raoult's Law.

Fig. 7 shows a typical absorption cycle flow diagram. Cooling water first goes through the absorber (where it extracts the heat of absorption which is liberated by the refrigerant vapor as it goes into solution), then through the condenser, and finally through the rectifier. Refrigerant from the evaporator enters the absorber where it goes into solution in the absorbent; the high concentration solution is then pumped to the generator where heat is supplied; the refrigerant (with some absorbent vapor) leaves for the rectifier and the warm low concentration solution is returned to the absorber. In the rectifier selective condensation occurs, the concentration of the absorbent in the condensate being much greater than its concentration in the entering vapor mixture; rectifier condensate is dripped back to the generator.

Operating Cycle. The components of one form of lithium bromide water absorption system are illustrated in Fig. 8.

Diagram A shows two closed vessels, with salt (lithium bromide) solution in one and water in the other. The salt solution in the absorber has affinity for water vapor and evaporates some of the water. The water that remains in the evaporator is thus cooled by evaporation, thereby producing a refrigeration effect.

Since these two vessels operate under a high vacuum, chilled water temperatures down to 38 F may be obtained. To utilize the refrigeration effect, a coil is placed inside the evaporator as shown in diagram B. A pump circulates water from the evaporator tank to a spray header to wet the surface of the coil. The evaporation and cooling effect of the spray on the coil surface chills the water as it is circulated through the coil in a closed circuit to a refrigeration load.

In an actual operating cycle the salt solution is continu-

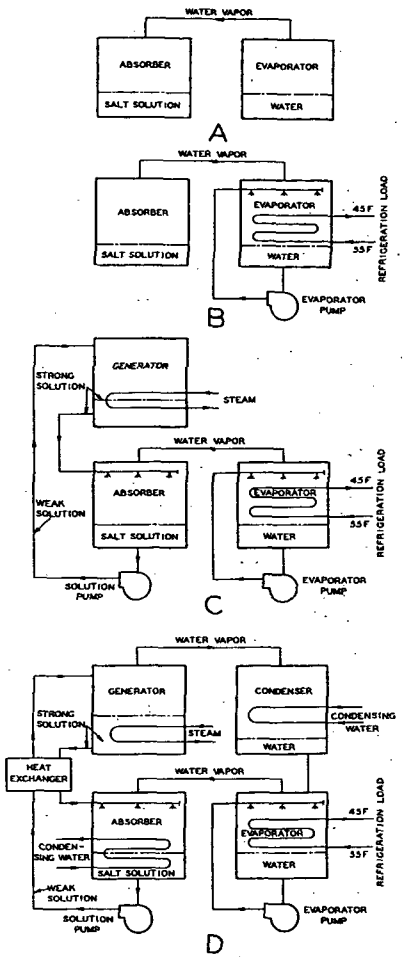

Fig. 8 .... Components of Lithium Bromide Absorption System

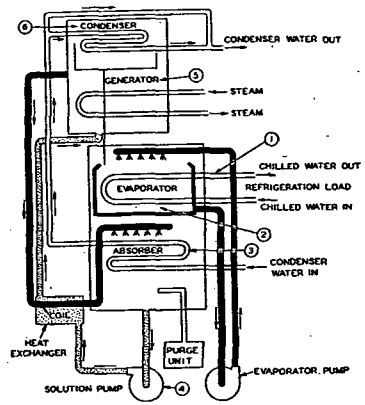

Fig. 9 .... Diagram of Lithium Bromide Water Absorption System

*ally absorbing water vapor, thus diluting the solution and reducing its ability to absorb additional water vapor. To keep the salt solution in the absorber at the proper strength a generator is added to the system as shown in diagram C. The weak solution is pumped from the absorber to the generator where heat is used to boil off the excess water vapor. The reconcentrated salt solution is then returned to the absorber to continue the cycle.

The water vapor boiled off in the generator is condensed and returned to the evaporator. A heat exchanger is added to the system (diagram D) to conserve heat in the cycle by using the hot concentrated salt solution from the generator to preheat the cooler weak solution from the absorber. Condensing water from a cooling tower or other available source is circulated through coils in the absorber and condenser to remove waste heat from the refrigeration cycle.

For the sake of simplification, the cycle is shown as operating with four separate chambers. In actual practice, the condenser and generator are combined into a *high pressure* shell, with the absorber and evaporator located in a second shell. Fig. 9 schematically shows the arrangement. A purge unit is included to remove any non-condensables from the machine, thus assuring maximum efficiency and capacity at all times.

Coefficient of Performance. The coefficient of performance (CP) of an absorption system using lithium-bromide and water is approximately 0.6. The heat required can be obtained from steam, hot water or other heated liquids.

Absorption type equipment is fully automatic from full load to no load. The performance does not vary greatly between 20 percent of capacity and full load. The operating costs of absorption equipment are considered competitive with those of other forms of refrigeration. For a typical lithium-bromide-water system, Figs. 10, 11, and 12 illus-

trate respectively the performance characteristics, the condenser water requirements, and the steam requirements.

BASIC REFRIGERATION EQUIPMENT

Compression Refrigeration Machines

Compression of the refrigerant gas drawn from the evaporator may be accomplished by one of several means. Positive displacement may be used as in the reciprocating; centrifugal force may be applied as in the centrifugal compressor; an ejector may be used as in the steam jet refrigeration cycle; or absorption of a low pressure refrigerant gas in a secondary fluid, followed by the absorbent's release upon application of heat, may be utilized. A detailed discussion of the equipment required for each of these types of systems is beyond the scope of this chapter. For a more comprehensive treatment, reference may be made to the bibliography. The present discussion is limited to positive displacement reciprocating compressors, and centrifugal compressors.

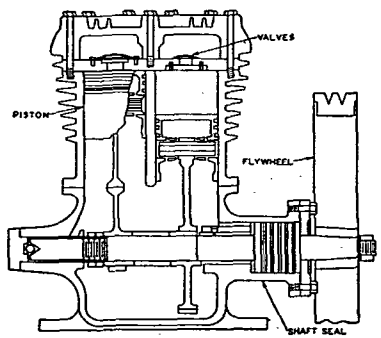

Fig. 13 .... Diagrammatic View of a Reciprocating Compressor

Reciprocating Compressors

Reciprocating compressors (see Fig. 10) may be classified according to (*a*) cylinder design, (*b*) compressor drive, (*c*) valves, and (*d*) lubrication and cooling.

Cylinder Design. Cylinder design may vary as to number, arrangement, and action (i.e., single-acting or double-acting). Single-acting compressors usually have their cylinders arranged vertically, radially, or in a V or W shape arrangement. Double-acting compressors, with refrigerant gas drawn in, and compressed on both the head and crank ends of the cylinder, are usually arranged horizontally. Reciprocating units are available with from one to sixteen cylinders with the V, W, or radial arrangements best adapted to the greatest numbers. The present trend is toward higher operating speeds with a low displacement per cylinder, together with an increase in the number of cylinders. Whereas the original reciprocating compressors were slow-speed (50 to 55 rpm) steam-driven devices, modern electric motor-driven compressors range up to 3500 rpm. Cylinder heads are usually bolted tight to the cylinders, but in some large compressors where there is danger of wet compression or of foreign materials entering the compressor space, a secondary head known as a safety head, may be seated at the end of the cylinder and held in position with heavy springs. Normally, this head remains stationary, but excessive pressures in the clearance space are relieved by movement of the safety head, and thus prevent damage to the cylinder.

Compressor Drives. Reciprocating compressors may be subdivided on the basis of source of motive power, and whether they are open or hermetic. Practically all modern compressors are electric motor-driven, although a few large, steam-driven compressors are still being installed where steam forms the most economical source of energy.

For summer air conditioning, the compressors may be driven by medium-speed heavy-duty internal combustion engines using natural gas as the fuel. Field tests indicated that fuel consumption of natural gas engine compressor drives is 13,000 Btu per ton-hour.

The natural gas engine compressor drives are designed as packaged units which combine engine speed variation and compressor cylinder unloading to meet fluctuating cooling requirements. Fuel consumption is in direct proportion to the actual cooling load throughout over 80 percent of the capacity range.

The division of compressors into open or closed types is dependent upon whether the motive power is received from an external source, or whether the motor is direct drive and sealed within the housing. In the open type, power is applied from an external source to one end of the compressor crankshaft extending through the crankcase, usually by means of a V-belt drive. The point of emergence of the shaft from the crankcase forms a weak point of refrigerant leakage, and is most frequently sealed with a bellows type crankshaft seal. Horizontal double-acting compressors operate with a sliding piston rod, moving back and forth through a stuffing box. If the motor is direct-drive and enclosed within the compressor housing, the compressor is classified as closed or hermetic. This eliminates the necessity of any shaft seal, and not only prevents refrigerant leakage at this point, but reduces operating noise. One disadvantage is the inaccessibility of moving parts for repairs, but lubrication is greatly simplified since both the motor and compressor operate in a sealed space containing the lubricating oil.

Compressor Valves. All refrigeration compressor valves are dependent for their operation upon a difference in pressure between the inside of the cylinder and the suction or discharge line. Although mechanically-operated valves might have some advantage, they have proved unsatisfactory because each change in the evaporator or condenser-operating pressures requires a change of valve setting. The pressure differentials required for operation of the valves depend upon the valve design and the compressor speed. The suction and discharge valves may be arranged with both located in the compressor head, or with the suction valve on the top of the piston and the discharge valve in the compressor head (uniflow arrangement). The valves themselves are usually classified as either poppet, ring-plate, or flexing.

Lubrication and Cooling. Lubrication of modern compressors is accomplished by either splash lubrication or forced lubrication. The latter is used on large compressors, while simple splash lubrication is used in the smaller units.

Large compressors are usually water-cooled with the water jacket either cooling the cylinder walls, or both the cylinder walls and the compressor head. Small compressors are either water-cooled or air-cooled with extended finned surfaces cast on the exterior of the cylinder. In a few cases small compressors may be found in which there is no attempt to add any purposive cooling other than through non-finned surfaces to the lower temperature air.

Water cooling is more effective than air cooling, but even under the best conditions cylinder cooling removes only a portion of the superheat in the refrigerant gas. This removal of heat from the cylinder results in some decrease in the work of compression, as well as reduction in condenser load.

Control of Reciprocating Compressors

Capacity Control of reciprocating compressors to match the imposed load is accomplished by a controller responding to load variations, and operating one of the several means for changing the compressor capacity. This controller may respond to the condition being controlled, such as space temperature in the case of a direct-expansion system, or water temperature in the case of a water chiller; or it may respond to suction pressure, which varies with the imposed load. The common methods of varying the compressor capacity are:

1. *Starting and stopping the compressor.* This is more common on small units where frequent cycling of the compressor offers no serious complications. On large installations two or more smaller compressors may be employed and these may be started and stopped in sequence, thus providing more capacity steps: Sequence control of multiple compressors is accomplished by the use of a program or step controller, and in most cases this is arranged to return to the off position when the system is shut down or in the event of power failure, and to provide a suitable time delay between steps on start-up to prevent the full electrical load from being thrown across the line at one time. Means for manually or automatically varying the sequence to equalize wear on the compressors are sometimes employed.

2. *Cylinder Unloaders.* These usually are available on all but the smaller compressors and are used on both single and multiple compressor installations. They consist of a device built into the cylinder head to hold the suction valve open for unloading the cylinder. Oil pressure or head pressure is applied to these devices to load the cylinders, hence the compressor always starts at minimum capacity. Depending upon the make of compressor, the application of pressure to the unloaders is accomplished by:

a. Solenoid valves usually operated by the program controller in sequence with starting and stopping of the compressor or compressors. The program controller starts the compressor at minimum capacity, then loads the cylinders in sequence as the demand increases. If more than one compressor is used, it starts and loads the second compressor in sequence after the first is fully loaded, etc.

b. A self-contained stepping valve built into the compressor and actuated by a bellows measuring suction pressure. This valve is supplied with oil pressure from the compressor oil pump and has an oil outlet connection to each cylinder unloader. This valve supplies oil pressure to, or releases it from, the cylinder unloaders progressively as the suction pressure increases or decreases. The suction-pressure bellows is opposed by a spring which has an external manual adjustment for selection of the desired operating range. The other side of the bellows may be open to atmosphere so that the suction pressure is controlled with reference to atmospheric pressure, or it may be sealed and provided with an air connection which permits variation of the operating range as a function of air pressure from a pneumatic controller. For example, if the spring is so adjusted that the basic operating range is 35 to 40 psi suction pressure when the pressure from the pneumatic controller is zero, it will be increased to 45 to 50 psi when the control pressure is 10 psi. Thus these self-contained cylinder unloaders not only can control the suction pressure within a fixed range, but this range can be moved up or down automatically to meet the varying demands on the system. Pneumatic controllers used for this purpose often are supplied with air pressure up to 25 psi to permit a wide range of suction pressure variation. Most of these self-contained cylinder unloaders also can be arranged for mechanically varying the suction pressure by means of an electric motor operator acting against the manual adjustment spring to permit the use of proportional electric or electronic controls.

3. *Speed Control.* Multi-speed motors are sometimes used, actuated by a multi-stage thermostat or a proportional thermostat and a program or step controller.

Safety Controls are provided on reciprocating compressors to stop the motor whenever certain conditions are outside of safe limits. These conditions include:

1. *Low Suction Pressure.* This is a pressure controller responsive to the suction pressure. It stops the compressor when the suction pressure drops below a safe limit. It is sometimes also used as a capacity control, as described in preceding section, paragraph numbered 1, when it is desired to start and stop the compressor in accordance with the load demand as determined by changes in suction pressure. When other means are provided for starting and stopping the compressor in accordance with load, the low-pressure control functions solely as a safety device.

2. *High Head Pressure.* This is a pressure controller responsive to the high-side pressure. It stops the compressor when the high-side pressure exceeds a safe limit. This is strictly a safety device and frequently is of the manual-reset type so that the compressor cannot again start until the reset button is manually operated. In many cases the high- and low-pressure switches are combined into a single unit.

3. *Low Oil Pressure.* This is a pressure controller which stops the compressor in the event of low oil pressure. It also is frequently of the manual-reset type.

4. *Low Line Voltage.* This is a low-voltage cutoff which stops the compressor when the line voltage drops below a minimum value.

5. *High Motor Current.* This may be built into the motor or into the motor starter. It stops the motor in the event excessive current persists for more than the brief interval required in starting.

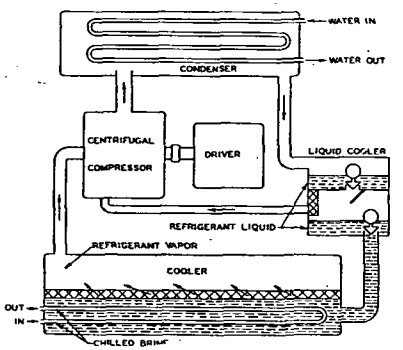

Fig. 14 .... Enclosed-Type Centrifugal Condensing Unit

6. *High Pressure Relief.* This is a device for preventing damage if excessive head pressures are encountered, and provides protection from damage beyond that provided by the high-pressure cutout. It may be a relief plug which blows out in the event of excessive pressure. This has the disadvantage of losing the entire refrigerant charge. A relief valve, which functions like a pop-safety valve, is preferred since it wastes only enough refrigerant to relieve the danger.

7. *Low Water Temperature.* If the compressor is used for chilling water, a low-limit thermostat usually is installed in the chiller to stop the compressor in the event a freezing temperature is approached. This is in addition to a controlling thermostat which also may respond to water temperature.

Centrifugal Compressors

Centrifugal compressors are used with very low pressure refrigerants; sometimes both evaporator and condenser work below atmospheric pressure. Trichlorotrifluoroethane ($C_2Cl_3F_3$) and monofluorotrichloromethane (CCl_3F) are the refrigerants commonly used in centrifugal machines.

Centrifugal compressors, like reciprocating compressors, can be divided into two general types, open and enclosed. In general, the open-type compressor is geared to the driving mechanism, and operates at higher speed than the driving

motor or turbine. A modern, completely enclosed, direct-driven centrifugal compressor is illustrated in Fig. 14.

Compression of the refrigerant is accomplished by means of centrifugal force; therefore, this type of compressor is inherently suitable for large volumes of refrigerant at low pressure differentials. Two or more stages are usually required and high speeds are necessary to obtain good efficiency.

The evaporator is usually constructed as an integral part of the centrifugal-type condensing unit, to chill water which is then circulated to the air-conditioning system. This is done because it would not be economical to pipe these large volumes of refrigerant any distance.

Centrifugal refrigeration compressors are particularly well suited to direct steam-turbine drive because of their high operating speed. Water cooling equipment of one design is operated between 3500 and 4000 rpm for units developing 1000 to 2000 tons capacity, and from 7000 to 8000 rpm for units developing 100 to 200 tons capacity. However, a great many applications, particularly in the smaller sizes, are electric motor-driven and equipped with standard gear-type speed increasers. Centrifugal systems are particularly well adapted to large capacities (up to 3000 tons) although it is also possible to secure units as low as 50 tons in rating. Because centrifugal units operate best with refrigerants possessing a high specific volume, and because of the simplification of lubrication difficulties, they are frequently used for extremely low temperature applications. They are adaptable to a wide range of temperatures from —130 F to 50 F. One important advantage is their flexibility under varying loads, since units may be designed to operate with reasonable efficiency at capacities as low as 20 percent of normal load.

Control of Centrifugal Compressors

Capacity Control usually is accomplished by a controller actuated by the chilled water temperature or evaporator pressure and either (1) varying the flow of vapor from the chiller to the compressor or (2) varying the compressor speed.

1. *Vapor flow control* for compressors driven by constant-speed motors is accomplished by the use of suction dampers or inlet vanes which are positioned by automatic operators to maintain constant water temperature leaving the chiller or constant suction pressure in the evaporator.

2. *Speed Control* for compressors driven by constant-speed motors may be accomplished through the use of an eddy current clutch or a hydraulic coupling under control of an automatic operator. Variable-speed motors for speed control are more common on the larger machines. Steam turbines for driving compressors can operate at various speeds under control of an automatic valve in the governor oil circuit.

Safety Controls provide protection for the compressor by stopping the motor or reducing the capacity through the capacity-control system. Those which usually stop the motor are similar to those described for reciprocating compressors and respond to (1) low oil pressure, (2) low refrigerant temperature, (3) low chilled water temperature, (4) high condensing temperature, (5) high motor temperature, (6) high motor current, and (7) low line voltage. Frequently controls are used that are actuated by some of these conditions to reduce capacity before the limit is reached in order to prevent system shutdown.

In addition to the above safety-controls most centrifugal machines have thermostatically controlled heating and cooling of the oil, and some have water-cooled motors with the water sometimes thermostatically controlled. Usually there is a system of interlocks which prevents the compressor from starting unless the condenser water pump and the chilled water pump are running.

Condensers

Condensers used for liquefying the refrigerant are of three general types: (1) air cooled, (2) water cooled, and (3) evaporative.

1. *Air-Cooled Condensers* are readily available in unitary equipment in capacities up to 20 tons of refrigeration. They are also available as separate assemblies for field-assembled systems in capacities up to over 100 tons per condenser. Air-cooled condensers first became popular on self-contained room air conditioners and they are now used almost exclusively on this type of equipment. The use of air-cooled condensers for larger equipment was introduced only recently but is rapidly gaining in usage where an adequate water supply is costly to obtain or where other water problems are encountered.

The conventional air-cooled condenser consists of an extended-surface coil across which air is blown by a fan. The hot discharge gas enters the coil at the top and, as it is condensed, flows to a receiver located below the condenser. Air-cooled condensers should always be located in a well ventilated space so that the heated air may escape and be replaced by ambient temperature air.

When adequate supply of city or acceptable well water is readily available at a moderate cost, it is still the preferred condensing medium. However, where some form of water saving is required, the air-cooled condensers are rapidly gaining favor over the cooling tower and evaporative condenser methods in the smaller and medium tonnage classes. Where some form of water saving is required, the capacity of the equipment, under the design conditions of higher wet-bulb weather in the case of cooling towers and evaporative condensers and higher dry-bulb in the case of air-cooled condensers, must be taken into account. The air-cooled condensing equipment does have a higher peak current demand per ton over the cooling tower and evaporative condenser methods, but there is some evidence that in actual installations, it does not have any materially higher seasonal power consumption per ton than the other methods of water saving in the warm-humid and hot-humid areas. The principal advantages of the air-cooled condensers are low installation costs, lower maintenance costs and simplicity, and for these reasons they are used almost exclusively in small self-contained units and frequently in the larger sizes of compression refrigerating equipment.

2. *Water-Cooled Condensers* are commonly used with compressors of one horsepower or larger in size, and they are found almost exclusively on large installations. Although water-cooled condensers may be of many designs, the shell-and-coil and the shell-and-tube are most commonly found in present day practice.

The amount and temperature of the condensing water determine the condensing temperature and pressure, and indirectly the power required for compression. It is therefore necessary to determine a balance so that the quantity of water insures economical compressor operation.

City water is often used as the condensing medium in the smaller capacities providing an adequate water supply and means for its disposal are available, its cost is not prohibitive, and there are no restrictions against its use.

Because there is a decided trend toward restricting the use of city water for air conditioning and refrigeration purposes, cooling towers are almost universally used with water-cooled condensers in the larger sizes. Since cooling towers produce the warmest condensing water during periods of greatest load, the refrigeration equipment must be designed to meet the maximum load at abnormal condensing water temperature. This makes little difference in efficiency of operation except at those times when the condensing water temperature is highest. In many localities this occurs for only about 5 per cent of the entire cooling period and can be disregarded as a factor in establishing yearly operating costs. Further information on cooling towers is contained in Chapter 40.

3. *Evaporative Condensers* provide another means of conserving water used for condensing purposes. In effect they combine the condenser and cooling tower in a single unit.

The fan draws air over the condenser coil which is kept wet by a water spray.

Evaporative condensers are made in sizes up to 300 tons or more. They must be located where air is available and usually at not too great a distance from the compressor to avoid long refrigerant lines. Like cooling towers they result in least efficiency at periods of maximum load. Chapter 40 provides additional information on evaporative condensers.

Evaporators and Coolers

Refrigeration evaporators must be designed for efficient removal of heat from the medium being cooled, as well as effective boiling of the refrigerant and a minimum drop of pressure through the coil. There are two general types of evaporators, dry and flooded. In the dry evaporator the refrigerant enters in the liquid state, and the design provides for complete evaporation with the vapors leaving slightly superheated. In flooded evaporators not all of the refrigerant is evaporated, the liquid-vapor mixture leaving the evaporator flows into a surge drum from which the vapors are drawn into the compressor suction line, and the liquid is recirculated through the evaporator.

The types of coolers used in connection with air-conditioning work fall into three general groups: (1) direct water coolers, (2) direct air coolers, and (3) brine coolers for circulation of the brine in a closed system, and thus cooling indirectly either water or air.

1. *Water coolers*. One method of the direct cooling of water is to install direct expansion coils in the spray chamber so that the water sprayed into the air comes in direct contact with the cooling coils. Another common and efficient method of cooling spray water is to use a Baudelot type of heat absorber where the water flows over direct expansion coils at a rate sufficiently high to give efficient heat transfer from water to refrigerant.

Another type of spray-water cooler is the shell-and-tube heat exchanger in which the refrigerant is expanded into a shell enclosing the tubes through which the water flows. The velocity of the water in the tubes affects the rate of heat transfer, and as the refrigerant is in the shell completely surrounding the tubes at all times, good contact and a high rate of heat transfer are insured. The disadvantage of such a system is that with the falling off of load on the compressor, the suction temperature or the temperature in the evaporator drops, and there is a possibility of freezing the water in the tubes, which, of course, might split the tubes and allow the refrigerant to escape into the water passage. This danger can be eliminated by automatic safety devices.

Another system of cooling spray water is to submerge coils in the spray-collecting tank, or in a separate tank used for storage. The heat transmission through the walls of the coils, however, is low and a great deal more surface is required than for any other type of cooler. However, with large storage tanks this type of cooling can be utilized to advantage.

2. *Air coolers*. When direct cooling of air is employed, the refrigerant is inside the coil and the air passes over it. Cooling depends upon convection and conduction for removing the heat from the air. The type of coil used can be either smooth or finned, the finned coil being more economical in space requirement than the smooth coil. The fins, however, must be far enough apart so as not to retain the moisture which condenses out of the air.

When refrigeration evaporators are used for cooling air or other gases by forced convection, they are usually termed blast coils or unit coolers. A blast coil may be placed in a duct or in an assembled unit, and the air forced across the coil and discharged through distributing ducts or directly into the space to be conditioned. Unit coolers, designed much like unit heaters, consist of a finned coil, propeller fan, and controls suspended directly in the space to be cooled.

3. *Indirect brine coolers*. The indirect cooler, where brine is cooled by the refrigerant and the resulting cold brine is used to cool either air or water, introduces several other considerations. It is not the most economical from a power consumption standpoint, as it is necessary to cool the brine to a temperature sufficiently low so that there is an appreciable difference between the average brine temperature and that of the substance being cooled. This requires that the temperature of the refrigerant must be still lower, and consequently the amount of power required to produce a given amount of refrigeration increases due to the higher compression ratio. There are other considerations which make such a system desirable. In the first place, where a toxic refrigerant is undesirable or cannot be used because of fire or other risks, especially in densely populated areas, the brine can be cooled in an isolated room or building and can then be circulated through the air-conditioning equipment. This arrangement eliminates any possibility of direct contact between the air and refrigerant.

REFRIGERATION CONTROL

Expansion Devices

In addition to means of controlling the compressor capacity and the necessary limit and safety controls as outlined under the section describing the compressors, reciprocating compressor refrigeration systems require a device for controlling the expansion of the refrigerant from the high liquid pressure to the low evaporator pressure.

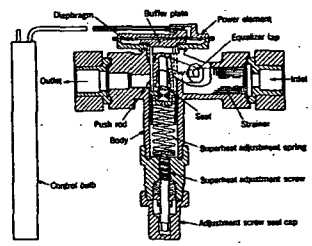

Fig. 15 .... Typical Thermostatic Expansion Valve

Automatic Expansion Valves. An automatic or pressure-controlled expansion valve operates to maintain a constant pressure in the evaporator. The liquid refrigerant passes through an orifice, the opening size of which is controlled by means of a needle valve connected to a flexible bellows. This bellows expands or contracts with variations in the evaporator pressure transmitted to the expansion chamber through the refrigerant outlet from the evaporator. The position of this needle valve is controlled by the degree of compression in an adjusted spring, balanced against the bellows, and these two forces operate to maintain a constant pressure in the evaporator by increasing or decreasing the flow of liquid refrigerant. Such an expansion valve is usually applied to evaporators of the direct-expansion type, but is not satisfactory for fluctuating loads such as are encountered in air-conditioning installations.

Thermostatic Expansion Valves. A thermostatic expansion valve controls the flow of liquid refrigerant to the evaporator so as to maintain the entire coil filled with evaporating refrigerant, and to keep a constant superheat in the refrigerant gas leaving the coil. The construction of such a valve is shown in Fig. 15 and is similar to that for an automatic expansion valve but incorporates, in addition, a power element responsive to changes in the degree of superheat of the refrigerant gas leaving the coil. This power element consists of a bellows connected by means of a capillary tube to a feeler bulb fastened to the suction line from the evaporator. The bulb, bellows, and tube are usually charged with the same liquid refrigerant used in the evaporator itself. A starved condition in the evaporator results in a greater superheat in the gas leaving the

evaporator, and this in turn operates through the power element to increase the flow of liquid refrigerant. A flooded evaporator reduces the discharge superheat, and thus tends to reduce the flow of liquid refrigerant. Such an expansion valve is satisfactory for operation with fluctuating loads since this type of control tends to keep the evaporator filled with refrigerant at all times.

Low-Side Float Valves. A liquid refrigerant control of the low-side float valve type consists of a ball float located in either a receiver or the evaporator itself on the low-pressure side of the system. A needle valve, operated through a simple lever mechanism attached to the float, permits the passage of more or less refrigerant, as the level in the receiver or the evaporator fluctuates. Such a control must be used in conjunction with a flooded evaporator, and has been applied extensively to household refrigerators and, to some extent, in commercial and industrial installations.

High-Side Float Valves. A high-side float valve differs from a low-side float valve in that the float is located in a receiver or container on the high-pressure side of the system. Proper operation again depends upon metering of the refrigerant through a controlled opening, depending upon the level of the liquid refrigerant in the container. Such a control has the disadvantage that the evaporator must be placed directly adjacent to the float container, or some intermediate pressure device must be applied to prevent flashing of the refrigerant upon pressure drop.

Capillary Tubes. A capillary tube may be used as a liquid refrigerant expanding device. Such a device consists of an extremely small bore tube (in the order of 0.04 inch in diameter) of five to twenty feet in length. Although such a restricting device operates as a very simple means of expanding the liquid refrigerant, it has the disadvantage that no modifications are possible to adjust the rate of expansion under various operating conditions. The bore and length of the tube, as well as the proportions of the rest of the system, are critical. It is for these reasons that its application has been limited to factory-assembled domestic and commercial units.

Refrigerant Flow Control

The capacity of the refrigeration system must be controlled in accordance with the load imposed on the system. Except for those cases where the compressor is started and stopped by a thermostat responding to load conditions, some form of control of the refrigerant flow is usually required. Controlling the flow of refrigerant in accordance with the load may be accomplished in a number of ways, some of which are:

1. *Solenoid valves* are frequently used for control of gas or liquid flow. A solenoid valve is placed in the liquid line ahead of the expansion valve. It is closed whenever the compressor is not in operation and thus leakage into the evaporator is prevented. In most cases it is controlled by a thermostat responding to the load. Solenoid liquid valves are widely used for control of refrigerant flow to individual evaporators in a multiple evaporator system operated by one compressor. The compressor capacity is controlled separately by a controller responding to suction pressure. Solenoid liquid and suction valves are sometimes used to isolate an evaporator completely for defrosting purposes.

When solenoid liquid valves are used for controlling refrigerant flow, a *pump-down cycle* of control is often employed. The thermostat closes the solenoid liquid valve and the compressor then pumps down until stopped by the low-suction pressure switch. The compressor cannot restart until the thermostat again opens the solenoid liquid valve.

2. *Expansion Valve Modulation.* This form of flow control utilizes the throttling characteristics of the expansion valve to starve the coil under reduced-load conditions. This may be accomplished by a device attached to the expansion valve or a pilot control which varies the setting of the expansion valve by changing the pressure in the equalizer line. Either of these are actuated by a controller sensitive to load conditions and the compressor capacity control is from suction pressure. Since short-cycling of the compressor is apt to occur if the flow of refrigerant is reduced too much, some limit to prevent this is required.

3. *Evaporator Pressure Control* is accomplished by back-pressure valves. These are placed in the suction line between the evaporator and the compressor, and maintain the evaporator pressure constant by regulating the amount of vapor drawn from the evaporator. The compressor capacity is controlled from suction pressure at the compressor. The use of back pressure valves permits a lower pressure at the compressor than would be permissible at the evaporator, thus minimizing short-cycling. On a multiple-evaporator system served by one compressor, the evaporators may be maintained at different temperatures. Back pressure valves can be equipped with an air connection for automatically varying the evaporator pressure in accordance with the demands of a pneumatic controller. Means for mechanically readjusting the valves by use of a proportioning electric operator also are available.

Condenser Control

The majority of refrigeration systems, other than fractional horsepower, use water-cooled rather than air-cooled condensers. Condenser control is used for the purpose of conserving water or limiting the condenser pressure, or both. Solenoid water valves on small compressors, or pneumatic or electric valves on larger compressors, are usually controlled simultaneously with starting or stopping of the compressor. A pressure-operated valve will provide proportional control of water flow in response to condenser pressure. Similar water valves controlled thermostatically by the temperature of water discharged from the condenser are sometimes used. Evaporative condensers may be controlled by an automatic damper responding to a condenser-pressure controller. Cooling tower fans sometimes are started and stopped by a thermostat in the condensing water or a pressure controller in the condenser. Some form of freeze protection for evaporative condensers and cooling towers is necessary if they are required to operate in cold weather.

Refrigeration Control for Air Conditioning

When refrigerating equipment is used for space cooling, two major control problems exist: one is control of the temperature and the other, control of the humidity. In some applications the amount of latent heat to be removed is small compared with the sensible heat. In such cases, sufficient dehumidification will usually occur without any special provisions. In other cases, such as theaters, where the latent load is relatively high, the air must be cooled below its dew-point temperature, and sometimes rewarmed to return it to the comfort range. Refer to Chapter 43 for general information on the subject of controls and for applications relating to air-conditioning systems.

REFRIGERATION PIPING

The pressure drop which occurs during passage of the refrigerant through connecting piping is similar in effect to that which occurs through suction and discharge valves of the compressor. Thus, the effect of the pressure drop in the suction line between evaporator and compressor requires that a lower pressure be maintained inside the compressor during suction than is maintained in the evaporator. The pressure drop through the connecting piping between the compressor and condenser requires that a higher pressure be maintained inside the compressor during discharge than in the condenser. These losses result in a greater compression ratio, and therefore greater power requirements, as well as a lower volumetric efficiency and higher displacement requirements. Pressure losses in the liquid line between condenser or receiver and the expansion valve may result in some flashing of the liquid refrigerant, unless the liquid is subcooled. In all cases, friction losses should be kept to a minimum, and piping should be selected which will give the smallest loss consistent with overall economy in the system.

Table 5 .... Dichlorodifluoromethane* (CCl_2F_2) Liquid Lines, Tons Capacity per 100 Ft Equivalent Length

Line Size, Inches	Pressure Drop per 100 Ft Equivalent Length, Psi			
	3	5	10	20
⅜ OD	0.88	1.14	1.80	2.58
½ OD	2.89	3.64	5.56	8.50
½ IPS	4.86	6.81	10.2	15.8
⅝ OD	4.86	6.81	10.2	15.8
¾ IPS	9.73	12.6	18.5	27.0
¾ IPS	9.73	12.6	18.5	27.0
⅞ OD	10.5	14.1	21.8	33.0
1 IPS	21.4	28.2	41.3	60.8
1⅛ OD	21.4	28.2	41.3	60.8
1¼ IPS	36.9	48.1	70.5	101.
1⅜ OD	36.9	48.1	70.5	101.
1½ IPS	62.0	80.2	114.	160.
1⅝ OD	62.0	80.2	114.	160.
2 IPS	124.	161.	231.	328.
2½ IPS	230.	297.	426.	607.
3 IPS	364.	469.	676.	972.
3½ IPS	539.	704.	1005.	1430.
4 IPS	753.	972.	1385.	1945.

Note: Tonnage values above those underlined give velocities of 300 fpm or less.
*Refrigerant 12.

Refrigerant liquid lines from the receiver to the expansion valve should preferably be designed with a pressure drop of less than 5 psi, and with 10 psi as the maximum. A velocity of 100 to 250 fpm is recommended to prevent a pressure drop great enough to cause vaporization of the refrigerant ahead of the expansion valve. If the evaporator is to be located at a higher elevation than the condenser or receiver, account should be taken of the pressure drop for each foot of static liquid lift. Approximate values are 0.26 psi per foot for ammonia, 0.57 psi per foot for dichlorodifluoromethane, 0.51 psi per foot for monochlorodifluoromethane, and 0.64 psi per foot for monofluorotrichloromethane. Where there is a possibility of vaporization of some of the liquid before reaching the expansion valves, means for subcooling should be provided.

Since a reduction of suction pressure at the compressor results in an appreciable reduction in capacity and more power input per ton of refrigeration, great care should be given to the proper sizing of suction lines between the evaporator and the compressor. Although comparatively high velocities, 500 to 5000 fpm, may be used, the optimum value will depend upon the refrigerant and the operating-pressure range. Since return of the oil to the compressor must be considered in the case of the fluorinated hydrocarbons and methyl chloride, for these refrigerants the minimum velocity should be 500 fpm for horizontal runs and 1000 fpm for vertical runs. For the former, the usual design velocities range between 1000 and 2000 fpm. Too high velocities create noise problems and excessive pressure drops. The total pressure drop in the suction line should be between one and two psi, if the velocity can be kept within the specified limits.

* Refrigerant 12.

Compressor discharge or hot gas lines may be designed with velocities from 1000 to 5000 fpm, except for dense gases such as carbon dioxide, where noise considerations will reduce the upper limit. A pressure drop of 2 to 4 psi is recommended for the discharge lines. Extensive tables are available in the literature for the determination of pressure drops through refrigerant lines with various refrigerants. The capacities listed in Tables 5, 6, and 7 are published in *ARI Equipment Standards* 520 (1946), of the Air-Conditioning and Refrigeration Institute, and are used by permission. Table 5 shows the tonnage capacity normally allowed for CCl_2F_2 liquid lines per foot equivalent length of pipe, and Table 6, the maximum tonnage for suction

and discharge CCl_2F_2 lines. Table 7 presents suction-line capacity factors for equal pressure drop.

ACCESSORIES

Dehydrators, oil separators, strainers, vibration eliminators, sight glasses, and various types of valves are accessories frequently needed for the proper installation and operation of refrigeration systems. Refrigerant-line dehydrators or dryers usually consist of copper containers fitted with tubing connections at either end, and contain a desiccant such as silica gel, activated alumina, or calcium chloride. The liquid refrigerant is circulated through the dryer during operation of the system, and the moisture content of the refrigerant charge is thus kept to a minimum.

Oil separators are installed between the compressor and condenser to prevent excessive oil removal from the compressor crankcase and its passage into the condenser and evaporator. The oil is separated from the gaseous refrigerant by gravity during its passage through a chamber of sufficient size to reduce the velocity. A float-operated valve maintains a maximum oil level in the separator, and additional oil is forced by pressure difference through a line back to the crankcase.

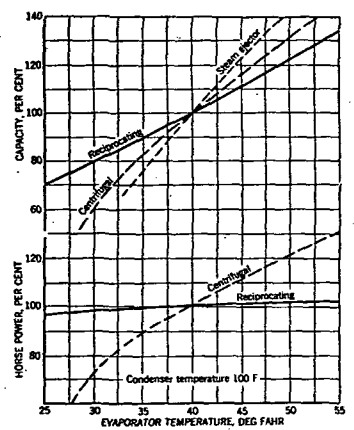

Fig. 16 .... Performance Characteristics of Compression Refrigeration Machines at Constant Speed

Screen strainers are frequently installed in the liquid line piping before solenoid valves and expansion valves, as well as before regulating valves in water lines leading to water cooled condensers. Sight glasses that permit visual inspection of the condition of the refrigerant are sometimes installed on factory-assembled commercial unit systems. It is particularly advisable to place such a fitting before the expansion valve, if the evaporator is located above the condenser.

Flexible vibration eliminators, usually consisting of a bellows design covered with woven copper wire, are sometimes installed in copper lines where units such as compressors are installed on flexible mountings, or where vibration is otherwise a problem. Packed or packless shut-off valves are necessary where it may be required to isolate portions of a system.

EQUIPMENT CHARACTERISTICS AND SELECTION

The various types of compression systems have quite different characteristics of capacity and power with varying evaporator and condenser temperatures, as may be noted from curves in Figs. 16 and 17.

From Fig. 16 it may be observed that power requirements for the centrifugal compressor increase much more rapidly than for the reciprocating compressor, with increase in evaporator temperature. Similarly, the capacities of the steam ejector and centrifugal compressors increase more rapidly than those of the reciprocating compressor with increase in evaporator temperature. Thus, both the steam-jet and centrifugal machines tend to be more self-regulating than the reciprocating. It is also evident from Fig. 16 that the steam-jet equipment is best suited for operation at high evaporator temperatures.

The effect of condenser temperature upon the power and capacity of the different types of compressors is shown in Fig. 17. It may be noted that the power required by the

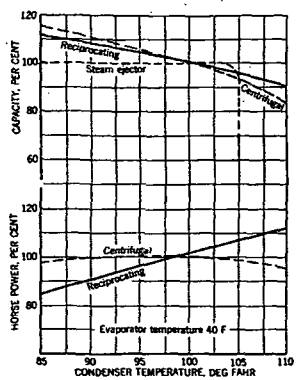

Fig. 17 .... Performance Characteristics of Compression Refrigeration Machines at Constant Speed

Table 8 .... Basis of Equipment Selection

Capacity Tons	Majority Used	Some Used	Few Used
0 to 10	Unit systems in conditioned space.	Unit central systems using duct distribution.	Built-up central systems.
10 to 25	Unit central systems using duct distribution.	Unit systems in conditioned space.	Built-up central systems using reciprocating compressors, adsorption, and absorption systems.
25 to 100	Built-up central systems using reciprocating compressors.	Unit central systems using duct distribution.	Central systems using adsorption systems or centrifugal refrigeration.
100 to 200	Built-up central systems using reciprocating compressors.	Built-up central systems using absorption and centrifugal compressors.	Built-up central systems using steam jet.
200 and Over	Built-up central systems using centrifugal compressors.	Built-up central systems using steam jet or absorption systems.	Built-up central systems using reciprocating compressors.

reciprocating compressor increases rapidly with increase in condenser temperature, while the power curve for the centrifugal compressor is relatively flat. It is also evident that the capacity of the steam-jet compressor is independent of condenser temperature until a certain point is reached, where it drops to zero. As previously stated, steam-jet equipment requires more condensing water than other types of compression systems. Consequently, steam-jet systems are well suited to those applications where condensing water is cheap, or where condensing water is rather high in temperature.

The selection of proper refrigeration equipment for any air-conditioning job is of utmost importance for satisfactory results. The most important factors in the selection of the equipment are:

1. Loads (as determined by the conditions of the space to be cooled).
2. Economics (both initial and operating costs).
3. Codes (local safety codes must be adhered to and influence the type of system to be used).

A broad division of equipment to be used for a particular installation or application may be made on the basis of the magnitude of the load. Current general practice is outlined in Table 8.

Unit or *packaged* systems, consisting of a reciprocating compressor, condenser, evaporator, and fans, are generally used in the smaller sized jobs where electric power is available, as they are manufactured complete, ready to install, and are the most economical (See Chapter 16).

The reciprocating compressor in the built-up central system (see Chapter 19) covers the widest range of application since it is applicable to either the direct-expansion or indirect systems, and can be driven by steam or gas engines, or by electric motors. The quantity of condensing cooling medium required is also less than for any other system, with the exception of the centrifugal compressor, which uses the same amount.

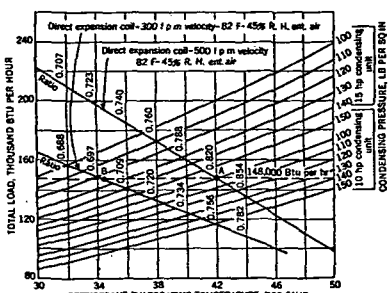

Fig. 18 .... Compressor and Coil Performance

Table 9 .... Typical Operating Conditions for Two Types of Load

Type of Enclosure	Load Btu per Hr.	Ratio Sensible to Total Heat	Air Entering Coil		Operating Balance Point		
			Temp. F	Rel. Hum. %	Evaporator Temp. F	Condenser Pressure Psi	Sensible Heat %
Restaurant							
Sensible	103,000						
Latent	45,000						
Total	148,000	0.695	82	45	34.4	123	69.9
Office							
Sensible	121,000						
Latent	27,000						
Total	148,000	0.820	82	45	42.2	100	82.1

Centrifugal compressors are used for large installations, and usually where the indirect system is required. The driving mechanism can be a steam turbine or electric motor. The steam-jet system is used where steam is available and cooling water can be had in large quantities.

It will be noted by referring to Fig. 16 that all systems using compressors have a common characteristic, namely, that the capacity varies with the evaporating temperature. Not only can the equipment be selected to produce a given result, but the performance can be predicted under varying load conditions by the simple expedient of using the variable of evaporating temperature as the abscissa, and the load or capacity as the ordinate in a series of curves.

Manufacturers of compressors and cooling coils furnish performance data for apparatus that can be plotted in the form of curves similar to those shown in Fig. 18. The performance of a compressor is plotted as a series of curves, each curve being drawn for a given condensing pressure. The performance of a direct-expansion coil at two different air velocities is plotted on the same graph. The operating point will be, of course, where the two curves cross.

Data given in Table 9 illustrate two types of conditioned enclosures having the same total load of 148,000 Btu per hour, but with two different ratios of sensible to total heat. In the case of the office with a ratio of 82 percent sensible to total heat, the operating point *A* in Fig. 18 is found to be 42.2 F evaporating temperature, with a face velocity of 500 fpm. In the case of the restaurant, with a ratio of 69.5 percent sensible to total heat, the air velocity is lowered to 300 fpm, and the evaporating temperature is lowered to 34.4 F as shown in point *B* of Fig. 18. In order to obtain the same capacity, a larger condensing unit is used. This illustration assumes zero pressure drop through the suction line. The pressure drop can be taken into account by shifting the compressor performance curves by the amount of pressure drop expressed in Fahrenheit degrees.

CHAPTER 39

THE HEAT PUMP

History and Development; Basic Circuits; Fundamentals; Types; Heat Sources and Sinks; Performance Characteristics; Temperature Levels; System Balance; Seasonal Performance; Annual Operating Cost; Components; Application; Criteria for Feasibility; Design and Selection; Systems for Larger Buildings; Sensible, Latent, and Low-Side Heat Storage

THE term *heat pump* as applied to a year-round air-conditioning system, commonly denotes a system in which refrigeration equipment is used in such manner that heat is taken from a *heat source* and given up to the conditioned space when heating service is wanted, and is removed from the space and discharged to a *heat sink* when cooling and dehumidification are desired. The thermal cycle is identical with that of ordinary refrigeration, but the application is concerned alike with the cooling effect produced at the evaporator and with the heating effect produced at the condenser. In some applications, both the heating and the cooling effects obtained in the cycle are employed simultaneously.

The heat-pump principle is also applied for purposes other than air conditioning, such as: supply of domestic hot water in residences and commercial buildings, recovery of low-temperature heat as a useful byproduct in industrial operations, and disposal of heat from processes involving evaporation of water or other fluids at depressed temperature and pressure. Defrosting of evaporator coils in refrigerating systems by intermittently admitting hot gas directly from the compressor is another application of the heat-pump method. Descriptions and diagrams of various heat-pump systems and criteria for feasibility are given later in this chapter.

HISTORY AND DEVELOPMENT

Over a century ago, William Thomson (Lord Kelvin)[1] suggested the use of a compressor as a *warming engine* to heat buildings, as an alternate for combustion of fuels. Somewhat prior to 1910 Dr. S. Z. Ferranti, Prof. J. Perry and Mr. T. V. Morley, in England, strongly advocated the undertaking of development in the design and application of heat pumps, but the economic outlook, then unfavorable, deferred further investigation. It was not until a paper on the principles and economics of heat pumps, prepared in October 1928 by T. G. N. Haldane, was presented before the British Institute of Electrical Engineers in December 1929,[2] that development was started in the United States. Haldane reported the trial results from early installations made in Scotland. Application for water heating was then as prominent abroad as use for space heating.

Dr. A. R. Stevenson, Jr. was an early advocate in this country, having first presented the possibility to the Refrigeration and Gas Committee of the American Gas Association in April 1926, and later to the Franklin Institute.[3] The concept held in this country today, that heat pumps for the large majority of space-heating applications should be regarded essentially as *year-round* air-conditioning devices, did not become generally accepted until about 1950.

History in the United States

Pioneering work on heat-pump development in the United States was conducted through the early 1930's mainly under sponsorship of a few investor-owned electric utility companies, with the objective of promoting wider use for their service. The seasonal character of electric load from summer air conditioning, after a record of steady growth, was then already making evident its likelihood of creating new peak demands on utility systems. This prompted the investigation of methods whereby such load could be made more favorable both to the customer and to the electric company.

The first major installation in the United States was made about 1931, for a new 3,800,000 cu ft office building of Southern California Edison Company in Los Angeles. Refrigeration equipment of the already existing air-conditioning system was modified to permit heat-pump operation with outdoor air in a conventional cooling tower serving as heat source. An installation made in Salem, New Jersey[4] in 1934 was the first commercial heat pump in this country designed for complete heating and cooling. A number of buildings occupied by subsidiaries of American Gas and Electric Company in Ohio, West Virginia, Virginia, and Kentucky were equipped during the middle and late 1930's. The home office of Louisiana Power and Light Company at Algiers, Louisiana was equipped in 1936, using purchased city water as source of heat. An office building[5] of United Illuminating Company at New Haven, Connecticut, erected in 1939, was equipped with a water-source heat pump. It utilized as a standby heating system a large water storage tank equipped with immersion electric heating elements. Throughout this early period all installations were custom built, employing standard equipment components modified where necessary to suit the dual-purpose functions. After World War II the use of heat pumps increased, particularly with the introduction of unitary equipment, in which the refrigeration system, fans, pumps, and the necessary automatic controls were assembled within a single housing.

In recognition of the status attained by heat pumps and their growing engineering importance, the AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS appointed a Technical Advisory Committee on the Heat Pump in 1947. An independent group from the electric utility industry, known as Joint AEIC-EEI Heat Pump Committee, was founded in February 1947. This body has worked closely with equipment manufacturers, giving advice on matters related to suitability of equipment types and control methods, to experience resulting from trial installations, and especially to the characteristics of electric loads. It has also under-

taken research projects in allied areas such as heat sources, utilization of solar energy as a supplementary heat source, and thermal storage methods.

The Joint Committee has lent encouragement to publication of two textbooks[6, 7] on the technology of heat pumps, and to the maintenance of a comprehensive bibliography,[8] a reference library, and installation statistics. Additional bibliographies and installation studies have been made by The Heat Pump Steering Committee of the Southeastern Electric Exchange.[9]

The summer air-conditioning load has high electric power demand and low annual load factor, and in addition, the highest demand peaks will occur on the relatively few extremely hot days during summer months, when the load-carrying capacity of the whole utility system (generation, transmission and distribution) is considerably lower than on cold days in winter. For example, the average annual load factor on a noncoincidental basis for summer air conditioning can be expected to remain between limits of 6 and 15 percent. This is far below the 64 percent present-day annual *load factor for the total electric load* of utility systems. Consequently, the large utility companies are giving support to the advancement of heat-pump technology as a means of broadening the field of application of the heat pump with its beneficial effect on the electric system load factor.[10]

Present Status

Large central heat pumps of modern design, within the capacity range of about 100 to approximately 1000 horsepower of compressor-motor rating, are now operating in a substantial number of buildings. Among noteworthy installations are those in the Oregonian Building and Equitable Building, both in Portland, Oregon; Appalachian Electric Building in Roanoke, Virginia; Columbus and Southern Ohio Electric Building in Columbus, Ohio. Detailed information on their design and performance has been presented in ASHAE papers[11, 12, 13] and in technical magazines.[14]

In the Southdale Shopping Center in Minneapolis, Minn., a 700-ton heat pump installation with its associated deep wells providing the heat sink and heat source, has a coefficient of performance on the heating cycle of approximately 4. Internal combustion engine driven heat pumps in this installation have been found to provide additional heating capacity because of the recoverable heat in the engine cooling water and the muffler.

Compressor types employed in large central systems vary from one large centrifugal unit to as many as eight multicylinder reciprocating units. A single or central system is generally used throughout the building, but in some instances the total capacity is divided among several separate heat-pump systems to facilitate zoning. Both well water and air are used as heat sources. Compression is accomplished in two stages for a few recent projects. Frequently provision is made for heating and cooling service to be supplied simultaneously to separate zones of the building.

Unitary heat pumps, available from or under development by many manufacturers, account for the large majority of residential and small commercial installations. Outdoor air is the heat source in the majority of installations, but models are built also for well water. Capacities cover the range from 2 to about 25 horsepower. Both hermetic and open-type compressors are used. The entire heat-pump circuit may be charged with refrigerant and sealed at the factory, or individual factory-sealed subassemblies may be connected together in the field. Some models are arranged for remote location of the outdoor-air heat exchanger that serves alternately as evaporator and as condenser. In appearance and dimensions, the casings of unit heat pumps closely resemble those of conventional air-conditioning units having equal capacity.

The normal design basis is to select *the size of compressor* and motor for the summer cooling and dehumidification capacity requirement. For heating service with outdoor air as the heat source, supplementary electric resistance heating elements are normally provided for use during such periods of low temperature as may be required by the climate and heating load of the structure. These heaters are sometimes objectionable to the utility because the resulting seasonal electric consumption is low in comparison with the electric input demands they create on the electric service facilities. Consequently, it is important that the application engineer for such installations give careful attention to minimizing the installed capacity of heating elements, as discussed later in this chapter.

With unitary systems, defrosting of the evaporator coils at suitable intervals with minimum interruption of heat supply to the building is usually accomplished automatically by admitting hot refrigerant gas taken directly from the compressor discharge.

Minimum industry performance standards of unitary heat pumps are covered by *ARI Standard 240-57, Unitary Heat Pump Equipment*, issued 1957 by Air-Conditioning and Refrigeration Institute. It applies to factory-made heat pumps and to matched assemblies as defined in the Standard, for residential, commercial and industrial service, but is not applicable to field-modified cooling units converted to heat-pump operation, nor to room air conditioners. The Standard provides that both heating and cooling capacity be expressed in Btu per hour under specific conditions, and includes minimum performance standards such as the ability to operate under maximum load conditions or adverse power and temperature conditions, and describes safety codes to which such equipment should be designed. It also outlines several performance requirements that are considered good practice in the design of either unitary heat pumps or built-up systems.

Window-type, or in-the-wall type heat pumps, now in factory production in ½ to 2 hp size range, resemble conventional units for summer air conditioning, similarly installed. Heretofore, capacity of these units on heating service has generally been less than needed in extremely cold weather to maintain the required temperature within the space served adequately by the same unit in summer. Except in regions having mild climate, they were useful principally for intermediate-season operation or to supplement the main heating system of the building. Some recently introduced models, however, have characteristics more suited to complete year-round operation.

As a result of more than a decade of experience gained in product development, factory production, field operation, and maintenance, heat pumps have become firmly established throughout a large part of the country. Moreover, heat pumps are being adopted for entire housing developments. As many as 1500 units have been installed for a single project.

The estimated number of central system heat-pump units operating at the end of 1958 throughout the United States is approximately 40,000. Installations have been made in practically every state, with the southeastern, southwestern, and west coast states predominating. It is probable that at least two-thirds of total units take heat from outdoor air, and, of the remainder, nearly all use water, with ground coils almost negligible among the more recent installations. Aggregate connected load may well reach 400,000 kilowatts. Approximately 150 domestic water heaters, mostly experimental or pilot-type models, are in operation.

BASIC CIRCUITS

Fundamentals

Since, from the refrigeration standpoint, a heat pump is similar to a conventional refrigeration system, its basic circuit may be represented by Fig. 3 in Chapter 38. Changeover between heating and cooling services may be accomplished by: (*a*) actuating valves in the refrigerant lines, so as to interchange the positions of heat exchangers constituting the evaporator and the condenser, respectively, in the refrigerant flow circuit, or (*b*) by switching the paths of air, water, or other fluid that convey heat from source to evaporator and from condenser to sink, respectively. The interchange function inherent in heat-pump control led to use of the term *reversed-cycle refrigeration* during the early development period of the heat pump, but this inaccurate name is now obsolete.

The operating principle of the heat pump is identical with that of the heat-power thermodynamic cycle governing the conversion between heat energy and mechanical work. It is derived from the Second Law of Thermodynamics (see Definitions, Chapter 1). The operating efficiency, or coefficient of performance (CP), of an elementary perfect refrigeration system for both cooling and heating effects is given by *Equations 2 and 3, Chapter 38*.

In actual systems, the coefficients of performance are defined in the following terms:

The *heating coefficient of performance*, $(CP)_h$, of an installed heat pump may be defined as the ratio of the total *instantaneous* useful heating effect produced by the heat-pump system at stated conditions, to the heat equivalent of the total energy input rate required to drive or operate the system. If total energy input of all auxiliaries such as fans and pumps is not included, it should be so stated.

The *cooling coefficient of performance*, $(CP)_c$, of an installed heat pump may be defined as the ratio of the *instantaneous* useful refrigeration effect produced by the heat-pump system at stated conditions to the heat equivalent of the total energy input rate required to drive or operate the system.

The term *performance factor*, (PF), is similar to coefficient of performance, but is used when referring to values based on an *extended period* of time, such as a day, month, or season. The period of time covered should be given when using this term. If supplemental heat is involved, its effect should also be specified.

Heat Pump Types

Heat pumps for air-conditioning service may be classified according to (*a*) type of heat source and sink, (*b*) heating and cooling distribution fluid, (*c*) type of thermodynamic cycle, (*d*) type of building structure, and (*e*) size and configuration. The more common types are shown in Table 1.

The *air-to-air* type is the most common type of system. It is particularly suitable for factory-built unitary heat pumps and has received favorable acceptance for residential and commercial applications. The diagram shown in Table 1 is typical of the refrigeration circuit employed. In smaller unitary heat pumps, it is common to replace the expansion and check valves with a capillary tube refrigerant control. A few installations have been made in which the forced-convection indoor heat-transfer surface has been replaced by a radiant panel.

In air-to-air heat-pump systems, as shown in second diagram of Table 1, the air circuits may be interchanged by means of dampers (motor-driven or operated manually) to obtain either heated or cooled air for the conditioned space. With this system one heat-exchanger coil is always the evaporator while the other is always the condenser. The conditioned air will pass over the evaporator during the cooling cycle while the outdoor air will pass over the condenser. The change from cooling to heating is accomplished by positioning the dampers which may be motor driven or operated manually.

A *water-to-air* heat pump uses water as a heat source and sink and uses air to transmit heat to or from the conditioned space.

Air-to-water heat pumps are commonly used in large buildings where zone control is necessary, and are also sometimes employed for the production of hot or cold water in industrial applications.

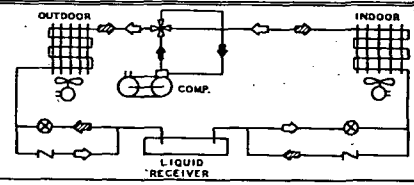
Earth-to-air heat pumps may employ direct expansion of the refrigerant in an embedded coil as illustrated in Table 1, or they may be of the indirect type described above under the water-to-air type.

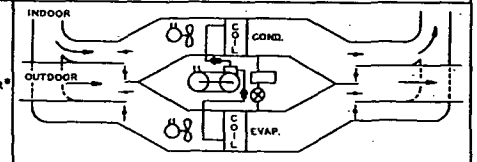
A *water-to-water* heat pump uses water as the heat source and sink for both cooling and heating operation. Heating-cooling changeover may be accomplished in the refrigerant circuit, but in many cases, it is more convenient to perform the switching in the water circuits such as is illustrated in Table 1.

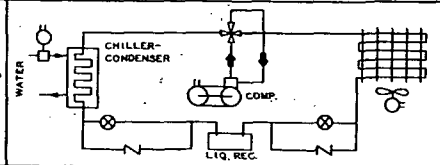
An *earth-to-water* heat pump (not shown in Table 1) may be like the earth-to-air type shown except for the substitution of a refrigerant-water heat exchanger for the finned coil shown on the indoor side. It may also take a form similar to the water-to-water system shown when a secondary-fluid ground coil is used.

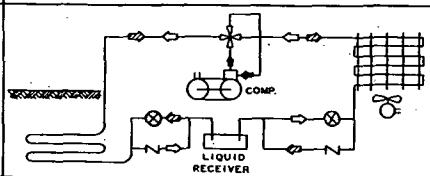
Some heat pumps which use earth as the heat source and sink are essentially of the water-to-air type. An antifreeze solution is pumped through a loop comprised of a pipe coil embedded in the earth and the chiller-condenser.

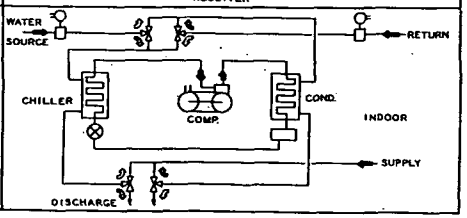
Many variations are possible in the refrigeration circuit and in the heat-source and sink arrangements. Some of these are described in later sections of this chapter.











Other types of heat pumps in addition to those listed in Table 1 are possible. An example is one which utilizes solar energy as a source of heat; its refrigerant circuit may resemble the water-to-air, air-to-air, or other types depending on the form of solar collector and the means of heating and cooling distribution which is employed.

Another variation is the use of more than one heat source. Some heat pumps have utilized air as the primary heat source, but are changed over to extract heat from water (e.g. from a well or storage tank) during periods of peak load. The use of solar energy requires another heat source during periods of insufficient solar radiation.

Industrial and Agricultural Heat Pumps

While the principal use of heat pumps may always be in space heating and cooling, the heat-pump principle also has applications in the industrial and agricultural fields, particu-

* ALL SINGLE STAGE COMPRESSION

larly in the process industries where large quantities of low temperature heat may be required. The heat-pump cycle, in many instances, can be effective in the utilization of waste heat.

In a number of processes, low-temperature heating and moderate refrigeration are required simultaneously. The concentration of fruit juices may be accomplished by a heat-pump system.

Fig. 1 illustrates the application of the heat-pump principle for drying. A large portion of the heat given off from the condenser while heating the stream of dry air is recovered by the evaporator from both the sensible and latent heat of the moisture-laden air downstream from the material being dried. This type of heat pump is expected to find particular application in the drying of tobacco and other agricultural products.

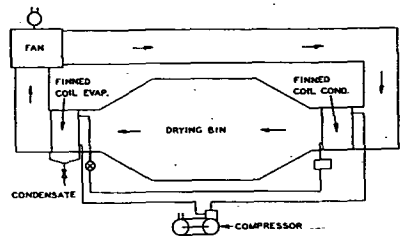

Fig. 1 . . . . Application of Heat Pump to Drying

Other Refrigeration Cycles

Any thermodynamic cycle that is capable of producing a cooling effect may theoretically be used as a heat pump. Other than the ordinary vapor-compression cycle, possible cycles include (a) the heat-operated absorption cycle, (b) the ejector cycle, (c) gas cycles, both open and closed[8] and (d) the thermoelectric cycle.[9]

None of these cycles as heat pumps is currently practicable due to limitations in efficiency, cost or size.

HEAT SOURCES AND SINKS

Table 2 shows the principal media being used with heat pumps as a heat source for heating and as a heat sink for cooling. The most practical choice for a particular application will be influenced primarily by geographic location, climatic conditions, initial cost, availability, and type of structure. Various factors to be considered for each source are given in Table 2. A more detailed discussion of design and selection factors for each source and sink follows.

Air

Outdoor air offers a universal heat-source, heat-sink medium for the heat pump. Extended-surface, forced-convection heat-transfer coils are normally employed to transfer the heat between the air and the refrigerant. Typically these surfaces are 50 to 100 percent larger than the corresponding surface on the indoor side of heat pumps using air as the distributive medium. The volume of outdoor air handled is also usually greater in about the same proportions. The temperature difference during heating operation between the outdoor air and the evaporating refrigerant generally is in the range of from 10 to 25 F deg.

The performance of heating and cooling coils for air is given in more detail in Chapter 23.

When selecting or designing an air-source heat pump, two factors particularly must be taken into consideration; (1) the variation in temperature experienced in a given locality and (2) the formation of frost.

The determination of the heating design temperature for an air-source heat-pump installation is usually more critical than for fuel-fired heating systems because the heat pump capacity is generally more closely matched to the design requirement for heating. This results from the desire not to oversize the installation with respect to cooling because of the large heating requirements. Moreover, the decreased heating capacity of the air-source heat pump at low temperatures establishes the *balance point*, i.e., the outdoor temperature at which the capacity matches the heat requirement.

When the surface temperature of an outdoor air coil is 32 F or lower, frost may form and if allowed to continue, will interfere with heat transfer. Research has shown that with a nominal amount of frost deposit (typically about 2 to 3 lb per sq ft of coil face area) the heat transfer capacity of the coil is not substantially affected.[10] The number of defrosting operations will be influenced by the climate, the air-coil design and hours of operation. Experience has shown that little defrosting is generally required below 20 F and below 60 percent relative humidity.[10] This may be confirmed by psychrometric analysis using the principles given in Chapter 23. However, it should be noted that under very humid conditions when small suspended water droplets may be present in the air, the rate of frost deposit may be about three times as great as would be predicted from psychrometric theory. Under such conditions, a heat pump may require defrosting after as little as 20 minutes of operation. In applying an air-source heat pump, the effect of this condition on loss of available heating capacity should be taken into account.

Early application of air-source heat pumps followed commercial refrigeration practice involving relatively wide fin spacing; (i.e., 4 to 5 fins per inch) on the theory that this would permit faster defrosting. However, experience has proved that with effective hot gas defrosting much closer fin spacing can be tolerated and obtains the advantage of a reduction in the size and bulk of the system. In current practice a fin spacing of 8 to 10 per inch is widely used and some of the newer units have outdoor coils with as many as 13 fins per inch.

Water

Water may represent a satisfactory, and in many cases an ideal, heat source subject to the considerations listed in Table 2. Well water in particular is attractive from the standpoint of its relatively high and nearly constant temperature, generally being about 50 F in northern areas and 60 F and higher in the south. Information on well water availability, temperature, and chemical and physical analysis is generally available from U. S. Geological Survey offices located in many major cities.

Surface or stream water may be utilized, but under winter conditions of reduced temperature, the cooling spread between inlet and outlet must be limited to prevent freeze-up in the water chiller which is absorbing the heat. Some large heat-pump systems have been in operation in Europe where

Table 2 . . . . Heat Pump Heat Sources and Sinks

Heat Source	Air	City Water	Well Water	Surface Water	Waste Water	Earth	Solar
Source classification	Primary	Primary or auxiliary	Primary	Primary	Primary or auxiliary	Primary or auxiliary	Auxiliary
Suitability as heat sink	Good	Good	Good	Good	Variable with source	Usually poor	May be used to dissipate heat to air
Availability (location)	Universal	Cities	Uncertain	Rare	Limited	Extensive	Universal
Availability (time)	Continuous	Continuous—except local shortages	Continuous—unless well runs dry	Continuous	Variable	Continuous, temperature drops as heat is removed, slowly rises when pump stops	Intermittent, unpredictable, except over extended time
Expense (original)	Low, less than earth and water sources except city	Usually lowest	Variable, depending on cost of drilling well	Low	Variable	High	High
Expense (operating)	Relatively low	High, usually prohibitive	Low to moderate	Relatively low	Low	Relatively moderate	Unexplored. Promising for reducing auxiliary operating cost
Temperature (level)	Favorable 75-95% of time in most of United States	Usually satisfactory	Satisfactory	Satisfactory	Usually good	Initially good—drops with time and rate of heat withdrawal	Excellent
Temperature (variation)	Extreme	Variable with location (10 to 25 F deg)	Small	Moderate	Usually moderate	Large—less than for air, however	Extreme
Design information	Usually adequate	Usually adequate	Usually adequate	Usually adequate	Adequate if source is constant in supply and temperature	Inadequate	Practically available
Size of equipment	Large	Moderate	Moderate (except for well)	Moderate	Variable (usually moderate)	Moderate (except ground coils)	Particularly large
Adaptability to mass production	Excellent, can be factory assembled and tested	Excellent	Excellent (except for well)	Excellent	Poor	Fair	Fair
Sources it may augment	Air, earth	Air, earth				Air, water	Air, earth water
Special problems	Least heat available when demand greatest. Coil frosting requires extra capacity, alternate source, or standby heat. May require duct work. Variable air temperature makes control difficult.	Scale on coils. Local use restrictions during shortages. Disposal. Water temperature may become too low to permit further heat removal.	Corrosion, scale may form on heat transfer surface. Disposal may require second well. Water temperature may become too low to permit further heat removal.	Water may cause scale, corrosion, and algae fouling.	Usually scale forming or corrosive. Often insufficient supply. Very limited application. Requires individual design.	Limited by local geology and climate. Installation costs difficult. Requires considerable ground area, may damage lawns, gardens.	Probably will require heat storage and other equipment or condenser side.

winter stream conditions around 35 F have permitted inlet-outlet temperature spreads of only 1 or 2 deg.

Under certain industrial circumstances, use may also be made of waste process water as a source, as for example spent warm water in laundries or warm condenser water from large industrial condensers, for specialized heat-pump operations.

Utilization of water during cooling operation follows, in general, conventional practice with water-cooled condensers.

Water-refrigerant heat exchangers generally take the form of direct-expansion water coolers either of the shell-and-coil type or of the shell-and-tube type and are circuited to permit usage as a refrigerant condenser during the heating cycle and as a refrigerant evaporator during the cooling cycle. Further information on this type of equipment will be found in Chapter 38.

Earth

Earth as a heat source and sink, by heat transfer through buried coils, has not been used extensively. This may be attributed to high installation expense, ground area requirements, and the difficulty and uncertainty of predicting performance.

Compositions of soil vary quite widely from wet clay to sandy soil, and have a predominant effect on thermal properties and attendant overall performance. The heat-transfer process in the soil is primarily one of bulk temperature change with time (e.g., transient heat flow). *Thermal diffusivity* α, the ratio of thermal conductivity to the product of unit density and specific heat, $\alpha = k/\rho c$, is a dominant factor and is difficult to determine at different building sites. The moisture content likewise has an influence, since energy in the ground may also be transported via moisture travel in the soil.

In general, earth coils, usually arranged to be spaced horizontally at from 3 to 6 ft, are submerged below the surface from 3 to 6 ft. Though a lower depth might be preferred, excavation cost requires a compromise. Mean undisturbed ground temperatures generally follow the mean annual climatic temperature for any place.

Many individual studies have been conducted to determine earth heat transfer with respect to heat-pump possibilities, involving theoretical as well as practical considerations (References 20 through 32).

As mentioned in the section Heat Pump Types, two general systems prevail for utilization of earth coils. The first is that of direct expansion of a refrigerant in a buried coil under winter heating conditions with refrigerant vapor condensation under summer conditions, and the other is the transfer of heat between a liquid pumped through a buried coil and the earth (indirect system). The direct system involves special provisions to insure the proper flow of liquid and vapor, that is, pitching downward to prevent trapping of liquid in pockets, etc. The indirect system is less sensitive since the liquid is pumped through the coils under regulated flow rates.

The coil length required, as quoted by some authorities, is 200 to 400 ft of ¾- to 1½-in. pipe per ton of refrigeration for a coil buried at a depth of 4 ft with average pipe spacing 4 ft on centers. To insure continued contact of the coil with ground material, despite earth settling tendencies, the space directly around the coil is sometimes backfilled with sand.

Solar

Although still largely in the research stage, increasing interest is being shown in solar energy as a heat source, either on a primary basis or in combination with other sources. The principal advantage of employing solar radiation as a heat-pump heat source is that, when available, it provides heat at a higher temperature level than other sources, thus resulting in an increase in coefficient of performance.[33] As compared to a solar heating system without a heat pump, the collector efficiency and capacity are materially increased due to the lower collector temperature required.

Research and development in the solar-source heat-pump field has been concerned with two basic types of systems: direct and indirect. In the direct system refrigerant evaporator tubes are embodied in a solar collector, usually of the flat-plate type. Research has shown that when the collector has no glass cover plates the same collector surface can also function to extract heat from the outdoor air.[34] The same surface may then be employed as a condenser using outdoor air as a heat sink for cooling. The refrigeration circuit employed may resemble that shown in Table 1 for an air-to-air heat pump.

An indirect-type system employs another fluid, either water or air, which is circulated through the solar collector. When air is used, the first system shown in Table 1 for an air-to-air heat pump may be employed, the collector being added in such a way that: (1) the collector can serve as an outdoor-air preheater, (2) the outdoor-air loop can be closed so that all source heat is derived from the sun, or (3) the collector may be disconnected and the outdoor air used as the source or sink.[35] When water is circulated through the collector, the heat-pump circuit may be of either the water-to-air or water-to-water type[36] illustrated in Table 1.

On all heat-pump systems employing solar energy as the only heat source, either an alternate heating system or a means of storing heat is required during periods of insufficient solar radiation. Heat storage is discussed in a later section of this chapter.

PERFORMANCE CHARACTERISTICS

Temperature Levels

Temperature differences are required to transfer heat from the heat source to the evaporating refrigerant of a heat pump, and similarly from the condensing refrigerant to the heating fluid. Hence the total temperature lift of the refrigeration system must be increased over that represented by the difference between the heat source and sink temperatures.

Fig. 2 illustrates typical temperature levels for both heating and cooling operation. Specific heat pumps may vary somewhat from the temperature levels shown depending on their design and specific conditions of operation. Equation 3

Fig. 2 . . . . Heat-Pump Temperature Levels

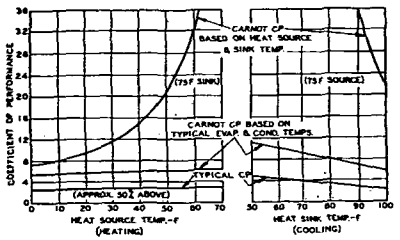

Fig. 3 .... Variation of Coefficient of Performance with Temperature

of Chapter 38 defines the coefficient of performance (CP) of a Carnot cycle heat pump. Applying the relationships given with evaporator and condenser temperatures illustrated in Fig. 2 yields the coefficient of performance (CP) for a Carnot cycle heat pump shown in Fig. 3. An actual heat pump will, as a rough approximation, be about 50 percent as efficient as a Carnot cycle heat pump and will have a coefficient of performance dependent on temperatures, as illustrated in Fig. 3.

System Balance

The performance characteristics of a heat-pump system can be predicted by evaluating and combining the performance characteristics of its individual components.[37] Data available from component manufacturers may be portrayed as shown in Fig. 4.

The conditions of system balance can be established by the following procedure:

1. Choose a combination of evaporator refrigerant temperature t_r and condensing temperature t_c.
2. Determine the compressor refrigerating effect from performance curves similar to *A* of Fig. 4.
3. Determine the compressor power input P_c, in kilowatts, from curves similar to *B* of Fig. 4.

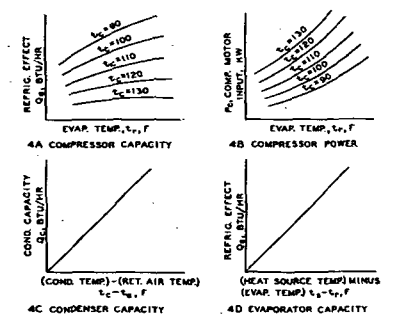

Fig. 4 .... Performance Characteristics of Heat-Pump Components

4. Determine the condenser capacity from

$$Q_c = Q_e + 3413\,P_c - Q_{ec} \qquad (1)$$

where

Q_c = condenser capacity, Btu per hour.
Q_e = compressor refrigeration effect (evaporator capacity), Btu per hour.
Q_{ec} = heat loss from compressor, Btu per hour. (Q_{ec} may have to be approximated if unavailable from compressor manufacturer. For many compressors Q_{ec} is negligible.)

5. Plot Q_c obtained from Equation 1 on a chart similar to *C* of Fig. 4. (See Fig. 5.)
6. Select other condensing temperatures in combination with the original evaporator temperature from Step 1 and repeat Steps 2 to 5 as necessary to determine the condenser capacity at which the system balances. Points *A* and *B* on Fig. 5 represent the results of these calculations. Two points will normally be sufficient to determine the balancing Q_c.
7. Select other evaporator temperatures and repeat Steps 1–6 (See Fig. 5.)
8. For each evaporator temperature find the corresponding heat source temperature t_s from chart similar to *D* of Fig. 4.

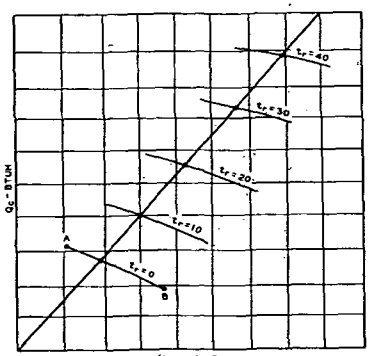

Fig. 5 .... Heat-Pump System Balance

With the conditions of system balance found from the foregoing procedure, it is a relatively simple matter to establish the heating performance characteristics. The net heating effect may consist only of the condenser heat, or, depending upon the system design, may also include heat losses from the compressor and motors, and the heating effect of a refrigerant subcooler coil.

The cooling performance can be determined in a similar manner.

For a heat pump which employs a constant temperature heat source, a few computations will generally establish the balancing conditions for t_r and t_c. For a heat pump having source temperature subject to considerable variation (e.g. air source), the balancing conditions for a wide range of t_r *will be necessary.*

Fig. 6 shows the performance characteristics of a typical heat pump determined either from actual system tests or

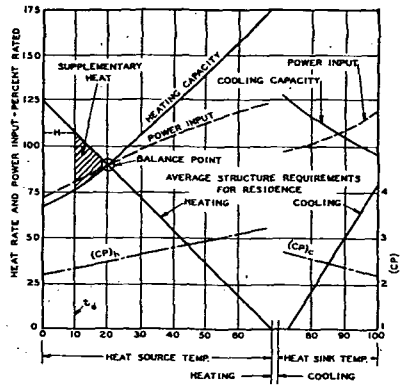

Fig. 6 .... Operating Characteristics of Single-Stage Unmodulated Heat Pump

from an analytical procedure such as already described. Also shown are the heating and cooling loads for a typical residence. The temperature at which the heat-pump capacity and the structure heat requirement are equal is referred to as the *balance point*. If the balance point is above the heating design temperature, t_d, then supplemental heat will be required as denoted by the shaded area.

Seasonal Performance

Fig. 6 illustrates some of the basic factors important in evaluating seasonal power consumption. Following the principles given in Chapter 37 the heating power consumption for any period of time may be estimated from

$$F = \frac{24HD}{3413(t_s - t_d)(\mathrm{PF})}$$

where

F = heating kilowatt hours
H = structure design heat loss, Btu/hr.
D = degree days for specified period.
t_s = outdoor temperature at which structure heat loss is zero (approximate indoor temperature when heat gain from other sources is small), Fahrenheit.
t_d = outdoor design temperature, Fahrenheit.
(PF) = performance factor for specified period.

For a heat pump with a constant heat-source temperature, the heating capacity will be essentially constant and the performance factor (PF) can be taken as the heating coefficient of performance $(CP)_A$.

For an air-source heat pump, with its varying heat source temperature, it is necessary to either break down the period of operation into relatively narrow temperature spans and to compute the power consumption in each, or, alternatively, to find the performance factor (PF) by weighted average of the different coefficient of performance (CP) and operating hours that apply at various temperatures. In either case it is necessary to have data on the time distribution of outdoor-air temperatures. The number of hours that will apply within a given temperature range may be based on past weather data for a specific location. For example, such data are available for a number of cities broken down by month and time of day.[38] However, where the required weather data are not available and when it is not necessary to break the heating season down into shorter periods, generalized data such as portrayed on Fig. 7 may be employed.

Fig. 7 is based on an analysis of 114 weather stations in the United States from Reference 38, in which the heating-season days were correlated with the TAC design temperatures. The TAC design temperatures shown in 1948 to 1958 editions of THE GUIDE were suggested by the ASHAE Technical Advisory Committee on Weather Design Conditions. They were temperatures which were equalled or exceeded during 97½ percent of the hours in December, January, February, and March chiefly for airport stations.

Maximum deviation for any single location from the averages portrayed is on the order of 5 deg at 70 F outdoor temperature and is due mainly to variations in summer climate. Since curves must pass through points representing the winter TAC design temperatures, their accuracy is best in the low-temperature range. The vertical scale also gives the outdoor design temperatures for heating, as given in Chapter 12, which take into account the probabilities of occurrence. Reference 1 of Chapter 12 provides the correlation of these design temperatures with the TAC temperatures.

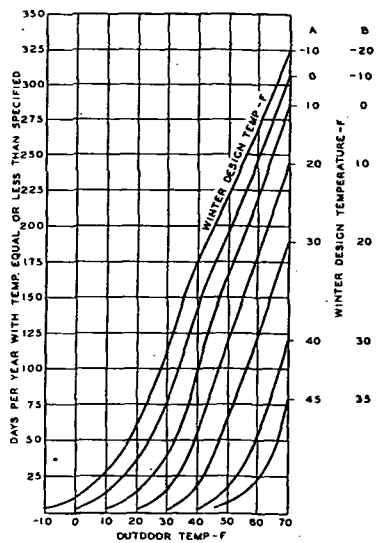

Fig. 7 .... Annual Cumulative Winter Temperature Distribution in the U. S.

Table 3 .... Number of Defrosts per Year[a] (100 Percent Running Time)

Climate (TAC)	−10 to 5	6–8	9–11	12–14	15–17	18–20	21–23	24–26	27–29	30–32	33–35	36–39	39–41
Normally dry	475	450	400	375	350	300	250	200	175	150	100	75	50
Normally damp	800	750	700	625	575	500	425	350	300	225	175	125	100

[a] The figures given must be multiplied by the running-time ratio for the period considered.

Extra power consumption allowance must be made where periodic defrosting of an air-source evaporator is required, and where supplemental heating is employed.

The number of defrosting operations required per month or a complete heating season is difficult to evaluate accurately. It will depend on the detailed design and control of the heat pump, the climate, and the hours of operation. Table 3 gives the range in annual number of defrosts that may be expected on typical small unitary heat pumps.

To obtain a total yearly operating cost, the energy consumption for cooling must be added to that required for heating. Suggested procedures for calculating cooling energy consumption are given in Chapter 46 and 54.

Annual Operating Cost

A tabulation such as is shown by Table 4 may be used for estimating the operating cost for commercial and industrial installations. It is necessary to know the monthly kilowatt electric demands and the corresponding kilowatt-hour consumption for the base electric load, as well as for the heat pump or any other electric equipment, in order to apply the proper electric tariff. The base loads, shown as Columns 1, 2 and 3 of Table 4, may include lighting, elevators, office machinery, exhaust and supply fans, circulating pumps, and similar items which are normally essential in a structure and are not affected by a particular air-conditioning design. The heat-pump kilowatt demand, during the month, which is required to satisfy the net day and night heat loss or heat gain (whichever is the greater), can be obtained from manufacturers' data. These resulting kilowatt demands are multiplied by a coincident factor to obtain the coincident demands, listed in Columns 4 and 7. These coincident demands can be added to the base load demands to obtain the total electric load in Column 10. The coincident factors can best be obtained from published data on similar installations. The procedure for finding the heating and cooling kilowatt hours, Columns 5, 6 and 8, has been previously described.

For residential installations, a detailed monthly estimate generally is not justified unless a monthly demand type of rate is in effect.

In making a power consumption estimate for unitary heat pumps, a detailed breakdown into periods less than a complete season, or the breaking down into small temperature spans, is not ordinarily justified. Manufacturers of this type of equipment provide estimating procedures which are simpler to use, yet are of sufficient accuracy for the purpose intended. These methods usually consist of an empirical equation, tabular data, or plotted curves which combine the influences of the size and thermal properties of the structure, the heating design temperature, the characteristics of the heat pump, and supplemental heat usage.

HEAT-PUMP COMPONENTS

For the most part, the components used in heat pumps and the practices followed bear a direct relation to the low temperature refrigeration art. This section will outline the major components used and point out characteristics or special considerations which apply to the heat-pump field.

Compressors

Reciprocating compressors are used more than any other type on systems in the general range of ½ to 100 tons, and frequently even larger. A brief description of this type of compressor is given in Chapter 38. For the most economical application, it is general practice to select the reciprocating compressor to provide the desired cooling capacity. The cooling capacity is the evaporator capacity and represents the ability of the compressor to pump refrigerant vapor between the existing temperature limits. When heating, the capacity of a particular compressor is the sum of the evaporator capacity (i.e., heat-source coil capacity) plus the heat equivalent of the compressor work.

Figs. 13, 14 and 15 in Chapter 38 shows the capacity and power characteristics of typical reciprocating compressors. A compressor normally employed for comfort cooling use will have a clearance volume (ratio of gas volume remaining in cylinder after compression stroke to total swept-cylinder

Table 4 .... Suggested Procedure for Computing the Operating Cost of Commercial and Industrial Heat-Pump System

Period	Base Load Lighting and Miscellaneous		Cost Base Load	Heat Pump			Supplemental Resistance Heating (If Used)		Total Heating and Cooling	Total Electric Load		Total Cost
				Coincident demand	Heat	Cool						
	Kw (1)	KwH (2)	KwH (3)	Kw (4)	KwH (5)	KwH (6)	Kw (7)	KwH (8)	KwH (9)	Kw (10)	KwH (11)	(12)
June												
July				Fill in one line for each month through May								
May												

volume) of about 5 percent. The capacity drop off at low evaporator temperatures corresponding to low heat-source temperatures is also evident. The drop off in power at low evaporator and condensing temperatures is also evident.

If the compressor has low clearance volume, say 2½ percent, then it is more suitable for low-temperature operation, and will provide, for example, about 15 percent greater refrigerating capacity at an evaporator temperature of 0 F and a condenser temperature of 110 F. However, this compressor has somewhat more power demand under maximum cooling load conditions than does one of medium clearance.

It is obvious that more total heat capacity can be obtained at low outdoor temperatures by deliberately oversizing the compressor. The compressor is oversized in order to obtain more heating capacity so it is necessary to provide some type of capacity reduction to bring the cooling capacity into balance. This can be done by means of two-speed motor drives, cylinder cutouts, or other methods as described in Chapter 38. The disadvantage of this arrangement results from the fact that the greater number of operating hours that occur at the higher suction temperatures must then be served with the compressor in the unloaded condition which generally causes lower efficiency. Therefore, the annual operating cost will tend to rise. It is also true that the additional first cost of the oversized compressor must be economically justified by the gain in heating capacity. One method proposed for increasing the heating output at low temperatures involves the use of *staged compression* in which one compressor may pump from −20 F suction temperature to 40 F condensing temperature and a second compressor compress the vapor from 40 F to 120 F. In such an arrangement it is possible to interconnect any two compressors so that they are in parallel, both pumping from say 45 F to 120 F at the normal cooling rating point, while at some predetermined outdoor temperature on heating they are reconnected so that they pump in staged relationship.

Fig. 8 shows the performance of such a pair of compressors for compressors of both medium and low clearance volume. It is apparent that at low suction temperatures the reconnection into a staged relationship does provide some added capacity. Also, it should be understood that the motor selection involved must be based upon the maximum loading conditions for summer operation even though the low stage compressor has a greatly reduced power requirement under the heating condition.

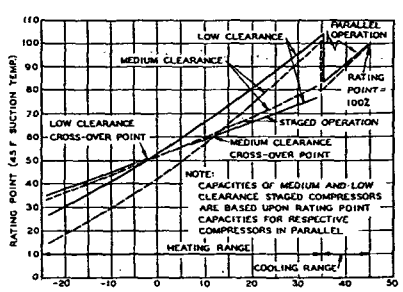

Fig. 8 .... Comparison of Parallel and Staged Operation

The coefficient of performance will be approximately the same whether they are coupled in parallel or compound-staged at any set of operating conditions depending somewhat on the motor characteristics when lightly loaded.

A *rotary* compressor has characteristics similar to a reciprocating compressor except that it is by nature possessed of low clearance and high volumetric efficiency. From this standpoint it is well suited to heat-pump service, providing about 30 percent greater capacity at 0 F—110 F lift than a medium-clearance reciprocating compressor. However, this characteristic tends also to increase the power demand at the maximum cooling load conditions. At this time, reciprocating compressors are most widely used for heat pumps, with rotary compressors restricted to the first stage of a staged-compression system and not used during the cooling cycle.

Heat Transfer Components

Refrigerant-to-air and refrigerant-to-water heat exchangers, as previously described in the section Heat Sources and Sinks, are similar to heat exchangers used in current air-conditioning practice. A refrigerant subcooler coil may be employed either in conjunction with an indoor air coil, or, on systems with a ventilation air supply, to preheat ventilation air. A substantial gain in capacity and coefficient of performance can result.

Refrigeration Components

Refrigerant piping, receivers, expansion devices and refrigeration accessories in heat pumps are usually the same as those used in other types of refrigeration and air-conditioning systems (see Chapter 38).

A *reversing valve* is used to change the system from the cooling to the heat operation. This change-over requires the use of a valve, or valves, in the refrigerant circuit,* except where the change is accomplished in fluid circuits external to the refrigerant circuit (see Table 1). Reversing valves are usually pilot-operated by means of solenoid valves which admit head and suction pressures to move the operating elements.

Expansion devices for controlling the refrigerant flow are normally thermostatic expansion valves as described in Chapter 38. Special requirements may sometimes be presented. If the circuiting is so arranged that the refrigerant line upon which the control bulb is placed can become the compressor discharge line, the resulting pressure developed in the power element of the valve may be excessive, requiring the use of a special control charge or pressure-limiting element. When a thermostatic expansion valve is applied to an outdoor air coil, a special *cross-charge* is desirable to limit the superheat at low temperatures, and thereby obtain a better utilization of the coil.

When an expansion valve is attached to a coil that is operated as a condenser, a bypass with a check valve is normally provided as indicated in Table 1.

On small factory-built systems, capillary tubes are normally used as expansion devices. While a single capillary tube on both heating and cooling is sometimes employed, better efficiency and performance can be obtained by using a more restrictive capillary tube for heating than for cooling. This may be accomplished by using two capillary tubes in either a series or parallel arrangement with a check valve to bypass one for cooling or to block one for heating, respectively.

On an air-source heat pump that must operate over a wide range of evaporating temperatures, a capillary tube will tend to pass refrigerant at an excessive rate at low back pressures, causing liquid floodback to the compressor. In some cases suction line accumulators or charge-control devices are employed to minimize this effect.

A *refrigerant receiver* is commonly used, as in other types of refrigeration systems, to provide a storage place for liquid refrigerant. It is particularly useful in a heat pump in order to take care of the unequal refrigerant requirements between heating and cooling.

Control Components

Heat pump control systems and components are of the same general type used in other types of heating and cooling equipment. Reference should be made to Chapter 43.

Practically all heat pumps for residential heating and cooling are controlled automatically from the temperature of the conditioned space. *Room air thermostats* are usually of the type that combine the control of both the heating and cooling function, the selection of function either being accomplished automatically in response to air temperature or manually by a selector switch. When supplementary heaters are employed, usually electric resistance heaters, it is common to control them with the second stage of a two-stage heating control. This restricts their usage to makeup of the difference between the heating requirement and the heat-pump capacity (see Fig. 6). To avoid unnecessary usage and excessive electrical demand, particularly when the thermostat setting is raised suddenly, it is customary to use one or more outdoor thermostats to limit the amount of resistance heat used at the higher outdoor temperatures. For information on electric resistance heaters see Chapter 17.

In residential heat pump applications, night-set-back, common with fuel-fired systems, is not ordinarily employed because substantial excess capacity is required for warm-up and because possible operating cost savings, if any, are deemed to be small.

On the larger type systems, a proportional action type of control is sometimes used for controlling compressor and supplementary stages in steps.

A variety of *defrosting control* schemes have been used to sense the need for defrosting air-source heat pumps and to initiate and terminate the defrost cycle.

A timer is sometimes used and set to cause defrosting at predetermined intervals for instance, about every two hours. After initiation of the defrost cycle defrosting can be terminated either by the use of a control sensing the coil pressure or a thermostat located so as to measure the temperature of the liquid refrigerant in the outdoor coil. When the temperature (or corresponding saturation pressure) of the liquid leaving the outdoor coil rises to about 40 F the completion of defrosting is assured. Termination of defrosting may also be obtained by use of a second time interval control.

Another method of starting the defrost cycle is to use a pressure control which reacts to the air pressure drop across the coil. Under conditions of frost accumulation the air flow will be reduced and the increased pressure drop across the coil will initiate the defrost cycle. Again the preferred method of terminating the defrost cycle is to use a refrigerant temperature control measuring the temperature of the liquid refrigerant in the coil.

A third method for defrosting involves a temperature differential control in which two temperature sensing elements are used; one responsive to the outdoor-air temperature and the other responsive to the temperature of the refrigerant in the coil. As frost accumulates, the differential between outdoor temperature and refrigerant temperature will increase, causing a defrost cycle to be initiated. The system will be restored to operation when the refrigerant temperature in the coil reaches a specified temperature indicating that defrosting has been completed. When the outdoor-air temperature decreases, the differential between outdoor-air temperature and refrigerant temperature decreases, and the defrost cycle is initiated sooner.

Other Components

Supplementary *resistance heaters*, commonly used with many unitary type heat pumps may be incorporated either within the unit or external to it. They may take any of the forms discussed in Chapter 17. When installed in the distribution ductwork, they are frequently controlled to temper the air during defrosting operation on units employing *reverse-cycle* defrost.

APPLICATION

Criteria for Feasibility

Factors to be considered in determining the practicability of employing a heat pump include the following:

1. Presence of a cooling load.
2. Relative amounts of heating and cooling.
3. Availability of suitable heat source and sink.
4. Equipment requirements and installed cost.
5. Operating cost.

These criteria may be applied whether the equipment to be considered is of the factory-built, unitary type or the field-assembled type. In fact, an analysis of these factors, in addition to determining feasibility of the heat pump for a particular application, should also be useful for choosing the equipment type.

Unless there is a need for cooling, heating with a heat pump is ordinarily not economically feasible. Under certain circumstances this may not be true, but usually a heat-pump system will have a higher first cost than a fuel-fired heating system.

With the almost universal need for comfort cooling, particularly in commercial establishments, but also to an increasing extent in residences, the feasibility of a heat pump becomes more favorable. Only a portion of the required equipment will then have to compete with a separate heating system. In fact, in large buildings, the existence of simultaneous heating and cooling loads in different zones for a large portion of the time is often uniquely suited to a heat-pump system.

The relative amounts of heating and cooling required may greatly influence the first cost and the suitability of a heat pump. In the usual case the size of the heating load is the predominating factor, particularly with structures in colder climates having low internal heat gain. The application of insulation and adequate sealing against unwanted air infiltration reduces the ratio of the heating to cooling loads.

The availability of a suitable heat source and sink generally involves making the optimum selection from the standpoint of overall economics. Factors to be considered were presented earlier in this chapter in the section Heat Sources and Sinks.

The heat source selected will usually also serve as a heat sink. It should be recognized that in applications requiring heating and cooling in different zones simultaneously, the heat source or sink need only handle the net heat input or output of the system.

To *estimate the equipment requirements and installed cost* it is necessary to make at least a tentative equipment selection. Before this can be done it will, first be necessary to determine the heating and cooling loads. For small structures this generally entails only the calculation of the peak heating and cooling loads. For larger buildings, a more detailed analysis may be required in order to take into account the loads at other than the design conditions, the time periods at which loads occur, ventilation schedule, variations in loads due to internal heat gains from lights, equipment and occupancy, and simultaneous heating and cooling loads in different zones.

It is implicit in a feasibility study of this kind that the objective is to obtain a comparison between the cost of a heat-pump system and a combination air-conditioning and fuel-fired heating system. Therefore, in order to estimate the first cost of both systems, a preliminary design and selection of each must be made.

It does not necessarily follow that the system with the lowest first cost is the optimum choice. An increase of initial cost for any system may be justified by savings in operating cost or by other benefits derived.

The principal factors to be taken into account in estimating *operating cost* are given in the section Performance Characteristics. The application or feasibility study of a heat-pump system with regard to operating cost involves the comparison between it and alternative types of systems considered. Operating cost of fuel-fired systems may be estimated by the procedures given in Chapter 37.

Heating and Cooling Distribution

The distribution of the heating and cooling effect from a heat-pump system is an important application consideration, particularly because of the relatively low temperatures involved as compared to fuel-fired heating systems.

In a commercial-type structure, any system of distribution which is satisfactory for cooling will generally be satisfactory for heating with a heat pump. Conversely, any system satisfactory for heat distribution with a heat pump will be satisfactory for cooling, except, however, that panel systems will seldom have sufficient capacity to handle normal cooling loads satisfactorily.

Heat distribution in the space can be accomplished by forced air at high, medium, or low pressures; primary air with induction units; individual fan and coil units; a split system composed of forced air and panels; or panels alone. All these methods of heating, except panels alone, are as applicable to cooling as to heating.

The distribution from the heat pump to space units can be by use of water or air. Quantities circulated, pipe or duct sizes, transfer units, and other characteristics of the distribution system will resemble very closely standard practice for cooling systems.

Heating and cooling distribution in residential heat-pump systems generally follows the same principles as for summer cooling. Refer to Chapter 46. It has been found with residential air distribution systems, comfort may be achieved with the air volumes and temperatures encountered with heat pumps when proper attention is given to the number and location of air outlets.[1]

Design and Selection

Irrespective of the size and type of building and whether unitary or field-erected equipment is being considered, the first steps that should be performed are those described under Criteria for Feasibility. In applying unitary heat pumps, the manufacturers of these units ordinarily provide sufficient data and instructions for proper application. The typical procedure followed for both unitary and field-erected heat pumps is outlined below:

1. Determine heating and cooling loads. It is desirable also to determine the amount that loads may be reduced by additional insulation, sealing, and shading. Savings effected in equipment due to distribution and to operating costs may more than offset the added cost involved. In larger buildings, loads should be determined for the different conditions of operation including simultaneous heating and cooling.
2. Establish heat source and sink. See previous section on this subject.
3. Determine type of distribution system.
4. Choose major components: compressors, heat exchangers, and air handlers. For unitary equipment, establish equipment size, type, and make.
5. Establish design of refrigeration system.
6. Choose auxiliary equipment: fans, pumps, valves, etc.
7. Determine equipment location. Since the heat pump operates without fuel and combustion products, considerable flexibility is permitted in its location. A single-package unit, may be located in a basement, crawl space, attic, roof, garage, or carport, in the conditioned space, or out-of-doors. For remote-type, or split units, one section is generally located outdoors and the other in a convenient indoor location. Considerable flexibility in locating equipment of a field-erected heat pump in one or more areas is possible.

   Factors to be considered in equipment location are: (*a*) Accessibility to heat source and sink, (*b*) Convenient location with respect to indoor distribution system, usually duct work, (*c*) Availability of condensate drain, (*d*) Required accessibility and sufficient space for servicing, (*e*) Convenience to electric power wiring, (*f*) Suitability of structure for supporting weight of equipment, (*g*) Effect of noise and vibration transmission, and (*h*) Appearance.
8. Determine control system and components.
9. Estimate first cost and operating cost.

Illustrative Systems for Larger Buildings

Fig. 9 shows a system employing well water as a heat source and sink. In this particular case a heat exchanger is used between the well water circuit and the fluid circuit to transmit heat to the heat pump, heat exchangers, and the indoor conditioning coils. Although this requires an extra step of heat exchange, it avoids the necessity for pumping well water throughout the building and permits a high rate of flow in the building water circuit with resulting improvement in heat transfer. The use of a water preconditioning coil as shown to preheat, or precool, ventilation air often reduces the size of refrigeration capacity required as well as the cost of operation. It should be noted that both heated and cooled water can be furnished simultaneously to indoor-air-handling or remote-room units as may be required by the existence of heating and cooling loads in different zones at the same time.

Fig. 10 illustrates an air-to-air heat pump system which is similarly suited to a structure having simultaneous heating and cooling loads. The refrigeration subcooling surface shown is used to preheat ventilation air and thereby effect substantial economies in equipment size and operating cost.

HEAT STORAGE

The use of thermal storage in a heat-pump system can improve its performance characteristics. Installations of heat pumps with thermal storage have been made principally in a few large building systems.[2, 3, 4]

All materials possess the property of thermal storage in

greater or lesser degree. In the case of a building, the structural materials are almost always in the process either of absorbing heat from or delivering heat to the interior space. This effect is more pronounced in cooling operation where greater air temperature variation is tolerated. Storage tends to reduce the rate of temperature change and helps in some measure to reduce the peak equipment requirements. In this sense every heating and cooling system can be said to involve heat storage in some degree.

Many attempts have been made, particularly in recent years, to increase the heat-storage effect by using special heat-storage materials as part of the heating or cooling system. The result is to reduce the size of the heating or cooling equipment necessary to take care of peak demands.

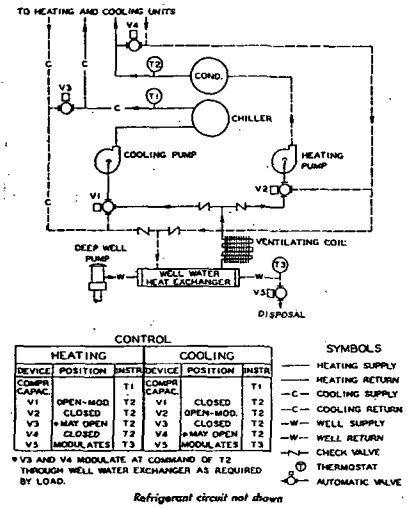

Fig. 9 .... Flow Diagram of Central-Type Heat-Pump System

In the case of the heat pump, a provision for heat storage can serve not only to reduce the size of the heat pump necessary for a given load, but also to provide a more desirable electrical load by shifting part of the load to the time of day when the cost of power is least. The off-peak electric hot water heater is a common example of such a heat-storage application.

In general, there are two types of heat-storage systems that have been employed: (1) sensible heat-storage systems and (2) latent heat-storage systems. Usually the latter is actually a combination of the two, making use of some sensible heat storage in addition to the latent effect. Heat storage in a heat-pump system may be utilized on the *high side*, when heat is available at a temperature suitable for direct heating; or on the *low side* as an intermittent heat source at temperatures lower than the heated space.

Table 5 .... Properties of Various Specific Heat Type Storage Materials

Material	Specific Heat Btu per (lb) (cu ft) (F deg)	Density lb/cu ft	Heat Capacity Btu per (cu ft) (F deg)
Water	1.00	62.4	62.4
Iron	0.11	490.0	53.9
Concrete	0.27	140.0	37.8
Brick	0.20	120.0	24.0
Gravel	0.20	100.0	20.0

Sensible Heat Storage

Water, with the highest sensible heat storage capacity on a weight basis, is an obvious first choice and has the advantage of low cost, easy storage, and good heat exchange properties. The danger of freezing can be reduced by various types of antifreeze solutions. In some cases, however, freezing may be desirable. The maximum temperature is limited by the cost of maintaining water under pressures when over 212 F, but this temperature is high enough for most heating systems. Rock and gravel beds have also been employed, and have a heat content per unit volume approximately 20 percent of the value for water. The earth has been utilized for heat storage, both for heating and cooling in a number of instances. A problem with most solid media such as these is one of heat transfer into and out of the medium.

Table 5 lists the thermal properties of some of the common materials used, or considered, for sensible-heat storage.

Latent-Heat Storage Systems

Because of the relatively large volumes required for all sensible-heat storage systems, many attempts have been made to utilize the latent heat of fusion of certain materials. Most materials have some capacity to absorb heat when changing from a solid to a liquid, and some materials have a large capacity to do so. Ordinary ice changing to water is a prime example of this kind and the possibility exists of utilizing it as low-side storage. For most heating applications, however, the temperature of this change is too low to be useful.

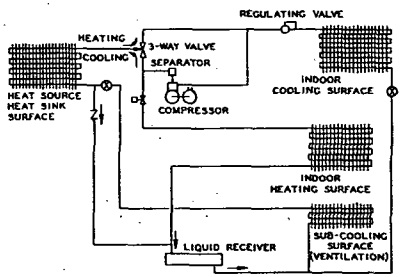

Fig. 10 .... Flow Diagram of Air-to-Air Heat Pump for Simultaneous Heating and Cooling

Table 6 .... Materials for Heat Storage Listed According to Latent Heat per Unit Volume[a] of All Materials Having Melting Points between 72 F and 176 F, Listed in Chemical Handbooks

Material	Formula	Melting Point F	Heat Content G-cal per g	Specific Gravity	Latent Heat of Fusion per Unit Volume (Theoretical)	
					G-cal per cc	Thousands of Btu/cu ft
Nitrogen pentoxide	N_2O_5	85	76.7	1.63	125.0	14.0–
Gallium	Ga	86	19.0	5.88	113.8	12.7–
Sodium phosphate, dodecahydrate	$Na_2HPO_4{\cdot}12H_2O$	94	66.8	1.52	101.5	11.4
Sodium sulfate, decahydrate	$Na_2SO_4{\cdot}10H_2O$	90	57.1	1.46	83.4	9.4
Water	H_2O	32	79.1	1.00	80.0	9.0
Nickel nitrate	$Ni(NO_3)_2{\cdot}6H_2O$	132	36.4	2.05	74.7	8.4
Calcium chloride	$CaCl_2{\cdot}6H_2O$	86	40.7	1.68	68.4	7.7
Osmium tetroxide	OsO_4	104	13.5	4.91	66.3	7.5
Zinc nitrate	$Zn(NO_3)_2{\cdot}6H_2O$	98	31.1	2.06	64.3	7.2
Calcium nitrate	$Ca(NO_3)_2{\cdot}4H_2O$	108	33.9	1.82	61.7	6.9

[a] Nine materials having melting points between 72 and 176 F listed according to latent heat of fusion. Selected as highest on a list of 100 organic and inorganic materials listed in chemical handbooks.

Prolonged searches have been made for materials which pass through a change of state as reliably and regularly as ice and water, but at temperatures high enough to be used for direct application to space heating. In order to be much superior to water, the latent heat capacity of such materials must be high. Most organic materials are eliminated from consideration on this basis alone. Furthermore, the absorption and release of heat must occur in predictable fashion. Many materials which have been tried exhibit the defect of subcooling, delayed change of state, or decomposition through time and repeated cycles. A study of all materials, both inorganic and organic, listed in chemical handbooks resulted in a list of over 100 materials having a fusion temperature between 72 F and 176 F. Most of these materials are extremely unpromising as heat storage media because of cost, corrosiveness, instability, or unavailability. For many of them, data on their heat of fusion are unavailable. All of these materials, where such data are available, have been listed in order of heat capacity per unit volume. Table 6 gives the nine materials which were highest on this list, and it is interesting to note that there are few common or low cost materials among this group. Others, notably the first two, are academic curiosities.

The material disodium phosphate is high on the list and has been used in a number of experimental installations. Results for the most part indicated a considerable unreliability at least in the particular form of the material which was used. Such factors as the rate of heat addition or release, size and shape of container, presence of nucleating media, and temperature gradients proved important in determining the percentage of heat storage actually available compared with the theoretical. In several small house heating installations employing heat pumps with condenser-side storage, the amount of disodium phosphate actually used was 3300 lb with theoretical latent heat storage capacity of 400,000 Btu. Indications were that the material was only partially effective in actual heat-storage performance. A method which makes use of a mixture of this material suspended in oil has been successfully tested in the laboratory, and through use of forced circulation of the oil, has exhibited high rates of heat transfer.[9]

Low-Side Storage

With a heat-pump system the possibility also exists of storing heat at relatively low temperature on the low side (heat source side) of the system. The freezing of water has already been mentioned as one possibility. Heat pumps with solar energy as the heat source have been studied with low-side storage.[10]

A limitation present with this type of storage system as compared to high-side storage is that the peak heating capacity of the system is limited to the heat-pump capacity when operating with the low-temperature storage reservoir as the heat source. In many structures, particularly in colder climates where the benefits of heat storage are potentially greatest, this is less than the peak heating load.

CHAPTER 40

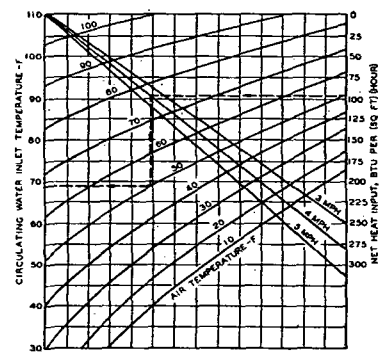
EVAPORATIVE APPARATUS FOR HEAT REJECTION

Water Cooling Methods, Water Use and Conservation, Rivers and Lakes, Spray Ponds, Atmospheric and Mechanical Draft Towers, Cooling Tower Theory, Design Conditions, Selection and Evaluation, Tower Location, Operation and Maintenance, Evaporative Condensers

REFRIGERATING systems and many other industrial processes generate heat that must be removed and dissipated. Small quantities of heat can be rejected directly to the atmosphere by convection and radiation. When large quantities are involved, the most effective procedure is to transfer the heat to cooling water flowing through a heat exchanger.[1] The water, if cheap and plentiful, may be wasted to a sewer or open waterway such as a stream or lake. The source of the cooling water may be wells, a public water system, or a lake or river.

WATER COOLING METHODS

Water Use and Conservation



The rapidly expanding demand for water is depleting what was once looked upon as an inexhaustible natural resource. The water table is receding in most localities. Communities are finding their present water systems inadequate to supply the increasing demands of domestic and industrial users. Heavy industrialization along flowing streams causes pollution. The temperature of the water that may be discharged into the stream is frequently limited in order to protect wild life. Many cities do not have adequate sanitary or storm sewers to handle cooling water. As a result of the increasing demand and the lack of an adequate supply or disposal system, users are being forced to conserve water by using recirculating systems. Heat must be removed from the circulating water by some type of water cooling apparatus.

Rivers and Lakes

Plants located on flowing streams can use a once-through system, discharging the heated water downstream from the intake to prevent mixing. Intake screens and sometimes settling basins, are needed to remove debris. The intake structure must be designed to handle flow conditions varying from flood stage to the minimum flow during periods of drought. The operation can be hampered during cold weather by ice clogging of the intake or by ice jams restricting the flow of the stream. Since water treatment is seldom economical, scale and corrosion may be a problem. Intermittent chlorination may be used, however, to control the growth of slime and algae on heat exchanger surfaces. If the stream temperature becomes too high, it may be necessary to cool the effluent before discharging it into the stream.

Lakes or ponds may also be used as a source of cooling water.[2] The water temperature in lakes or streams tends to follow the average dry-bulb temperature of the surrounding air. The temperature gradient of a lake will vary with the season of the year. Applying a heat load will raise the average water temperature and decrease the temperature gradient from the surface to the bottom although stratification will remain. The cold water intake should, logically, be located as far below the surface of the water as practicable, and remote from the hot water return to prevent bypassing. Dikes or piers have been built into lakes to prevent bypassing where cold water intakes are adjacent to hot water returns, but they offer little advantage unless they extend into a lake for a distance of at least 300 ft.

Warm water discharged near the surface spreads out as a thin film. The temperature near the surface of a cooling pond will average about 4 F deg above the bottom temperature. A suction pipe located at the bottom of the pond will not withdraw water at the temperature of the lowest stratum. A hydraulic gradient is set up which withdraws water from all strata, and the intake temperature will be about 2 F deg below the surface temperature. The heat dissipation is a function of wind velocity and the temperature difference between water surface and the dry-bulb temperature. Fig. 1 is a typical performance chart for lake cooling, with wind velocity measured 5 ft above water level. Throne[1] has developed additional charts for other conditions. The heat dissipation of a

Reprinted from Power Magazine, September 1951, page 88.

Fig. 1 . . . . Performance Chart for Lake Cooling

lake increases from 0 to 10 Btu per (sq ft) (hr) (F deg temperature difference) of air and lake water surface, for duty up to 150 Btu per (sq ft) (hr) and wind velocities up to 6 mph with air temperatures varying from 20 to 80 F.

Spray Ponds

Heat is dissipated from the surface of a lake by evaporation, radiation, and convection. The spray pond divides the water into small drops, greatly extending the water surface, and brings it into intimate contact with the air.[1] The heat transfer is largely due to evaporative cooling as explained in the section Cooling Tower Theory. The driving force is the difference in enthalpy rather than temperature difference. The water temperature tends to approach the wet-bulb rather than the dry-bulb temperature of the air. This offers an inherent advantage in making it possible to cool the water to a temperature lower than the dry-bulb.

Cooling occurs in a spray pond as the water is propelled upward and then falls to the surface of the pond. The pond itself acts largely as a collecting basin. A typical nozzle arrangement is shown in Fig. 2. The design criteria in Table 1 provide a guide that can be used in laying out a pond.

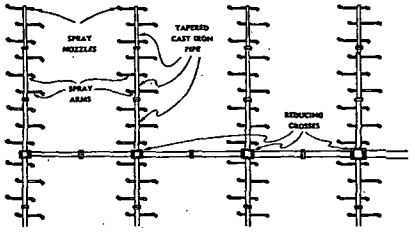


Fig. 2 .... Typical Nozzle Arrangement for a Spray Pond

The wind varies constantly in both direction and velocity. The wet-bulb temperature is usually changing also. These variations result in a continually changing temperature of the water as it strikes the surface of the pond. The pond acts as a reservoir so that the water temperature at the suction of the pump represents an average of past operating conditions. These characteristics make it difficult to test a spray pond or to develop ratings. As a result, spray ponds are not used when water temperatures must meet narrow limitations. They are usually designed for a 10 to 15 F deg cooling range and about a 10 deg approach of cold water temperature to the wet-bulb temperature.

The water leaving a spray nozzle will rise to a height of approximately 1 ft per psi of nozzle pressure. It will strike the surface of the pond in a circular pattern having a radius of about 10 ft. The cooling occurs within an *active filled volume* having a height equal to the elevation of the nozzles above the surface plus 1 ft per psi nozzle pressure, and a plan area extending 10 ft beyond the outer nozzles. The heat is transferred to the quantity of air passing through the *air area* which is the projected area of a vertical plane through the *active filled volume* and broadside to the direction of the air movement. The length of air travel is the horizontal distance the air moves through the *filled volume*.

Table 1 .... Spray Pond Design Data

Conventional Up-Spray System

	Units	Standard	Min	Max
Water capacity per nozzle	gpm	35 to 50	25	60
Nozzles per 12 ft length of pipe		6	4	6
Height of nozzles above water level	ft	6	5	12
Nozzle pressure	psig	6	5	7
Size of nozzles and nozzle arms	in.	2	1½	2
Distance between spray lateral piping	ft	25	13	38
Distance nozzles from pond side unfenced	ft	25 to 35	20	50
Distance nozzles from pond side fenced	ft	15 to 20	15	25
Height of louver fence	ft	12	12	12
Depth pond basin	ft	4 to 5	2	—
Friction loss allowed per 100 ft pipe	ft	1 to 3	—	—
Design wind velocity	mph	5	3	—

A reasonably accurate estimate of spray pond performance can be based on the outgoing wet-bulb temperature of the air passing through the filled volume. This temperature, obviously, cannot exceed the hot water temperature. It can approach the hot water temperature if it passes lengthwise through a long spray pond, but will have a small temperature rise when passing broadside through a narrow pond. The values in Table 2 can be used to obtain a reasonably accurate estimate of the cold water temperature with respect to the calculated outgoing wet-bulb temperature.

Wind passing through a pond carries away entrained water as drift. This creates a nuisance in the area on the leeward

Table 2 .... Degree Adjustments to be Applied to Leaving Air Wet-Bulb Temperature to Find Cooled Water Temperatures of Spray Ponds[a]

Cooling Range F deg	Entering Wet-Bulb[b] Temp. F	Adjustment in F Degrees		
		Length of Air Travel[c] (Feet)		
		100	50	25
10	80 WB	−3	+2	+4
	70 WB	−2	+3	+5

[b] Wet-bulb temperature of air entering *spray-filled volume*. See text.
[c] Length of air travel through *spray-filled volume*.

side of the pond. This must be considered when selecting the location of the pond. The drift loss can be minimized by enclosing the spray pond within a louver fence 10 to 12 feet high. Fogging, which can occur during cold weather presents another hazard to buildings or roadways. A pond should be located with due regard for seasonal variations in wind directions to provide maximum cooling during the hot summer months, and minimum hazard to roadways during the winter months.

Lower water temperatures can be obtained from a spray pond than from a cooling lake, and a much smaller area is needed. This reduces the initial cost when a natural lake is not available. This saving in cost is offset by the cost of piping, supports and spray nozzles. Pumping costs may also be higher due to the back pressure imposed by the spray nozzles.

Atmospheric Wind Towers

An atmospheric spray-filled tower (Fig. 3) is essentially a spray pond with louvered walls and an elevated spray system

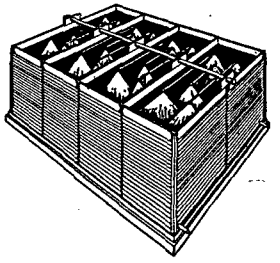

Fig. 3 .... Spray Filled Atmospheric Cooling Tower

which usually sprays downward. While the spray pond uses large nozzles handling 25 to 50 gpm each, the spray tower will have ¼ in. to ¾ in. nozzles handling 2 to 5 gpm each. Water loadings vary from 0.6 to 3.0 gpm per sq ft of plan area, and the heights vary from 6 to 15 ft. The design conditions are generally based on a 3 mph wind, but the down-spray nozzles have an aspirating effect that can induce a downward air movement of up to 400 fpm. Despite this positive air movement, wind is needed to carry the hot vapors away and prevent recirculation.

Atmospheric spray towers seldom exceed 50 ft in length. They frequently serve small refrigerating systems or cool jacket water of internal combustion engines. The performance can be estimated by calculating the outgoing wet-bulb temperature, as with the spray pond. The cold-water temperature will be approximately equal to the outgoing wet-bulb temperature, and performance can be estimated on that basis. An inadequate spray system will increase the water temperature several degrees. Spray towers require less basin area, less piping, and no more mechanical equipment than spray ponds. These savings may be largely offset by the extra cost of the structure.

The atmospheric deck tower contains wooden latticework decks regularly spaced from top to bottom. This filling interrupts the falling water, greatly increases the exposed water surface, and prolongs the time of contact with the air. Towers, such as shown in Fig. 4, are 20 to 50 ft high and 8 to 16 ft wide. The hot water is distributed at the top by a spray system or, more frequently, by open troughs. Except for the vagaries of the wind, the performance is quite predictable. This is done by the method described later for cross-flow mechanical-draft towers.

The cooling range of spray ponds or spray towers seldom exceeds 15 F deg and it is difficult to obtain less than a 10 F deg approach unless the cooling range is shorter than that. These performance limitations do not apply to the atmospheric deck tower. The design can control performance by variations in tower height, water loadings, and density of the filling.

The drift loss of a deck tower is considerable, and the nuisance is similar to that caused by the spray pond or spray towers. Both spray and deck towers are frequently located on building roofs, but the drift nuisance is seldom tolerated in congested areas. Water cooling systems that depend on the wind for air movement are not suitable for many services where the temperature requirements are more exacting.

Mechanical-Draft Towers

The mechanical-draft tower is equipped with fans to provide a positive and constant air flow. Since performance does not depend on the wind, it is possible to design mechanical-draft towers for exacting conditions. The fans may operate to provide forced or induced draft, depending on their location at the inlet or outlet of the tower. The tower may be cross-flow as shown in Fig. 5 or counter-flow as shown in Fig. 6. The addition of the fan makes it possible to design wider towers that are more compact than the long, narrow atmospheric towers. Early mechanical-draft towers were frequently of the spray-filled, forced-draft type. These spray-filled towers are rarely used at present except in congested areas where fire codes prohibit the use of wood filling.

The mechanical-draft tower is subject to recirculation of the exhaust vapors. These vapors will usually rise vertically on a still day and cause no trouble. Wind blowing across a

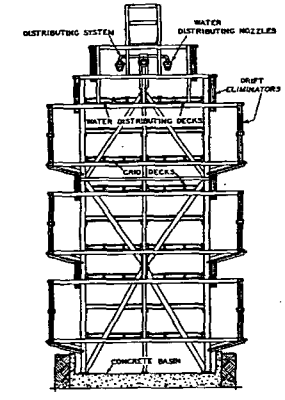

Fig. 4 .... Atmospheric Deck Tower

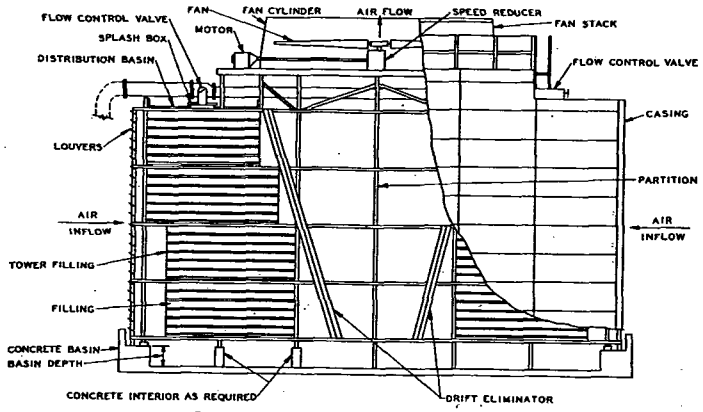

Fig. 5 .... Crossflow Mechanical Draft Tower

tower creates a low-pressure area on the leeward side. The exhaust vapors may then move downward and flow back into the tower. This increases the entering wet-bulb temperature and affects the performance accordingly. Recirculation is worse with forced-draft towers because of their low exit velocities. As a result, most towers built since 1940 are of induced-draft type. The forced-draft towers, however, have the advantage of locating the mechanical equipment away from the humid exhaust-air stream.

Air velocities usually vary from 300 to 400 fpm in counter-flow towers. The lower friction losses in cross-flow towers make it practicable to operate them at velocities up to 600 fpm. The water loading of counter-flow towers varies from 1.2 to 8 gpm per sq ft of plan area. The upper limit is largely determined by the blanketing effect of the distribution system. Since this blanketing is less pronounced in cross-flow towers, the loadings, based on plan area of the filling, can go up to 14 gpm per sq ft or higher.

Mechanical-draft towers require less plan area than ponds or atmospheric towers because of the higher water loadings. This is quite important in roof installations where the available space may be limited. This feature can be of great importance also in large industrial applications where space may be at a premium. Reduction in plan area will usually result in a saving in piping costs also.

Most manufacturers guarantee a drift loss that will not exceed 0.2 percent of the circulating rate, and the usual losses are probably less than that figure. The nuisance from drift is therefore much less with mechanical-draft towers.

COOLING TOWER THEORY

Basically, a water-cooling tower is a heat exchanger in which heat flows from the water to the air (1) by a flow of sensible heat from the warm water to the cooler air, and (2) by an exchange of latent heat resulting from the evaporation of a small part of the circulating water to increase the humidity ratio of the air by a corresponding amount. The general principles involved are similar to those encountered in the processes of diffusion in absorption and extraction equipment.[4, 5]

The generally accepted concept of cooling tower performance is based on enthalpy potential as the driving force. This is based on the relationship in an air-water mixture proposed by Lewis[6] showing that the numerical value of the coefficient of sensible heat transfer when divided by the coefficient of diffusion, approximately equals the specific heat of air at constant temperature. The relationship, involving three numerical values, each having different units, also explains why the wet-bulb temperature of a mixture of air and water

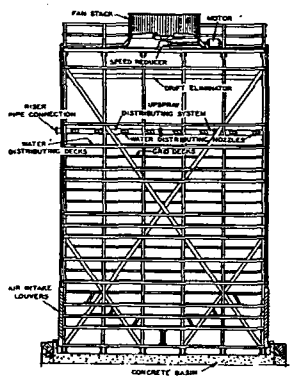

Fig. 6 .... Counterflow Induced Draft Cooling Tower

vapor approximates the temperature of adiabatic saturation. The relationship was applied by Merkel[7, 8] to combine the two coefficients into one overall coefficient based on enthalpy potential.

Details of the theoretical analysis have been published by various authors[9, 10, 11, 12] and those interested in the derivation of the equations should refer to these references. The derivations are based on the following assumptions:

1. Each particle of water is surrounded by a film of air that is at the temperature of the water and saturated with moisture.
2. The specific heat of water is unity at the temperatures encountered.
3. A constant wet-bulb temperature at varying humidity ratios represents constant enthalpy.
4. There is no weight loss of water due to evaporation during the cooling process.
5. The Lewis relationship applies.

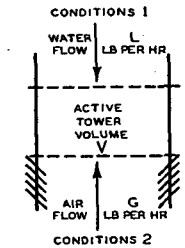

Fig. 7 .... Operations in a Typical Water Cooling Tower

Considering the cooling tower shown in Fig. 7 on the basis of these assumptions, the heat transfer per square foot of plan area in an incremental volume dV is

$$(G)(dh) = Ka(h'' - h_a)dV \tag{1}$$

Integration gives the familiar equation

$$\frac{KaV}{G} = \int_1^2 \frac{dh}{h'' - h_a} \tag{2}$$

It is more convenient to analyse cooling tower performance on the basis of water temperature, so

$$dh = \frac{L}{G}\,dt \tag{3}$$

and

$$\frac{KaV}{L} = \int_1^2 \frac{d\theta}{h'' - h_a} \tag{4}$$

where

- a = overall average wetted area (surface of water drops plus wetted tower surface), square feet per cubic foot of active tower volume.
- G = weight rate of flow of air, pounds of dry air per hour.
- h_a = enthalpy of air-vapor mixture, Btu per pound of dry air.
- h'' = enthalpy of saturated air-vapor mixture at water temperature, Btu per pound of dry air.
- K = overall energy unit conductance, Btu per (hour) (square foot overall average wetted area) (Btu enthalpy difference per pound of dry air).
- L = water rate, pounds per hour.
- θ = temperature of water in tower, Fahrenheit.
- θ_1 = temperature of inlet water, Fahrenheit.
- θ_2 = temperature of outlet water, Fahrenheit.
- V = active tower volume, cubic feet.
- Z = height of filled volume, feet.

Either Equation 2 or 4 applies, but Equation 4 is more commonly used to reduce performance conditions to a numerical value called the *Number of Transfer Units* (NTU). A *transfer unit* is related to a set of performance conditions which are such as to make the right-hand side of the equation equal unity. This is a condition in which the temperature change equals the mean driving force. The (NTU) evaluates the degree-of-difficulty by expressing the rate of temperature change per square foot of plan area per Btu of mean driving force.

The (NTU) applies to a vertical column of tower having one sq ft of plan area, a height Z and a volume V. Since V and Z are numerically equal

$$\frac{Ka}{L} = \frac{1}{Z}\int \frac{d\theta}{h'' - h_a} \tag{5}$$

This is the Unit-Volume Coefficient, obtained by dividing (NTU) by height. It evaluates the rate of temperature change per cubic foot of tower per square foot of plan area per Btu of mean driving force. This refers to temperature change without regard to the amount of water being cooled. Transposing L

$$Ka = \frac{L}{Z}\int \frac{d\theta}{h'' - h_a} \tag{6}$$

This is the overall coefficient and evaluates the Btu transferred per cubic foot of tower per square foot of plan area per Btu of mean driving force.

Equation 4 may be evaluated by a process of mechanical or graphical integration with the aid of a temperature-enthalpy diagram such as is shown in Fig. 8. The water enters the tower at temperature θ_1, having enthalpy h_1''. As it is cooled, the enthalpy of the air film surrounding it follows the saturation curve to temperature θ_2 where the enthalpy is

h_1''. Air enters the tower at wet-bulb temperature t_1' having an enthalpy of h_1, which is plotted vertically below h_1''. Since the heat removed from the water equals the heat added to the air, the enthalpy increase per pound of dry air equals the temperature change of the water multiplied by the liquid/gas (L/G) ratio. The enthalpy of the air, therefore, increases along a straight line having a slope equalling L/G and terminating at h_2 which is vertically below h_1''. The driving force at any section of the tower is $h'' - h_a$, the vertical distance between the two operating curves.

Example 1: It is desired to cool 300 gpm (150,000 lb of water per hr) from 110 to 84 F with 3050 cfm (125,000 lb of dry air per hr) with an entering wet-bulb temperature of 75 F. Calculate the (NTU) showing the successive steps in tabular form.

Solution: The sequence of steps in the mechanical integration is shown in Table 3.

Water temperature is entered in Column 1 in even, but not necessarily equal, increments. One-degree increments are used from 84 to 90 F where the potential difference is small, and the effect of the reciprocal is large. Little accuracy is sacrificed by using 5-degree increments from 90 to 110 F where the potential difference is larger and its reciprocal smaller. Column 2 shows the enthalpy of saturated air corresponding to the temperatures in Column 1. Air enters the tower at a wet-bulb temperature of 75 F, having an enthalpy of 38.61 Btu per lb of dry air. This value is entered at the top of Column 3. The enthalpy of the air increases by $\Delta h = \frac{L}{G}d\theta$. The L/G ratio is $\frac{150{,}000}{125{,}000} = 1.2$ so Δh equals 1.2 Btu from 84 to 90 F and 6 Btu from 90 to 110 F. These increments are added to the initial enthalpy to obtain the successive values in Column 3. The enthalpy potential difference in Column 4 is the difference between Columns 2 and 3. This driving force appears in the denominator of Equation 2 so the reciprocal of Column 4 is entered in Column 5. The (NTU) within each increment equals the temperature change multiplied by the average of the entering and leaving values from Column 5. The products are entered in Column 6. The summation of Column 6 in Column 7 gives the (NTU) for the cooling ranges in Column 8. Hence, the mechanical integration reduces the given conditions to the numerical value of 2.0517 *Transfer Units*.

Example 2: The cooling tower designed to handle the conditions in *Example 1* has a fill height of 8 ft and a plan area of 96 sq ft. Calculate the unit-volume and overall coefficients and explain their significance.

Solution: The (NTU) of 2.0517 as determined in *Example 1* signifies the tower must cool the water 2.0517 deg per Btu of mean driving force. This cooling is accomplished in 8 ft of fill height, so the unit-volume coefficient is $\frac{2.0517}{8} = 0.2565$. This means that each cubic foot of tower must cool the water 0.2565 degrees per Btu of mean driving force. The water loading is $\frac{150{,}000}{96} = 1563$ lb per (sq ft) (hr). The overall coefficient is $0.2565 \times 1563 = 400.91$. This signifies that the tower must transfer 400.91 per cu ft (hr) (Btu of mean driving force).

Column 7 of Table 3 shows how the (NTU) increases with cooling range. A plot of Columns 7 vs. 8 can be used to determine the (NTU) for intermediate cooling ranges. This curve can also be used to determine temperature distribution because equal increments of transfer units correspond to equal increments of tower height. The linear relationship between (NTU) and height provides the basis of the procedure used to analyze crossflow cooling towers.[13]

Since the water temperature varies both horizontally and vertically in a cross-flow tower a double integration is required. This is accomplished by using equal increments of *transfer units*, representing equal increments of distance, and calculating the corresponding temperatures. Counter-flow integration progresses from the bottom of the tower upward. The cross-flow integration starts at the top of the air inlet, and progresses downward and inward.

Required and Available Coefficients

Any set of performance conditions can be accomplished by an infinite number of cooling tower designs. Calculating the (NTU) serves to evaluate the degree-of-difficulty of the problem. The *unit-volume* coefficient is more specific, but it also applies to an infinite number of towers of a given height. The *overall coefficient* has the most significance when comparing towers of different designs that are being considered for a given duty. It evaluates the effect of variations in air rate, height, and plan area on the *required* coefficient. A higher *required* coefficient indicates that more effective filling is needed. The effectiveness of a filling is determined almost entirely by the density of the splash surface and wetted surface per cubic foot of filled volume.

These calculations evaluate the problem, not the tower. The *available* coefficient of a specific cooling tower is determined from its operating characteristics. The tower must be tested at various conditions and the data from each test reduced to a corresponding coefficient. A cooling tower coefficient is not constant, but varies with operating conditions. Its characteristic is established by correlating variations of the coefficient with corresponding operating conditions.

The characteristic of a cooling tower closely approximates the relationship expressed by the general equation:

$$Ka = cL^nG^m \qquad (7)$$

The cooling tower manufacturer uses this procedure to determine the characteristic of each cooling tower design.

An examination of the steps taken in the solution of *Example 1* will show that various air rates could have been specified. Increasing the air rate would have reduced the degree-of-difficulty and resulted in a smaller (NTU) for a given set of conditions. Decreasing the air rate would have the opposite effect. Therefore, the *required* coefficient for a given set of conditions varies with the air rate. A tower will operate at a given set of conditions when the *required* coefficient equals the *available* coefficient as determined from Equation 7.

DESIGN CONDITIONS

The design conditions used in selecting a cooling tower are (1) the circulating water rate, (2) cooling range, (3) entering wet-bulb temperature, and (4) the approach of the cold-water to the wet-bulb temperature. These conditions are selected by considering the function of the cooling tower in the overall system. The system includes a process having a heat load that is to be transmitted to the circulating water through a heat exchanger. The cooling tower rejects the heat load to the atmosphere. Certain design conditions of the system affect the design of the cooling tower. They include (1) the heat load, (2) the temperature at which it is to be removed, and (3) the wet-bulb temperature of the atmosphere to which the heat is finally rejected. The cooling tower and heat exchanger are then selected to serve these conditions. The relationship of the cooling tower to the system is shown schematically in Fig. 9, with the process represented by two heat sources operating in series.

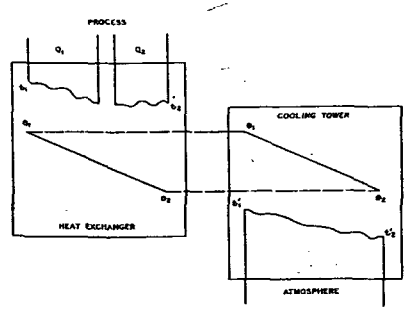

Fig. 9 .... Relation of Cooling Tower to Process

Heat Load

No definite sequence can be followed in selecting the design conditions because each item affects the choice of the others. The heat load comes closest to being a fixed quantity so can be considered first.

The amount of heat rejected by typical processes is shown in Table 4. The heat is rejected at a constant temperature when vapors are condensed, as illustrated by Q_1 in Fig. 9. A second type of heat load, represented by Q_1, consists of reducing the temperature of a fluid. Each type of heat load has specific requirements that affect overall design. The temperature at which the heat is removed from a process may be as important in the overall design as the heat load itself. As this temperature level decreases, the degree-of-difficulty increases at an accelerated rate, calling for larger and more expensive equipment. Higher temperatures usually result in higher operating costs, and loss of capacity in the process.

* Head pressure.

Condensing Systems

Each vapor has a pressure at which condensation occurs for any given temperature. This pressure increases with temperature up to the critical temperature of the vapor, above which no amount of increased pressure causes condensation. Condensation in a process occurs at constant temperature because a constant pressure will exist in the heat exchanger. The condensing pressure is usually the controlling factor in the process, although this is obtained by designing for the corresponding temperature. Table 5 lists typical condensing data for commonly used vapors.

A transfer of heat from the vapor to the circulating water requires a temperature differential between the two media. Since the vapor must condense at a constant temperature, the condensing temperature t_2 in Fig. 9 must be higher than the hot water temperature θ_1. It is for this reason that the condensing temperature is largely determined by the temperature of the warm water leaving the heat exchanger, and the entering cold-water temperature has only a small effect. The terminal temperature difference is controlled by the amount of heat transfer surface in the condenser. Economically sized condensers are usually designed to operate with 3 to 10 F deg temperature difference between the vapor and hot water.

Fluid Cooling

Different conditions exist when cooling a fluid such as milk, natural gas, or distillate. When this is done in a counter-flow heat exchanger, two terminal differences are involved. The fluid can be cooled to a temperature approaching that of the entering cold water, and the circulating water can be heated to a temperature approaching the hottest temperature of the fluid. A terminal temperature difference must exist at both the hot and cold end of the exchanger, but the temperature of the fluid leaving the exchanger can be colder than the hot water temperature.

Water Circulating Rate

The heat load on the system is determined by the process being served, and when this value is fixed, the circulating water rate determines the temperature rise in the heat exchanger. The cooling range in the cooling tower is obviously equal to the rise in the exchanger when the two are operating in equilibrium. The type of heat load and the characteristics of a cooling tower govern the selection of the optimum circulating rate. Increasing the circulating rate while holding the other operating conditions of a cooling tower constant, will reduce the cooling range. The cold-water temperature will increase, but the hot-water temperature will decrease to a greater extent. A high circulating rate and a short cooling range is advantageous when condensing vapors because the lower hot-water temperature has more effect on condensing temperature than the smaller increase in cold-water temperature. This advantage can be offset by greater power requirements for pumping, and possibly by the increased cost for larger piping.

Cooling a fluid presents a different problem. The cooling tower must deliver the cold water at a temperature that is below that of the cooled fluid, and this is more easily accomplished with a low water rate. The process may involve several heat loads, one of which requires a low temperature and the other can be removed at a much higher level. The size of a cooling tower is governed more by the cold-water temperature than by the cooling range. Once the cold-water temperature is fixed, it is desirable to increase the range as much as possible. A single cooling tower serving several heat loads in series is usually more economical than a number of individual towers.

A refrigerating system rejecting 250 Btu per ton imposes a load on the cooling tower of 30 (F deg) (gallons) per ton. The standard practice is to design the towers for 3, 4 or 5 gpm per ton, corresponding to cooling ranges of 10, 7½ and 6 F deg, respectively. Towers serving steam condensers usually operate with a range of 12 to 19 F deg. Oil refineries usually design for a cooling range of 25 F deg or more.

Heat Exchanger

The cooling tower operates in conjunction with the heat exchanger in transferring heat from the process to the atmosphere. Increasing the size of either one will reduce the required size of the other. The optimum conditions are determined by considering the initial and operating costs of several combinations of cooling towers and heat exchangers.

Process Characteristics

The type of process must be considered when selecting the design conditions of the system. This is particularly true of the temperature at which heat is removed from the process. Ammonia refrigerating systems are frequently designed to operate at 185 psig head pressure, corresponding to 96 F condensing temperature. This will require cooling water leaving the condenser at about 90 F. It will be impractical in most localities to select a cooling tower that will not exceed that temperature during brief periods. An increase in the temperature of the circulating water will raise the head pressure and increase the power requirement of the compressor. The increased head pressure also reduces the refrigerating capacity, but the system can be designed to perform acceptably at such times. A carbon dioxide refrigerating system represents a more serious situation. The critical temperature of the refrigerant is 88.4 F so the system will not function if that temperature is exceeded. The design conditions are also influenced by the process served by a refrigerating system. The maximum refrigerating load does not necessarily coincide with peak wet-bulb temperatures so a reduction in capacity may not be serious. That may not be true in the case of air conditioning if the maximum capacity is needed when wet-bulb temperature may be at its highest.

The efficiency, capacity and operating costs of a steam electric generating station all improve as the condensing temperature decreases. Designing for maximum performance at the most adverse conditions will result in a plant having excess capacity most of the time. The most adverse conditions occur during summer daylight hours, and peak power loads formerly came during winter evening hours. This gave the happy combination of peak demand during favorable operating conditions, and a low demand when the conditions were adverse. The power industry is profiting from the expansion of air conditioning, with the result that the peak load is beginning to coincide with the most adverse operating conditions. A generating plant can be designed to accept higher operating costs during such periods, but higher operating temperatures can reduce capacity below the required demand.

The capacity of an industrial operation such as an oil refinery will vary with the temperature of the cooling tower. Such a process may be so involved that it is not practicable to vary the output with fluctuation of the weather. These plants usually are compelled to operate at a constant rate that can be maintained from day to day. All processes using cooling water are faced with variations in water temperature. Higher temperatures increase operating costs and reduce capacity. These can be overcome by installing a larger plant or a larger cooling system, with the result that one portion of the equipment will have excess capacity during most of the year. The overall design must be based on (1) the minimum permissible capacity under the most adverse conditions and (2) an economic study showing the effect of changes in the size of the components on initial cost and operating expense.

Wet-Bulb Temperature

The wet-bulb temperature is beyond the control of the designer. It fluctuates during the day, and throughout the year. The annual averages should be studied and correlated with the characteristics of the process. Peak wet-bulb temperatures are usually of short duration so have little effect on annual operating costs, but the effect of these conditions in limiting capacity must be considered. The design wet-bulb temperature should be selected on the basis of the number of hours of the four summer months of June through September (or of the year) that it can be exceeded during an average year. A common practice in air conditioning is to select a wet-bulb temperature that will not be exceeded more than 5 percent of the time during the four summer months. Various groups are cooperating in compiling weather data for this type of study. A limited portion of the data are tabulated in Table 2, Chapter 13. More complete summer weather data, statistics, charts, maps, and technical analysis have been prepared by Albright.[13]

When the circulating rate and water temperatures have been selected, the size of the cooling tower will be increased by selecting a higher wet-bulb temperature. Selecting the design wet-bulb temperature makes it possible to consider various combinations of cooling towers and heat exchangers. The overall design will, of necessity, consider the worst possible conditions. This will correspond to the maximum wet-bulb temperature for the locality, and the highest permissible process temperature. All components should be selected with these conditions in mind, but testing will be easier if the same size equipment is designed and guaranteed around a lower wet-bulb temperature. Table 6 shows that an ammonia refrigerating system might be designed for a 78 F wet-bulb temperature. That temperature will prevail 12 hours a summer, and for brief periods of time. Designing the same equipment around a lower wet-bulb temperature greatly increases the amount of time that tests can be conducted at or near the design conditions.

Table 6 . . . . Alternate Design Conditions for Ammonia Refrigerating System, Showing Annual Hours the Design Wet-bulb Temperature is Attained

Wet-Bulb Temp. F	Hot Water Temp. F	Head Press. psi	Hours Attainable
78	92.0	185	12
75	88.5	174	161
70	86.0	166	750

SELECTION AND EVALUATION

The characteristics of the various types of water cooling equipment will influence the final selection. The requirements of the process, and physical conditions of the plant will impose further restrictions. These factors will determine the design conditions to be used and indicate the general type of equipment that will be most desirable. A wide variety of cooling towers will, nevertheless, be capable of meeting the design conditions. Competitive designs may be similar, but they will not be identical. The same design can be considered in various frame sizes, representing different plan areas or heights. An increase of frame size will enable a tower to meet the conditions with less total air flow, and will reduce horsepower requirements. As a general rule, an increase of frame size increases the initial cost but reduces operating costs. Optimum size is determined from an economic evaluation that will include such items as the following:

CAPITAL INVESTMENT

1. Total erected cost of cooling tower.
2. Basin, grillage, and value of the space occupied.
3. Cost of pump and prime mover.
4. Electric wiring to pump and fan motors.
5. Electrical controls and switch gear.
6. Cost of piping from tower inlet to point on tower nearest to plant.
7. Sump, screens, overflow, and make-up lines not furnished by manufacturer.
8. Shut-off and control valves not furnished by manufacturer.
9. Walkways, ladders, etc., providing access to tower.

OPERATING COSTS

1. Demand charge, if it enters into cost.
2. Energy costs for fans and pumps, based on 3000 to 7000 hr per yr.
3. Amortization of investment, over a period varying from 3 to 30 years.
4. Maintenance and repairs.

Other factors to consider are safety features, conformity to building codes, general design and rigidity of structures, availability of spare parts, experience and reliability of manufacturer, and operating flexibility for economical operation at varying loads or seasonal changes. Failure to perform in accordance with the guarantee usually proves costly to the

purchaser regardless of subsequent adjustments made by the manufacturer. The capability of a cooling tower should be evaluated prior to purchase, and acceptance tests conducted during the warranty period.

TOWER LOCATION

Small cooling towers are frequently located on the roof or offset of a building, but large towers must be located on the ground. Proper location and orientation are needed in either case to insure satisfactory performance. A most important factor is to provide for a free flow of air to and from the tower. The air flow to a tower can be obstructed by adjacent structures or by screening walls in the case of roof installations. Such walls must be provided with openings that are at least equal to the inlet area of the tower. If the opening in the wall is not immediately adjacent to the tower inlet, the wall must be set back far enough to allow the air to flow around or under the tower to the inlet.

Downdrafts are created by wind blowing over a cooling tower or adjacent structures. The exhaust air is carried downward and can re-enter the tower from the leeward side. Since such recirculation raises the entering wet-bulb temperature a location should be selected that results in the least loss of performance during the hottest weather. Recirculation is usually the least with an end wind unless the tower is over 300 ft long. Adjacent structures and topography affect the wind. They should be considered carefully together with U. S. Weather Bureau data for the locality. A cooling tower should not be located where the prevailing summer wind will carry heat to it from an external source or from another cooling tower.

A properly designed cooling tower will have a drift loss not more than 0.2 percent of the circulating rate. A small amount of water in the exhaust air is unavoidable, but it can be objectionable if the droplets fall on parked automobiles, nearby windows or power lines. Evaporation leaves a deposit of the dissolved solids.

The moisture content of the air passing through a cooling tower is increased due to the evaporative cooling of the water. Condensation is unavoidable if the vapors strike a cool surface and cause a hazard that can be serious during freezing weather. During periods of high relative humidity, fogging occurs as the exhaust air mixes with the atmosphere and is cooled below its dew point. Fogging is usually worse in the spring or fall when the ambient air is humid and cool but not too cold. Warm air during the summer is capable of absorbing the excess moisture without producing a fog. Less water evaporates in the tower during extremely cold weather because the humidity ratio is reduced, so the fog is dissipated rather rapidly.

The drift nuisance is usually confined to an area immediately adjacent to the tower although high winds can carry it several hundred feet at times. Fogging, however, is less localized and can occur close to the tower or settle to the ground a considerable distance away.

Noise problems occur when cooling towers are located in congested areas. This applies particularly to small towers rather than large industrial installations. The sound is created by the falling water or fans and air movement. The water noise does not carry far but is quite noticeable adjacent to a tower. The sound of the fans may be audible at a considerable distance away from the tower if it is not deflected by intervening structures. Deflecting screens are of some value, and acoustical treatment is quite effective but expensive. It is commonly believed that objectionable noise can be eliminated by a reduction in the tip speed of the fan. This is seldom successful because the sound is a function of horsepower as well as tip speed. Both of these must be reduced to lower the sound level.

OPERATION AND MAINTENANCE

Most cooling tower manufacturers issue operating and maintenance instructions. These bulletins should be placed in the hands of operating personnel for their guidance.

Water Treatment

The general discussion of this subject in Chapter 55 offers detailed information on scale deposition, corrosion, and control of biological fouling. The dissolved solids in a circulating system are concentrated as water is lost by evaporation. The evaporation averages 0.8 percent of the circulating rate for each 10 F deg of cooling range. Excessive concentration is prevented by wasting a portion of the circulating water as blowdown. The make-up water, replacing losses due to evaporation, drift and blowdown, introduces dissolved solids into the system. An equal amount of solids must be removed by the drift and blowdown. Expressing all terms as a percentage of the circulating rate, the number of concentrations in the system is:

$$\text{No. of Conc.} = \frac{\text{Evaporation} + \text{drift} + \text{blowdown}}{\text{Drift} + \text{blowdown}} \quad (8)$$

The form of Equation 8 shows that a small amount of blow down is highly effective, but higher rates are of little advantage. Drift loss alone will maintain about 15 concentrations. This is rapidly reduced to 3 or 4 concentrations with 1 percent blowdown, but an increase to 100 per cent blowdown brings the system down to one concentration. Draining the system periodically is a poor substitute for continuous blowdown, because the concentration builds up to the maximum within a few hours.

Towers operating continuously are usually arranged for blowdown by maintaining a water level in the collecting basin that allows the desired quantity to be wasted at the overflow connection. Placing the blowdown connection in the hot-water line adjacent to the tower inlet prevents unnecessary waste when the pump is stopped. This is recommended for intermittent operation.

Many small installations rely on blowdown for water conditioning, and use no supplementary water treatment. Larger installations find it desirable to use chemical treatment in the system, and most of these processes require a controlled blowdown rate. Chapter 55 discusses the chemicals used to control scale, corrosion and biological fouling.

Wood Deterioration

Wood is one of the most durable materials, but it can be destroyed by chemical action or by organisms producing decay. Until 1950, the deterioration of cooling tower lumber was looked upon as the result of chemical action, but later investigations indicate it is largely due to micro-biological attack.[14] Deterioration can be expected if sodium carbonate is present in the water. This was formerly classed as a chemical attack although sodium carbonate is a rather poor pulping agent. The deteriorated wood almost invariably contains wood-destroying organisms, so the actual cause of the deterioration can be chemical, micro-biological or a combination of the two.

Chlorine is frequently used to control the growth of slime and algae that foul the circulating system. This is a powerful oxidizing agent that attacks the wood if used excessively. The action bleaches the surface of the wood and loosens the fibers, allowing them to wash away and collect in the heat exchangers or on the screens. A more common type of surface attack, however, is caused by soft rot organisms. The more durable species of wood contain fungicidal materials that are removed by oxidizing agents such as chlorine. These materials are also removed by normal leaching.

Decay organisms are widespread in nature, serving a useful and necessary purpose in sewage disposal systems or in the disintegration of dead trees in the forest. The same process is highly undesirable when it occurs in structural lumber. It is prevented by impregnating the lumber with preservatives that are toxic to the organisms. The use of treated lumber in cooling towers has been increasing since 1953. Service records accumulated since that time indicate that the service life of cooling tower lumber can be economically extended by preservative treatment. The use of treated wood increases the initial cost of a cooling tower about 10 percent. Preservatives can be applied by the double diffusion method to existing cooling towers built of untreated lumber.[14]

Winter Operation

The basin and piping must be drained, or otherwise protected, if a cooling tower is shut down during freezing weather. Towers that are shut down frequently are preferably operated with a *dry basin*. The tower is installed at an elevation that allows the basin to drain into an indoor tank to which the circulating pump is connected.

Water-cooling towers operating in freezing weather are subject to ice formation, particularly at the air inlet. This is not influenced by the temperature of the circulating water since the icing occurs where fine drops splash out and strike relatively dry surfaces in the entering air stream. Stopping the fans temporarily allows the water to fall vertically across the inlet, and much of the ice is melted. Ice that is not melted in this manner can be removed by reversing the fans for 15 or 20 minutes. Air flow is obstructed by the ice, causing water temperatures to increase drastically. Since the water temperature increases when icing occurs, it is not possible to use thermostatic controls to stop or reverse the fans.

CONTROL OF COOLING TOWERS

Other than the usual electrical interlocks with the refrigeration system, few automatic controls are used on cooling towers. Sometimes the fan is turned off automatically to reduce capacity in cool weather. Towers not of the dry-basin type may have drain valves controlled by outdoor thermostats to prevent freeze-up of the water in the pan.

EVAPORATIVE CONDENSERS

The evaporative condenser combines the functions of the condenser and cooling tower by using a minimum amount of water on a surface, cooling it to approximately the wet-bulb temperature of the surrounding atmosphere.

The end view of a typical evaporative condenser is shown in Fig. 10. The fan draws the air over a condenser surface which is kept wet by a water spray. The discharge refrigerant gas from the compressor enters the top of the condenser coil. The liquid refrigerant is drained from the bottom of the coil into a liquid receiver, and then circulates through the remaining portion of the system in the usual way.

The water is circulated through the spray nozzles and drops into the sump where its level is maintained by means of a float valve. The eliminator plates are placed in the path of the water-air mixture so as to remove the entrained water. Since the air leaving the unit is almost completely saturated, care must be taken in locating discharge ducts to prevent condensation.

Evaporative condensers are available in sizes up to 300 tons or more. These units use only a small portion of the water required for a waste-water cooled condenser. The water is vaporized by the heat of the refrigerant. Each pound of water used extracts approximately 1000 Btu from the refrigerant, whereas under commonly used rating conditions where the water temperature rise is 20 F deg, each pound of water extracts only 20 Btu from the refrigerant. The water used including the loss by entrainment in the discharge air, the blow down, and the evaporation, amounts to about 3 to 5 percent of that which would be required for a water-cooled condenser.

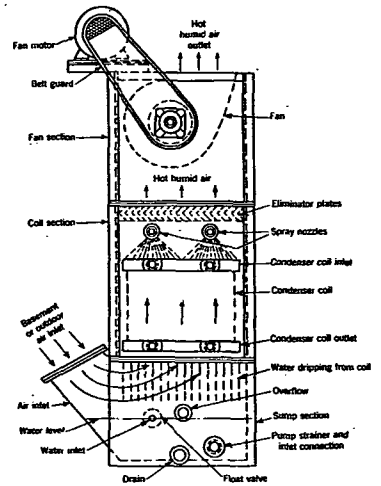

Fig. 10 .... Schematic View of an Evaporative Condenser

The evaporative condenser requires more maintenance, occupies greater space (must be located where air is available), and has a higher first cost than the water-cooled condenser, but where the use of water is restricted or expensive, the evaporative condenser has become widely accepted. Compared with a water-cooled condenser and cooling tower, which have about the same heat dissipating capacity, the evaporative condenser has the advantage of lower cost and smaller space requirements.

Control of Evaporative Condensers

An electrical interlock is usually provided to prevent the refrigeration system from operating until the pump and fan

of the evaporative condenser have been started. In some cases, an automatic damper is used on the inlet of the evaporative condenser to provide proportional control of head pressure on the refrigeration system. See Chapter 43 for general information on controls.

CHAPTER 41

EVAPORATIVE AIR COOLING AND HUMIDIFICATION

Apparatus for Humidification, Spray Generation, Spray Distribution, Unit Humidifiers, Air Washers, Humidification with Air Washers, Dehumidification and Cooling with Air Washers, Evaporative Air Cooling, Types of Direct Evaporative-Cooling Equipment, Design Considerations, Controls, Maintenance

EVAPORATIVE air cooling and humidification increase the moisture content of an air stream or the air in a selected space, with or without a change in dry-bulb temperature.

Evaporative air cooling applies the well-known phenomenon of evaporating water at ambient temperature into an air stream. If no heat is added during the process, the dry-bulb temperature of the air stream is reduced along the thermodynamic wet-bulb temperature line with a consequent increase in latent heat and moisture content.

Humidification, used industrially and in residential air-conditioning and heating systems, may be accomplished by evaporative air-cooling apparatus, by the direct introduction of water spray into the air stream or space either by heated evaporating pans or steam jets. Some equipment can be used for both cooling and humidification.

APPARATUS FOR HUMIDIFICATION

Humidification may be direct or indirect, i.e., water in droplets or vapor form may be introduced directly into the humidified space, or previously humidified air may be circulated in or through the space. Evaporative air cooling is always indirect although the cooling may be accomplished by wetted surface or secondary cool surface.

The classification of apparatus used for humidification and evaporative air cooling is shown in Table 1.

HUMIDIFICATION SPRAY GENERATION AND DISTRIBUTION

Spray generation is obtained by (1) compressed air, (2) impact, (3) hydraulic separation, and (4) mechanical separation. Atomization can be accomplished by the use of a compressed air jet to reduce the water particles to a fine spray. With the impact method, a jet of water under pressure impinges directly on the end of a small round wire. Where hydraulic separation is employed, a jet of water enters a cylindrical chamber and escapes through an axial port with a rapid rotation which causes it to separate in a fine cone-shaped spray. In the mechanical separation process, water is thrown by centrifugal force from the surface of a rapidly revolving disc and separates into particles sufficiently small to be utilized in certain types of mechanical humidifiers.

Spray distribution is obtained by (1) air jet, (2) induction, and (3) fan propulsion.

Air-jet distribution utilizes the atomizing jet to distribute the spray through the space. Induction distribution utilizes the aspirating effect of an impact or centrifugal spray jet to induce air flow through a casing or duct for distribution of the spray. Fan propulsion uses a power-driven fan to distribute the spray.

Atomizing Humidifiers

In several types of atomizing humidifiers nozzles are placed within the room. Compressed air effects complete atomization of the water which is converted into vapor by the heat of the room air. In some of these nozzles an aspirating effect draws the water into the nozzle and atomizes it. Others are operated on a combined air and water pressure. It is usual for nozzles of the water-pressure type to be controlled by a diaphragm valve actuated by the pressure of the atomizing air.

High-Duty Humidifiers

Water is supplied at about 150 psig to an impact-type spray-generating nozzle located in a cylindrical casing. A drainage pan provides for the collection of unevaporated water which is returned to a filter tank. A powerful air current from a fan mounted above the unit, flows through the cylinder and is charged with moisture. Air discharges from an opening below at a high velocity in a complete and nearly horizontal circle. The spray is evaporated and the resulting vapor is diffused and distributed.

Spray Humidifiers

This type uses a spray nozzle in a cylindrical casing equipped with a drainage pan. The aspirating effect of the nozzle induces a moderate air current through the casing which distributes the entrained spray. The general method of circulating and returning the water is similar to that employed for high-duty humidifiers. A suitable pump and centrally-located filter tank are required.

Self-Contained Humidifiers

In this type mechanical or centrifugal means are used to generate and distribute spray. They may be used either singly or in groups. In large installations, where suitable connections are provided to permit the cleaning and servicing of individual units without affecting the room as a whole, group control of the water and power may be employed.

UNIT HUMIDIFIERS

The term unit humidifier denotes an assembly of elements the principal function of which is to humidify. The essential

element of a unit humidifier is an atomizer or evaporator. To this may be added a fan, a heater, outlet vanes or diffusers, and a housing to enclose the various parts.

Unit humidifiers fall into four general classifications, depending on the method of causing evaporation. These are as follows: (1) *Nozzle Type*, (2) *Rotary Type*, (3) *Cascade Type*, and (4) *Heater Type*.

In the *nozzle* type of humidifier water is sprayed into the air and evaporation is effected by adiabatic exchange of energy. Units of this type in simplest form, spray a fine mist of water directly into the air in a space. They are used to a great extent in the textile industry.

The *rotary* type of humidifier generates and distributes by mechanical separation using rotating discs. In all other respects, this type of humidifier is similar to the nozzle type. It has the advantage over the nozzle type of being less likely to become clogged.

In the *cascade* type the humidification takes place by water falling in sheets over a series of baffles or trays. This type is usually furnished with a fan, air heater, and air filter, all enclosed in a housing.

In the *heater* type of humidifier the water is heated either to the boiling point or to a temperature at which the water vapor readily passes into the air stream. In the simplest form the heating element using steam, hot water, gas, oil, or electricity is placed in a pan or vessel of water, and the vapor passes from the surface of the water to the stream of air.

A modification of this type of humidifier is the combination of spray nozzle and heater type in which the water is sprayed over a hot surface and evaporated. It has the disadvantage of accumulating scale on the surfaces of the vessel or heating surface.

Unit humidifiers are usually controlled by a two-position room humidistat operating a controlled device which functions to start and stop the humidifying action. This may be a valve on the water supply to the humidifier. The fan, if used, normally is also turned off by the humidistat. The controlled device operates the source of heat in the heater type of humidifier. See Chapter 43 for a general discussion of humidity controls.

AIR WASHERS

Spray-Type Washers

A spray-type air washer consists essentially of a chamber or casing containing a spray nozzle system, a tank for collecting the spray water as it falls, and an eliminator section at the discharge end for removal of entrained drops of water from the air. A pump recirculates water at a rate greatly in excess of the evaporation rate. Intimate contact between the spray water and the flowing air causes heat transfer between the air and the water, resulting in either humidification or dehumidification, depending upon the method of operation and the relative temperatures of air and spray water.

To prevent backlash of spray ahead of the washer chamber, and to provide more uniform air distribution, perforated inlet plates, horizontal louvers or vertical eliminator baffles may be provided in the washer inlet. Inlet diffusion plates may be required when the air and water spray are in the same direction because eddy currents may be present. Eliminator baffles are used where one or more of the water sprays opposes the air flow and is sufficiently close to the entering end that water might come out. At the outlet end of the washer, suitable eliminator plates are placed and may or may not be provided with flooding devices. These plates or blades, for the removal of entrained moisture, may cause four to six directional air changes and present as many as four effective hooked edges for trapping the water. Blades usually have bends at 30 deg to the direction of air flow. Sharper bends add substantially to the resistance without improving the elimination materially. Vertical type baffles may be provided with flooding devices where the air contains large quantities of particulate matter or lint, as in cotton mills, to prevent build-up on the baffle blades.

Table 1 . . . . Classification of Apparatus Used for Humidification and Evaporative Air Cooling

Designation	Humidification		Evaporative Air Cooling		
	Indirect	Direct	Primary Wet Surfaces	Dry Surface or Secondary Cool Surface	Two Stage
Residential	1. Evaporating pans with "wick action" water transport. 2. Externally heated evaporator pans (electric or steam heat). 3. Porous, extended surface pad types.	1. Atomizers or sprays.	1. Drip type, usually nonmetal pads. 2. Slinger type, usually metal pads. 3. Rotary type, usually metal screens.	1. Blast coils cooled by cooling tower water.	
Commercial or Industrial	1. Air washers, spray and fill types.	1. Pneumatic atomization. 2. Pressure atomization. 3. Centrifugal atomization. 4. Steam jets.	1. Drip type, usually non-metal pads. 2. Slinger type, usually metal pads. 3. Spray or washer type. 4. Rotary type, usually metal screens.	1. Blast coils cooled by cooling tower water.	1. Secondary cool surface cooling followed by primary wet surface or spray cooling.

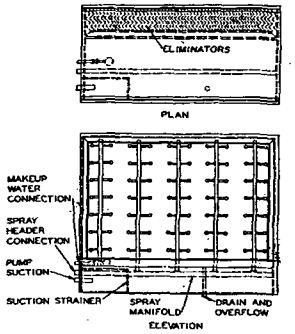

Fig. 1 . . . . Typical Single-Bank Air Washer

Figs. 1 and 2 show the essential construction features of conventional spray-type air washers. Intimate contact between the air and water is secured (1) by breaking the water into fine drops, (2) by passing the air over the surfaces continuously wetted by water, or (3) by a combination of the two.

Essential requirements in the air washer operation are: uniform distribution of the air across the spray chamber, air velocities of from 400 to 700 fpm in the washer chamber, an adequate amount of spray water broken up into fine droplets at pressures of from 15 to 30 psig, good spray distribution across the air stream, sufficient length of travel through the spray and wetted surfaces, and the elimination of free moisture from the outlet air.

Expected performance, physical size, length, number of sprays, etc., vary greatly depending on the functions of the

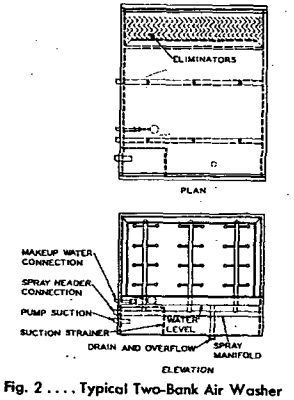

Fig. 2 . . . . Typical Two-Bank Air Washer

installation. In general, the width and height of an air washer will depend on the space available. Washers of nearly equal height and width are desirable from an air flow and economic standpoint, although these proportions are not necessary. The length of washers varies considerably. A space of approximately 2½ to 4½ ft between spray banks is used, and the first and last banks of sprays are located about 1 to 1½ ft from the entering or leaving end of the washer. In addition, air washers may be furnished with heating or cooling coils within the washer chamber. These coils may affect the overall length of the washer.

Spray water requirements for spray-type air washers used for washing or evaporative cooling vary from 4 gpm with a single bank to 10 gpm for double banks per 1000 cfm. Pumping heads will usually be in the range from 55 to 80 ft of water

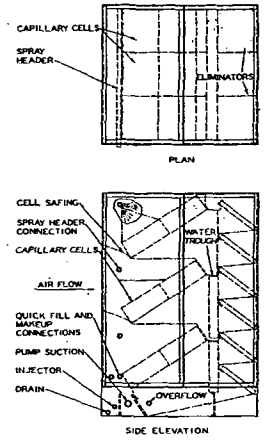

Fig. 3 . . . . Typical Fill-Type Air Washer

depending on spray pressure, height of apparatus, pressure losses in pipe and strainers, etc.

The resistance to air flow through an air washer varies with the type and number of baffles, eliminators, and wetted surfaces; number of spray banks and their direction; air velocity; size and type of other resistances such as cooling and heating coils; and other factors such as air density. Resistance may be as low as ¼ in. or high as 1 in. water column. It is therefore necessary that the manufacturer be consulted with regard to the resistance of any particular washer design combination.

Fill-Type Washers

Other air washer types achieve contact between air and water by passing the air through cells packed with glass fibers or sheets of specially designed media. See Fig. 3. These washers have the cells arranged in tiers over which water is distributed at low pressure. The cells are followed by conven-

tional blade type or glass mat eliminators. With water drainage provided for each cell tier, most of the stratification found in spray-type washers is avoided.

An essential requirement of operation of this type of air washer is good distribution of water over the face of the cells. When compared with conventional spray-type washers, the water requirements are much lower, approximately 4 gpm per 1000 cfm for ordinary washing and evaporative cooling, and the pumping head is approximately one-half the head of conventional spray-type washers.

Humidification with Air Washers

Air humidification can be accomplished in three ways with an air washer. These are: (1) use of recirculated spray water without prior treatment of the air; (2) preheating the air and washing it with recirculated spray water; and (3) using heated spray water. In any air washing installation the air should not enter the washer with a wet-bulb temperature less than 35 F. This is a precaution to eliminate the danger of freezing the spray water.

Method 1. Except for the small amount of energy added from outside by the recirculating pump in the form of shaft work, and for the small amount of heat leakage from outside into the apparatus, including the pump and its connecting piping, the process would be strictly adiabatic. Evaporation from the liquid spray would therefore be expected to bring the air immediately in contact with it to saturation adiabatically; and, since the liquid is recirculated, its temperature would be expected to adjust to the thermodynamic wet-bulb temperature of the entering air.

It does not follow from the foregoing reasoning that the whole air stream is brought to complete saturation, but merely that its state point should move along a line of constant thermodynamic wet-bulb temperature as explained in Chapter 3. The extent to which the leaving air temperature approaches the thermodynamic wet-bulb temperature of the entering air, or the extent to which complete saturation is approached, is conveniently expressed by a ratio known as humidifying effectiveness or saturating effectiveness, and is defined in Equation 1 as

$$e_s = \frac{t_1 - t_2}{t_1 - t'} \times 100 \qquad (1)$$

where

- e_s = humidifying or saturating effectiveness, percent.
- t_1 = dry-bulb temperature of the entering air, Fahrenheit.
- t_2 = dry-bulb temperature of the leaving air, Fahrenheit.
- t' = thermodynamic wet-bulb temperature of the entering air, Fahrenheit.

The following may be taken as representative of the humidifying or saturating effectiveness of a spray-type air washer for the arrangements stated:

Arrangement	Length Ft	Effectiveness—%
1 bank downstream	4	50-60
1 bank downstream	6	60-75
1 bank upstream	6	65-80
2 banks downstream	8 to 10	80-90
2 banks opposing each other	8 to 10	85-95
2 banks upstream	8 to 10	90-98

The humidifying or saturating effectiveness of a washer is dependent upon the essential items of design mentioned in the section Air Washers. Other conditions being the same, a low velocity of air flow is conducive to high humidifying effectiveness.

Method 2. The preheating of the air increases both the dry- and wet-bulb temperatures, and lowers the relative humidity, but does not alter the humidity ratio (pounds of water vapor per pound dry air). At a higher wet-bulb temperature, but the same humidity ratio, more water can be absorbed per pound of dry air in passing through the washer, assuming that the humidifying effectiveness of the washer is not adversely affected by operation at the higher wet-bulb temperature. The analysis of the process occurring in the washer itself is the same as that explained under *Method 1.* The final desired conditions are secured by adjusting the amount of preheating to give the required wet-bulb temperature at the entrance to the washer.

Method 3. Even if the heat is added to the spray water, the mixing occurring in the washer itself may still be regarded as adiabatic. The state point of the mixture should move in a direction determined by the specific enthalpy of the heated spray as explained in Chapter 3. It is possible, by elevating the water temperature, to raise the air temperature, both dry-bulb and wet-bulb, above the dry-bulb temperature of the entering air.

In each of the methods, 1, 2, or 3, the air leaving the air washer may require reheating to produce in the conditioned space the required dry-bulb temperature and relative humidity.

Dehumidification and Cooling with Air Washers

Lowering of the wet-bulb temperature of an air-vapor mixture can be accomplished by an air washer if the temperature of the spray water is lower than the wet-bulb temperature of the air. Moisture removal is obtained when the spray water temperature is lower than the dew point of the entering air. In these cases the final dry-bulb temperature and relative humidity of the leaving air are dependent upon the design factors of the air washer.

Both sensible and latent heat are removed in the process of dehumidification by cold spray water. Extraction of sensible heat occurs during the entire time that the air is in contact with the spray medium. Latent heat removal takes place as condensation occurs. Therefore, the lower the spray temperatures, the greater the amount of moisture removal per pound of dry air, all other conditions remaining the same.

Where a limited supply of cold water is available, multiple-stage washers may be used to great advantage. In such washers the cool water is pumped through the multiple spray systems in series and counterflow to the air flow. Such an arrangement brings the delivery air in contact with the coldest water, securing a maximum amount of cooling and saving water.

When using cold well water or water from city water mains, care should be used to secure accurate data on the water temperatures. Table 2 lists some approximate water main averages which may be used as a guide but should be verified from local records. This is particularly true with city water main temperatures. In the case of well water temperatures, Fig. 4 shows the approximate temperatures of water to be expected from wells at depths of 30 to 60 ft.

Air washers for dehumidifying and cooling usually have separate recirculating pumps for each washer. These pumps deliver a mixture of cold and recirculated water under the control of a three-way valve.

* These averages taken from various city water main locations, with some actual values slightly higher and some lower than values shown. Some values were supplied by H. E. Degler, Marley Company. Some were obtained from City Water Department records. The highest values given by the various authorities are usually those listed.

Performance of an air washer, when cooling and dehumidifying, depends upon a number of factors, among which are:

(1) Air velocity through spray chamber area.
(2) Spray nozzle pressure.
(3) Size factor (larger washers are more efficient than smaller ones).
(4) Spray density (gpm/sq ft/spray bank).
(5) Water temperature rise.
(6) Air wet-bulb temperatures—entering and leaving.
(7) Water-to-air weight ratio.
(8) Water temperatures—entering and leaving.
(9) Length of air washer in direction of flow.
(10) Number and arrangement of spray banks.

Where increase of overall heat transfer between the air

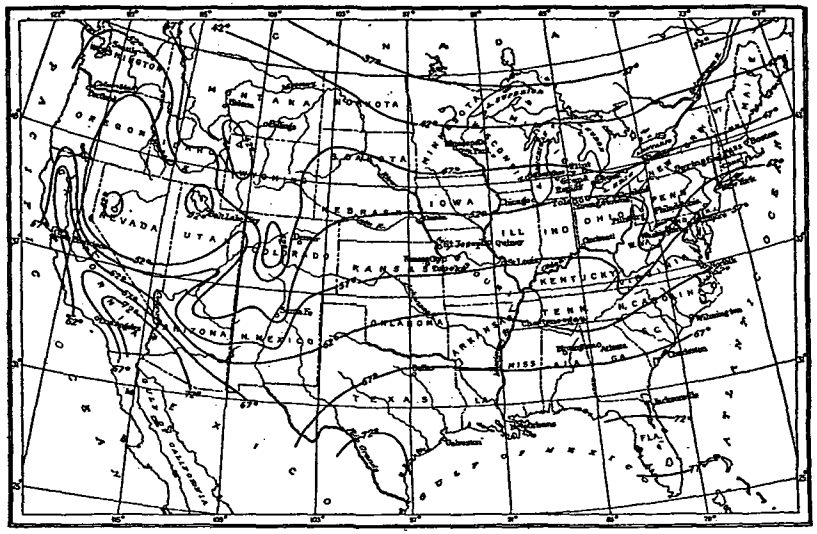

Fig. 4 .... Approximate Well Water Temperatures at Depths of 30 to 60 Ft[1]

and water is required, multi-stage washers are used. These washers are equivalent to a number of washers in series, and the water has to be pumped from one stage to the other in a direction counter to the air flow.

The most common air washer arrangement for cooling and dehumidifying air has two spray banks and is eight to nine feet long. If the air washer has ability to cool and dehumidify the entering air to a wet-bulb temperature equal to the leaving water temperature, it is convenient to assign to such a washer a performance factor of 1.0. The actual performance factor of any washer is the actual enthalpy change divided by the enthalpy change in a washer of 1.0 performance factor.

Calculation of the required performance factor, F_P, for any washer application involving cooling and dehumidifying can be made from Equation 2:

$$F_P = (h_1 - h_2)/(h_1 - h_3) \qquad (2)$$

where

h_1 = Enthalpy at entering air wet-bulb temperature, Btu per pound.

h_2 = Enthalpy at leaving air wet-bulb temperature at actual condition, Btu per pound.

h_3 = Enthalpy at wet-bulb temperature leaving a washer with $F_P = 1.0$, Btu per pound.

Knowing the performance factor of a particular air washer, the actual conditions of operation can be graphically determined as shown in Fig. 5. Points 1 and 2 are plotted on the saturation curve representing total heat at the entering and leaving air wet-bulb temperatures, t_1' and t_2'. Point 5 represents the condition at which leaving air wet-bulb and leaving water temperatures would be the same. This point is determined by solving Equation 2 for the unknown quantity, h_3.

$$h_3 = h_1 - \frac{(h_1 - h_2)}{F_P}$$

A diagonal line is drawn through Point 5 with a negative

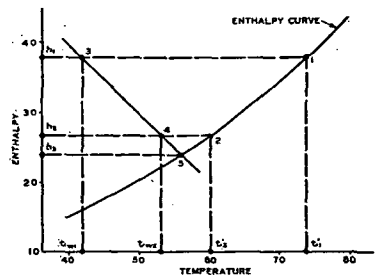

Fig. 5 .... Graphical Solution of Conditions Produced by an Air Washer

slope equal to the water-to-air weight ratio. Points 3 and 4, at which this diagonal line intersects horizontal lines through points 1 and 2, show the required entering and leaving water temperatures t_{w1} and t_{w2}. A check of the solution can be made from the fundamental heat balance equation,

Heat absorbed by the water = heat removed from the air.

The graphical method as described can be used to arrive quickly at solutions of air-washer cooling and dehumidifying problems where there are a number of unknown factors, including quantity of water to be used and the entering and leaving water temperatures. It can be adapted to problems of heating and humidifying as well as to water cooling (indoor washer-cooling tower) and multi-stage applications.

The actual performance factor of a particular washer must, however, be obtained from the manufacturer's data and depends on the many factors listed previously.

Control of Air Washers

Chapter 43 discusses methods of controlling air washers to meet system or space requirements.

EVAPORATIVE AIR COOLING

Evaporative air cooling is undoubtedly the oldest method used in man's attempt to produce comfort in hot climates. In pre-biblical times,[2, 3, 4] wetted grass mats and porous jars utilized the evaporative process to cool air or water. The early settlers of Southwestern United States found the Indians using these same devices. In the 1930's a rush of inventions appeared which mechanized evaporative cooling and various devices were developed and manufactured to utilize evaporation directly in the air stream or indirectly to cool the air in a heat exchange process.

Evaporative air cooling equipment may be placed in two general classes, direct and indirect. The first of these uses primary wet surfaces which evaporate water directly into the fresh air supplied to the space being cooled. This may be done with a series of sprays as in an air washer or by use of an extended wetted surface material such as aspen wood excelsior, glass fibers, metal wire, or expanded paper. As these devices are relatively simple and economical, they represent the vast majority of equipment in use today.

The second class of evaporative air cooling is termed indirect. The indirect cooler uses the evaporative principle to cool air or water in a device similar to a cooling tower. The resultant cool air or water is then used by means of a secondary heat exchanger to cool the air in the occupied space. The simplest form of this consists of a cooling tower, a circulating pump, and a chilled water coil. The pump circulates the chilled water from the cooling tower sump through the blast coil in the building ventilating system. More complex arrangements of this principle have been used. By applying recirculating, regenerating principles, temperatures below the initial wet-bulb may be produced.[5, 6] The complexity and cost of these devices has made them relatively obsolete with the advent of economical refrigeration equipment.

Types of Primary Wet-Surface Evaporative Cooling Equipment

Currently, the drip or desert-type coolers (see Fig. 6) constitute the largest percentage of evaporative coolers. These devices use evaporative pads, usually made of aspen wood fibers, and a water circulating pump to lift the sump water

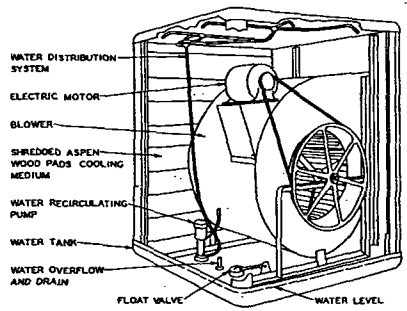

Fig. 6 .... Typical Drip-Type Evaporative Cooler

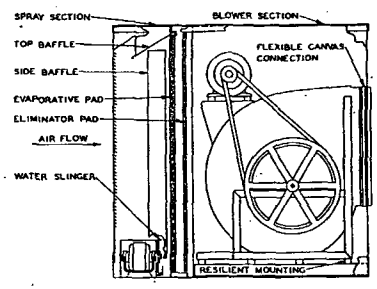

Fig. 7 .... Typical Spray-Type Evaporative Cooler

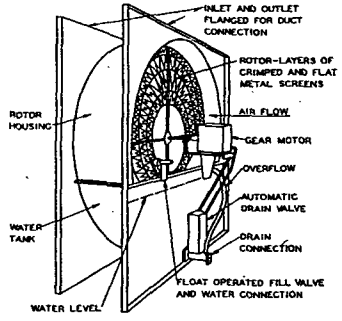

Fig. 8 .... Typical Rotary-Type Evaporative Cooler

up to a distributing system from which it runs down through the pads and back into the sump. A fan (usually included within the unit) pulls the air through the evaporative pad and delivers it to the space to be cooled.

The spray-type cooler (see Fig. 7) contains an evaporative pad usually made of glass fiber, a water slinger, a centrifugal vaporizer, or spray nozzles to throw a fine spray into the air stream and the evaporator pads. Eliminators are usually required on the downstream side of the evaporator pads. These devices are supplied with or without the air-handling fan.

The rotary-type cooler (see Fig. 8) is a device which continually wets and washes the evaporator pad by rotating it through a water bath and into the air stream. The evaporator pads are usually of copper wire construction to provide the necessary structural and corrosion resistance.

The air washers previously discussed in this chapter are also used for direct evaporative cooling.

Control of sump water within these evaporative coolers consists of a float valve for level control and a bleed-off device. Overflow stand pipes, automatic valves or recirculating pump bypass connections are used for bleed-off. An evaporative air cooler operating with an efficiency of 80 percent is generally considered optimum. In this case, efficiency is the same as humidifying or saturating effectiveness found from Equation 1.

Design Considerations

Various methods for designing evaporative cooling systems are in common use. Simplified rule of thumb methods use an assumed air change rate as a basis. Good engineering practice requires an evaluation of the building heat gain, internal loads, and the cooling season wet-bulb temperature pattern.

The suitability of evaporative air conditioning for a particular application is, in the first instance, determined by the climatic conditions. The lowest temperature theoretically attainable with the most common systems of the direct or single-stage type is that of the wet-bulb temperature of the entering air. The process is one of adiabatic saturation and in practice is almost always operated with 100 percent outdoor air. Since the lowering of the dry-bulb temperature of the air during the evaporative process is always accompanied by a corresponding increase in moisture content, it follows that the greatest application of evaporative cooling for conditions for human occupancy is in areas in which periods of high temperature are always accompanied by low outdoor relative humidities. The areas in which the climate is suitable for the reliable production of optimum comfort conditions by evaporative cooling are limited. Despite this, evaporative air conditioning is extensively used over areas with less favorable climates as a means of improving conditions for human occupancy. It finds wide application also in industrial applications, particularly in those in which an improvement of dry-bulb temperatures can be used to advantage, and in which high humidities are desirable or at least not objectionable.

Proper analysis of the cooling season climatic data is most important. The most acceptable approach appears to be based on an analysis of the average high wet-bulb temperatures of the area for the periods when cooling is needed. Criteria established on this basis must, of necessity, take into account the extent to which departures from optimum conditions both in degree and duration can be tolerated.

There is no latent heat load on evaporative cooling equipment as with refrigeration cooling, since it operates on a 100 percent outdoor air basis. The air quantity handled by a typical evaporative cooling system is higher than with refrigerated cooling or heating systems. These relationships can be seen by comparison of *Example 1* with the sample air-conditioning cooling load calculation, *Example 11* of Chapter 13.

Example 1: An evaporative cooling system is to be installed in the one-story office building shown in Fig. 6 of Chapter 13. Outdoor design conditions are assumed to be 95 F dry-bulb and 65 F wet-bulb. The heat gains, calculated in *Example 11* of Chapter 13, which are used in the design of this type of system are:

All walls, roof and doors	78,500 Btu/hr
Glass areas	5,970
Occupants	17,000
Lighting	62,700
Total sensible heat load =	164,170 Btu/hr

Find the required air quantity, the temperature and humidity ratio of the air leaving the cooler (entering the office), and the temperature and humidity ratio of the air leaving the office.

Solution: A temperature rise of 10 F deg in the cooling air is assumed. Equation 20 from Chapter 13 may then be used to calculate the air volume required to be supplied by the evaporative cooler:

$$Q_m = \frac{q_s}{1.08(t_i - t_s)}$$

$$= \frac{164{,}230}{1.08 \times 10} = 15{,}200 \text{ cfm}$$

where

Q_m = required air quantity through equipment, cubic feet per minute.
q_s = instantaneous sensible heat load, Btu per hour.
t_i = indoor air dry-bulb temperature, Fahrenheit.
t_s = room supply air dry-bulb temperature, Fahrenheit.

This air volume rate represents a 2.6 minute air change for a building of this size.

The evaporative air cooler is assumed to have a saturating effectiveness of 80 percent. This is the ratio of reduction of the dry-bulb temperature to the wet-bulb. The dry-bulb temperature of the air leaving the evaporative cooler is found from Equation 3:

$$t_2 = t_1 - e_s(t_1 - t') \qquad (3)$$

For the conditions of this problem Equation 3 becomes:

$$t_2 = 95 - 0.8(95 - 65)$$

$$t_2 = 71 \text{ F}$$

The humidity ratio of the cooler discharge W_2 is found from the psychrometric chart $W_2 = 0.01185$ lb per lb dry air.

Equation 8, Chapter 13, may be adapted to solve for the remaining unknown, the humidity ratio of the air leaving the space being cooled W_3, from Equation 4:

$$q_s = Q_m \times 4840(W_3 - W_2) \qquad (4)$$

where

q_s = latent load, Btu per hour.
Q_m = rate of entry of air to the space from the cooler, cubic feet per minute.

The humidity ratio of the air leaving the space, W_3, from Equation 4, is therefore:

$$W_3 = \frac{q_s}{Q_m \times 4840} + W_2$$

The only latent load of the space for this design is the occupancy load, 21,250 Btu/hr as calculated in *Example 11* of Chapter 13. Substituting this and the other known quantities in Equation 4:

$$W_3 = \frac{21{,}250}{15{,}200 \times 4840} + 0.01185 = 0.01214 \text{ lb/lb dry air.}$$

The remaining values of wet-bulb and relative humidity for the problem may be found from the psychrometric chart. Fig. 9 illustrates the various relationships of the outdoor air, supply air to the space, and the discharge air.

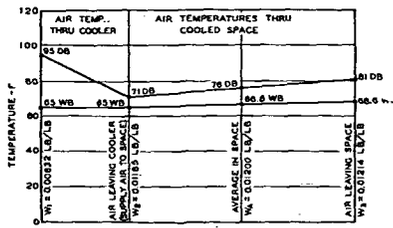

Fig. 9 .... Conditions Within Evaporative Cooler and Cooled Space for Example 1

The design of evaporative air-cooling systems is similar to other heating or cooling systems. It should be kept in mind that considerably more air will be handled as no recirculation is used and, therefore, duct, fan, and grille sizes will be larger. This problem has been solved in a number of ways. Large, open buildings such as supermarkets have been successfully cooled and heated by the use of four evaporative air coolers for cooling, two of which are fitted with duct heaters for space heating. In this way a balance between the summer cooling and winter heating air quantity is obtained. In climates which are not particularly suited to direct evaporative air cooling, a combination of refrigeration and evaporative cooling may be economical.

There are many industrial demands for cooling where direct evaporative cooling is economical. Successful application of this type has been made for electric-motor cooling, turbine cooling, and spot cooling in the factories such as textile mills, steel mills, and foundries. Laundries, with their large exhaust air loads, may also take advantage of evaporative cooling. In cattle and poultry barns evaporative cooling has been used with excellent results even in climates which give poor results with human occupancy. This is possible because the blood temperature of these animals is higher than human.[3] Greenhouses use evaporative cooling to reduce temperature and raise humidity.

Two Stage Evaporation Air Cooling

On industrial or commercial installations two stage evaporative cooling will sometimes be found to be effective and economical. Such a system uses a cooling tower and a blast coil ahead of the evaporative air cooler. Using a 6 or 8 row coil and a well designed cooling tower, the air discharged from the blast coil can be within 15 F of outdoor wet bulb. This part of the cooling takes place at constant humidity ratio. Passing the cooled air through an evaporative air cooler further reduces the dry-bulb temperature, the process following the thermodynamic wet-bulb temperature line on the psychrometric chart. Use of this two stage system will result in smaller required air quantities and consequent low duct costs. Careful design can frequently allow the same duct and grille system to be used for heating and maintain proper duct and register velocities.

Control of Evaporative Air Coolers

Control of evaporative air-cooling systems may be accomplished by ordinary dry-bulb thermostats or a combination of a dry-bulb thermostat and a humidistat. These controls are set to turn on at a dry-bulb temperature and off at a pre-set high humidity. When two-speed fans are used, automatic control of fan speed may be employed to provide better control results.

Evaporative air-cooling systems can also be used for ventilation on mild days and at night when air temperatures are relatively low and straight ventilation produces comfortable results. A valve on the water supply to the evaporative air cooler may be operated by a thermostat in the outdoor air to accomplish this automatically. See Chapter 43 for general information on controls.

Maintenance

Much of the discussion of maintenance and operation problems at the end of Chapter 40, Evaporative Apparatus for Heat Rejection, is pertinent to evaporative air cooling and humidification equipment as all these devices use the evaporation of water as the cooling mechanism.

Some air washers and all evaporative air coolers contain extended surface, evaporator pads of one sort or another. Because of these pads, control of the scale-forming mineral content of the water is required or the extended surface pads will soon plug up with scale and the air flow will be reduced. Another effect of scale deposit is to cause channeling of the water and air and so give local high velocities and consequent entrainment. Some scale will be deposited on these pads during drying after shut-down. If replacement or cleaning is required more frequently than once a year the scale control method is usually at fault. Chemical water treatment with polyphosphates is helpful to prevent hard scale. Regular blowdown or bleed-off of sump water is usually the best control to prevent corrosion and hard scale deposit.

CHAPTER 42

DEHUMIDIFICATION BY SORBENT MATERIALS

Types of Sorption Dehumidifiers; Liquid Sorption Systems: Liquid Sorbents, Machine Operation and Design; Solid Adsorption Systems: Solid Desiccants, Machine Operation and Design; Sorption Dehumidifiers for Elevated Pressures; Applications for Sorption Dehumidifiers; Moisture Load Calculations; Vapor Transfer to Dehumidified Space

DEHUMIDIFICATION as used herein is the reduction of the water-vapor content of a given volume of air or other gas. The term thus describes a special case of dehydration which covers the removal of moisture in any form from matter. The degree of dehumidification required varies greatly with different applications, and is one of the prime considerations influencing the choice of a method.

Dehumidification may be accomplished by chilling, as described in Chapters 19, 23, and 41, by the use of sorbents, or by compression in combination with chilling, sorbents, or both chilling and sorbents.

Sorbents are substances which have the property of extracting and holding other substances (usually gases or vapors, e.g., water vapor) brought into contact with them. All materials are sorbents to a greater or lesser degree. The weight of water held by a substance will increase or decrease, depending upon whether the vapor pressure of the water held by the substance is less or greater, respectively, than the partial pressure of water vapor in the surrounding atmosphere. As generally used, however, the term sorbents refers to those materials having a capacity for moisture which is large compared to their volume and weight. Such materials are divided into two general classifications:

1. *Absorbent*—A sorbent which changes either physically, chemically, or both, during the sorption process. Calcium chloride is an example of a solid absorbent, while liquid absorbents include solutions of the halogen group (lithium chloride, lithium bromide), and the ethylene glycols.

2. *Adsorbent*—A sorbent which does not change physically or chemically during the sorption process. Certain solid materials, such as activated alumina, silica gel, activated bauxites, and activated charcoal have this property. The action of adsorbents, most of which adsorb some gases and condensible vapors besides water vapor, is selective. Thus, in the case of a mixture containing both water and organic vapors, silica gel would remove the water vapor in preference to the organic vapors, while the reverse would be true in the case of activated carbon. The selective property of adsorbents is made use of in some instances for the removal of objectionable and contaminating vapors from an air or gas mixture. (See Chapter 7.)

LIQUID ABSORPTION SYSTEMS

Liquid Absorbents

A liquid absorbent has the property of absorbing moisture from, or adding moisture to, the air, depending upon the vapor-pressure difference between the air and the solution. The equilibrium vapor pressure of the solution is dependent upon the temperature and concentration of the solution.

Absorbents for a liquid dehumidifying system should have the following characteristics:

1. Suitable vapor-pressure characteristics. The absorbent should not crystallize at temperatures 10 to 15 deg below the temperature range used in the operating cycle.
2. Noncorrosive, odorless, nontoxic, and nonflammable.
3. Stability. It should not break down over the range of use.
4. Low viscosity and good heat-transfer characteristics.
5. Widely available and economical to produce.
6. Capable of being regenerated at temperatures obtainable with low-pressure steam.

The equilibrium contact dew point is plotted against contact temperature for various concentrations of a typical organic liquid absorbent in Fig. 1. The same data for a typical inorganic absorbent is shown in Fig. 2. The concentration of the liquid absorbents used in commercial equipment is dependent on the temperature of the cooling medium, and on the latent and sensible heat-removal requirements.

The equilibrium contact dew points in Figs. 1 and 2 show the dew point of air in equilibrium with the liquid absorbent. Reference should be made to the published performance data for commercial apparatus for the solution of air-conditioning and air dehumidification problems. Fig. 3 shows a rating curve for a liquid absorbent dehumidifier using lithium chloride solution.

Liquid Absorption Operation

The operating cycle of a liquid absorption system with extended-surface contactor coils is shown by Fig. 4. For dehumidifying operation the strong absorbent solution is pumped from the sump of the unit and sprayed over the contactor coils.

The hygroscopic solution at the required temperature and concentration is in intimate contact with the air which is flowing over the coil surface in the same direction as the liquid absorbent. Equipment is also available for flow countercurrent to the flow of liquid absorbent. Moisture is absorbed from the air by the solution due to the vapor-pressure difference between the air and the liquid absorbent. The moisture content of the outlet air can be maintained at a constant condition by automatically regulating the flow of water through the cooler with a modulating water valve.

The heat generated in absorbing moisture from the air is called the heat of condensation of the water vapor in the solution. This consists of the latent heat of condensation of water vapor and the heat of solution or the heat of mixing. The heat of mixing varies with the liquid absorbent used and with the concentration and temperature of the absorbent. The solution is maintained at the required temperature by cooling with city, well, refrigerated, or cooling tower water, or refrigerant flowing inside the tubes of the contactor coil. The quantity of water required is a function of the water temperature and the total heat, either sensible, latent, or both, removed from the air by the hygroscopic solution.

The dry-bulb temperature of the air leaving the liquid absorbent contactor is a function of the temperature of the liquid absorbent and the amount of contact surface between the air and the solution. In most commercial equipment the

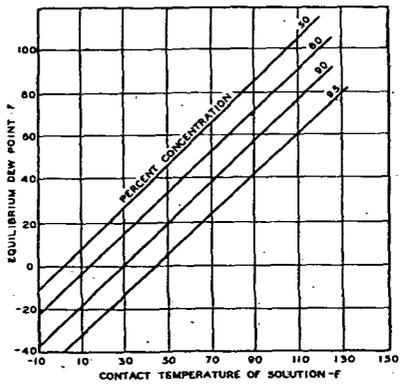

Fig. 1 .... Temperature—Equilibrium Dew-Point Characteristics for Typical Organic Absorbent

dry-bulb temperature of the air leaving the dehumidifier will be within 1 to 5 deg of the liquid absorbent temperature.

Cooling and heating coils are installed in the ductwork after the dehumidifier if the air is to be cooled or heated.

The liquid absorbent is maintained at the proper concentration for moisture removal by automatically removing from the liquid the water vapor absorbed from the air. A small percentage of the solution, usually 10 to 20 percent of the flow to the contactor coils, is passed over the regenerator coil where the liquid is heated with steam or other heating medium. The liquid absorbents commonly used may be regenerated with steam at 2 to 25 psig. The vapor pressure of the liquid absorbent at temperatures corresponding to 2

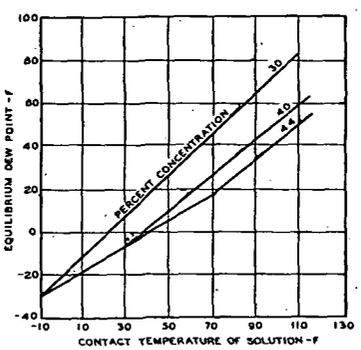

Fig. 2 .... Temperature—Equilibrium Dew-Point Characteristics for Typical Inorganic Absorbent

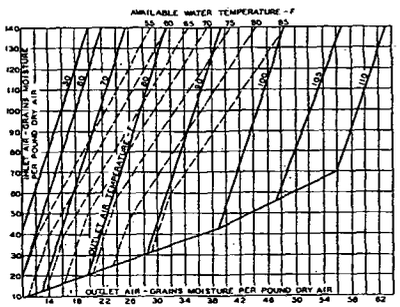

Fig. 3 .... Performance Data for Liquid-Absorbent Dehumidifier Using Lithium Chloride

psig steam is considerably higher than that of the outdoor air. The hot solution at the relatively high vapor pressure is in contact with outdoor air in the regenerator where water is absorbed from the solution by the scavenger air due to the vapor-pressure difference between the outdoor air and the hot solution. The hot-moist air from the regenerator is discharged to the outdoors and the concentrated solution flows to the sump where the process is repeated.

The steam flow to the regenerator coil is regulated by a control responsive to the concentration of the solution circulated over the contactor coils. This may be a level control, specific gravity control, boiling point control, or a similar instrument.

For humidifying operations the liquid absorbent is maintained at the required temperature by adding heat in proportion to the water absorbed by the air from the solution. Water is automatically added to the solution to maintain the proper concentration.

SOLID ADSORPTION SYSTEMS

Solid Desiccants

The ability of an adsorbent (desiccant) to remove water vapor from a gas is explained by the fact that the vapor pressure of the water in the adsorbent (when in the re-

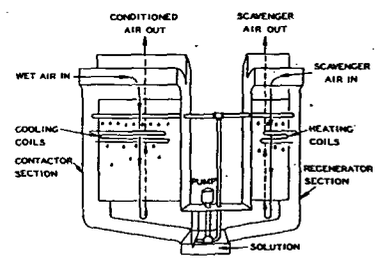

Fig. 4 .... Flow Diagram for Typical Liquid-Absorbent Dehumidifier

activated condition) is less than the partial pressure of the water vapor in the surrounding atmosphere. For instance, when an active adsorbent is brought into contact with a gas of high humidity, there is a tendency for the vapor pressure of the water in the adsorbent to reach equilibrium with the partial pressure of the water in the surrounding gas, with the result that water is extracted by the adsorbent and its weight increased, while the moisture content of the gas is correspondingly reduced. (The adsorbent is said to be saturated for a given condition when equilibrium is attained.) The weight of water a given adsorbent will extract is dependent upon the relative humidity (ratio of the partial pressure in the gas to the saturation pressure at a given temperature) and the temperature of the adsorbent. The process is reversible; if the temperature of the adsorbent is raised until the vapor pressure of the adsorbed water becomes greater than the partial pressure of the vapor in the surrounding atmosphere, water will be released by the adsorbent. After the adsorbent cools to room temperature, for instance, the vapor pressure of the water in the adsorbent falls below the partial pressure of the vapor in the atmosphere, and the adsorbent will again start extracting water. The elimination of water by the addition of heat is known as reactivation, and is a means of regenerating the adsorbent so that it may be used repeatedly.

Adsorption is proportional to the amount of surface (internal and external) of the sorbent. The materials that are used commercially as solid adsorbents have a porous structure of submicroscopic dimensions, which gives them extensive surface area. An adsorbent should meet the following requirements in order to be satisfactory for dehumidification purposes:

1. Have a high adsorptive capacity under normal atmospheric conditions.
2. Be chemically stable, resisting contamination from impurities.
3. Be physically rugged to resist breakdown from handling and use.
4. Be capable of reactivation at temperatures generally obtainable.
5. Be heat-stable at reactivation temperatures.
6. Have a weight per unit volume such as to avoid excessive bulk.
7. Be available at reasonable cost.

There are a number of solid adsorbents available, which are used in solid adsorption systems. The reader is referred to the various manufacturers for detailed information regarding performance of the various desiccants. These include activated aluminas and bauxites, silica gels, and alumino-silicates marketed under various trade names. Reactivation temperatures for these desiccants are generally between 200 and 600 F.

Machine Operation and Design

Dehumidification by a solid desiccant such as silica gel or activated alumina may be performed either under static or dynamic operation. As the name implies, the static method entails no artificial means for circulating the gas to be dried into or through the desiccant. Instead, the air immediately surrounding the adsorbent is initially dried and subsequently, through convection and diffusion, water vapor from spaces and objects further away pass into the air surrounding the desiccant and then to the desiccant where it is adsorbed. Obviously this type of dehumidification is best suited for small containers. This method of preservation was used extensively by the armed services during World War II for overseas shipments and domestic storage.

On the other hand, dynamic dehumidification entails the forced passage of the air being treated through the desiccant bed. This method is used in installations such as dehumidified warehouses and ships of the "Mothball Fleet" where large volumes of air must be dried.

The only requisites for a dynamic dehumidifier are a desiccant bed, a fan to force the humid air through this bed, and a heater to periodically reactivate the adsorbent. As the air passes into the activated desiccant, it surrenders a certain amount of its water vapor. The rate of moisture pickup and the humidity condition of the leaving air are functions of a great many variables, some of which will be discussed later. The ratio of the amount of water adsorbed by the desiccant in a given time to the amount of water vapor in the air entering the desiccant bed during that time is known as *adsorption efficiency*. A characteristic of adsorbents in dynamic use is that this adsorption efficiency remains constant and at a relatively high level from the beginning of an adsorption cycle until some later point in the cycle at which time the efficiency begins to drop. This point is known as the *breakpoint*, and the time from the beginning of adsorption to this point is known as the *breakpoint time*. In the ideal case the breakpoint would coincide time-wise with the sudden rise in the dew-point temperature of the effluent air. Although additional drying can be effected beyond the breakpoint, good commercial practice dictates that the desiccant be regenerated at or near this point. Adsorption carried beyond the breakpoint continues at an increasingly slower rate until the adsorbent is completely saturated. This point is known as *completion*.

Adsorbents, such as silica gel and activated alumina, contain, even when reactivated, a small amount of water. This is usually about 5 to 7 percent of the dry weight of the desiccant and is known as residual moisture. Attempts to remove it result in a physical change in the substance and a reduced adsorptive capacity. The term *useful concentration* is used to designate the percent of moisture in the adsorbent over and above the residual quantity. It is generally based on the dry weight of the desiccant.

When regeneration of the adsorbent is desired, the heater is energized and the direction of air flow through the bed is usually reversed. The dry-bulb temperature of the effluent air rises rapidly at first, and then virtually levels off for a period of time. This period of level or slowly increasing temperature represents the period during which the major portion of the heat input is being used to boil off the adsorbed water. This temperature pattern continues until most of the water contained in or on the desiccant is released. When the latent heat requirements begin to diminish, the heat input goes into sensible heat gain to the passing air stream. This is reflected in a rather sharp increase in the dry-bulb temperature of the effluent air. This period, measured from the beginning of desorption, has been designated *temperature-rise time*. Although additional regeneration (at a slower rate) can be attained by continuing the heat addition process beyond the temperature-rise time, once again good commercial practice calls for reactivation to be ended near this point. Regeneration past this point until the adsorbent is in moisture equilibrium with the air stream is known as *complete desorption* or *desorption to completion*. The energy expended in the heater per unit weight of water desorbed for any given time is called *economy of desorption* and usually has the dimensions of kilowatt hours per pound of water desorbed.

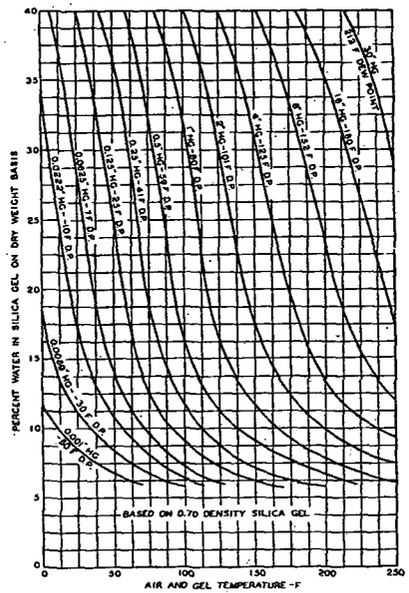

Fig. 5.... Silica Gel—Water-vapor Equilibrium Curves

During the process of adsorption there is a liberation of heat which results in an elevation of the effluent air temperature. This heat is equivalent to the latent heat of vaporization of the adsorbed liquid plus an added quantity known as the *heat of wetting*, which is defined as the heat developed when a liquid and a solid surface contact one another. As the adsorbed vapor condenses, the latent heat is converted to sensible. All of the released heat, known cumulatively as the heat of adsorption, is dissipated into the desiccant, the enclosure, and the passing air stream. In comfort air conditioning it is often necessary to cool this effluent air prior to its introduction to the conditioned space, but in most other dehumidification applications this heat is not objectionable, and no provisions are made for its removal. For this reason the process is known as adiabatic adsorption, meaning that the released heat is taken up for the most part by the passing air stream, that the adsorbent chamber is insulated, and that no attempt is made to cool the effluent air. Although ordinary air-conditioning dehumidification only approaches the adiabatic process, it is called adiabatic to differentiate it from the isothermal adsorption process in which the outlet gas is cooled to inlet temperature.

It is appropriate now to discuss the factors which influence the rate and amount of water-vapor adsorption by the desiccant. Although such factors as the shape and volume of the desiccant pores and the surface tension and wetting ability of the condensed vapor are important, the foremost considerations when working with a given adsorbent and a given vapor, for example, airborne water vapor, are the temperature of the adsorbent and the dry-bulb and dew-point temperatures of the air. The latter temperature is important since it is a function of the partial pressure of the water vapor in the air. The relationships existing between these variables are best illustrated by the Silica Gel–Water-vapor equilibrium curves shown in Fig. 5. In this set of curves, silica gel and air temperature versus percent water in silica gel (dry weight basis) form the abscissa and ordinate, and air dew-point temperatures (with the corresponding vapor pressures) are the parameters. Several important characteristics of the adsorbent are brought out by these curves. For example, note that each of the curves becomes asymptotic to the X-axis somewhere between 5 and 6 percent moisture content. This is because, under normal reactivation temperatures, there is always this amount of water in the gel. Known as residual moisture, it is omnipresent and an attempt to remove it results in a physical change in the desiccant and a reduced adsorptive capacity. The term *useful concentration* is used to designate the percent moisture in the gel over and above the residual amount. The variation in this useful concentration during a test measures the magnitude of adsorption or desorption since the residual amount theoretically remains unchanged assuming no excessive activation temperatures. Note that at constant air and gel temperature the amount of moisture adsorption varies directly with the air dew-point temperature, i.e., as the air approaches saturation condition (dry-bulb temperature equal to dew-point temperature) the equilibrium moisture content of the gel increases. It can also be seen that at saturation the percent water in the gel is in the neighborhood of 40 percent of the dry weight of the gel for all temperatures.

With a fixed dew-point temperature, the moisture concentration decreases as the temperature of the air and gel is increased.

Some of the many variables that influence the results of a dynamic dehumidification operation are:

1. Type of desiccant.
2. Grain size of desiccant.
3. Shape of bed.
4. Area of bed normal to air flow.
5. Depth of bed.
6. Dry weight of desiccant.
7. Packing of the desiccant in the bed.
8. Weight of air flowing per unit of time.
9. Temperature of entering air.
10. Moisture content of entering air.
11. Contact time between air and adsorbent; a function of inlet face velocity and bed depth.
12. Barometric pressure.
13. Pressure drop through bed.
14. Duration of cycles.
15. Reactivation temperature.
16. Rate and magnitude of heat supply during reactivation.
17. Heat storage capacity of the bed.
18. Temperature gradient of the bed.
19. Air leakage from the apparatus.

Solid adsorption dehumidifiers are mostly of the stationary dual-bed type in which one desiccant bed is adsorbing while the other is being reactivated by electricity, gas, or steam.

Fig. 6 shows a schematic flow diagram for a typical dual-bed dehumidification unit. There are two types of units: (a) Shallow-bed; (b) Deep-bed.

Shallow-bed machines have comparatively thin desiccant beds and moisture removal is not complete in one pass through the bed. Low dew points may be maintained by progressive lowering of the room dew point as increasingly drier air enters the machine. The machine capacity must be in excess of internal moisture load and infiltration of moisture from external sources. Increased dryness can be obtained by reducing outlet air flow and recirculation of excess air from the dry air outlet to the humid air inlet on

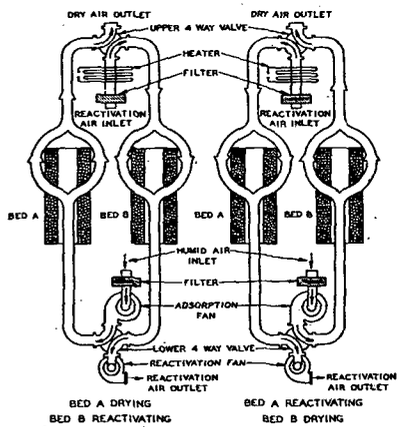

Fig. 6.... Typical Dual-Bed Dehumidification Unit Air-Flow Diagram

the machine. Fig. 7 shows a typical cycle diagram for a shallow-bed machine.

Deep bed machines have desiccant beds 10 in. and more in depth. Deep bed units are used when extreme dryness is required in one pass through the dehumidifier and the air cannot be recirculated. Fig. 8 shows a typical cycle diagram for a deep-bed dehumidifier.

Most fixed-bed machines work on a predetermined time cycle. Smaller machines usually have a nonadjustable cycle. Larger units have adjustable time cycles that can be changed for various operating conditions.

The average hourly moisture removal capacity of a dehumidifier can be determined as follows:

$$W = \frac{60Q(G_i - G_o)}{7000v} \qquad (1)$$

where

W = moisture removed, pounds per hour.
Q = air volume, cfm.
60 = conversion of cubic feet per minute to cubic feet per hour.
G_i = moisture content of air entering dehumidifier, grains of moisture per pound of dry air.

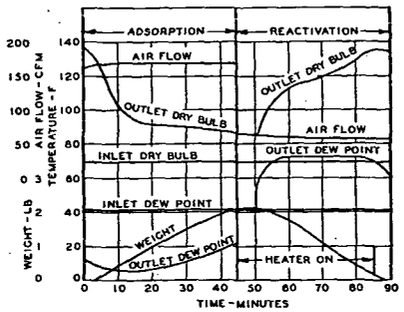

Fig. 7.... Typical Cycle Diagram for Shallow-Bed Dehumidifier

G_o = moisture content of air leaving dehumidifier, grains of moisture per pound of dry air.
v = specific volume of the air, cubic feet per pound.
7000 = conversion from grains to pounds.

Moisture removal capacity may be increased by (1) higher inlet dew point; (2) for a constant entering dew point, lower temperature and greater saturation; (3) larger air quantity, which causes a decrease in the dryness of the effluent air.

If the air to be dehumidified is very warm, and especially where a very low dew point is required, it is advantageous to install a precooler to reduce the temperature of the inlet air. In this way the working temperature in the adsorber is lowered, and the overall performance appreciably increased. Some equipment manufacturers install cooling coils in the adsorbent beds for the same purpose, while others divide the adsorbent bed and install coolers between the sections.

* PARTS OF MOISTURE PER MILLION PARTS DRY AIR BY VOLUME

Fig. 9 . . . . Moisture Content of Air at One Atmosphere Pressure

Fig. 9 shows the moisture content of air at one atmosphere pressure.

SORPTION DEHUMIDIFIERS FOR ELEVATED PRESSURES

The same sorption principles which pertain to low-pressure (approximately atmospheric) dehumidification apply to drying of high-pressure air, process gases, etc. The sorbents described previously can be used with equal effectiveness.

Equipment design may vary considerably in detail, but most basic adsorption units utilize dual bed construction for continuous operation and either internal or external heat source with air or process gas as reactivation purge for liberating previously adsorbed moisture. A single adsorbent bed may be used for intermittent drying requirements. Absorption units are generally constructed in the same manner as atmospheric pressure units, except that they are enclosed in vessels suitable for the operating pressure.

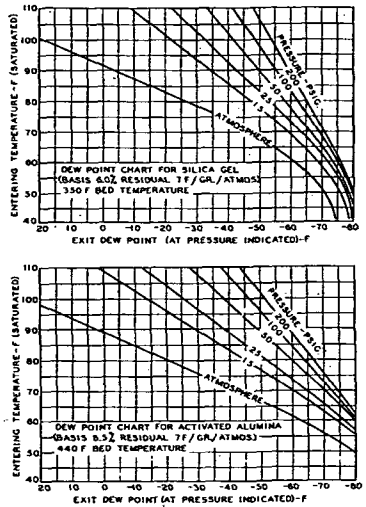

Fig. 10 . . . . Typical Performance Data for Solid Sorption Dehumidifiers at Elevated Pressures

Either compressing of the gas to be dehumidified or precooling by water, brine, or refrigeration will reduce the total moisture load to be handled by the sorbent permitting use of smaller drying units and permitting lower dew-point performance. The performance of the complete system consisting of precooler and adsorbent dryer must be investigated at various temperatures to determine the most economic operating level.

Applications include drying compressed air for processing, testing, and instrument use. Drying of air and gases have made many processes possible or effective in the chemical, petroleum, and steel industries.

Typical performance data for solid sorption dehumidifiers for pressures up to 200 psig are shown in Fig. 10.

A dew-point conversion chart is shown in Fig. 11. This chart is of value to determine changes in air dew points due to compression or expansion.

USES OF SORPTION DEHUMIDIFIERS

Sorption dehumidification equipment is used where it is desirable to control the removal of moisture from the air independent of the dry-bulb temperature of the air. Such a procedure is required in many industrial processes where the relative humidity must be controlled during the manufacture and preservation of the product.

In comfort air-conditioning dehumidification, with cooling, may serve advantageously under certain design conditions such as high moisture load in comparison to sensible heat load, high ratio of fresh air to recirculated air, and internal load variation.

Liquid absorbent dehumidification, in combination with refrigeration, is applied in industrial areas requiring either dew-point or dry-bulb temperatures below the freezing point of water, eliminating the formation of frost or ice on refrigeration coils. This particular function is illustrated by its use in wind tunnels to produce dew points as low as —60 F. It is also employed in low temperature process tunnels and chill rooms.

Other applications include supplying dry air to prevent condensation of moisture on cold surfaces, dehumidification of warehouses or storage rooms for military supplies as well as certain commercial products, and maintaining a dry atmosphere in cargo holds on ships. A more recent development is found in the dehumidification of underground caves.

MOISTURE LOAD CALCULATIONS

The application of dehumidification equipment to maintain spaces at low dew point requires careful calculation of the internal moisture gain in the room from all sources. The internal moisture gain consists of latent load from the occupants, process load from any products which give up moisture, exposed water surfaces in the space, open gas flame, water-vapor migration through cracks around the doors, windows, and other openings in the room (infiltration), and moisture transmitted through the building surfaces.

The latent load from people, exposed water surfaces, open gas flame, and moisture transmitted through building surfaces are found in the appropriate GUIDE chapters. The internal latent load due to water-vapor transfer through cracks, conveyor slots, and open doors has not been standardized and is generally calculated by engineers on the basis of judgment and experience.

Calculation of the dehumidification required to maintain lower than normal moisture content in a given room begins with determination of the rate of moisture gain in the room from all sources. It is common practice, when maintaining a low humidity ratio, to recirculate a large percentage of the air in the room through the dehumidifier, and to add only enough outdoor air to meet the needs of the problem. The humidity ratio of the mixture of outdoor and recirculated air and the dehumidifier performance data can be used to calculate the humidity ratio of the air leaving the dehumidifier. The difference between the humidity ratio of the air in the room and that of the dehumidified air entering the room represents the effective dehumidification per pound of air. The rate of internal moisture gain in grains per minute, divided by the effective dehumidification in grains per pound of air, equals the air quantity required in pounds per minute. The following typical example using arbitrary values shows a general method of determining the dehumidifying requirements. Sensible heat determination considerations are discussed in other chapters, and are purposely omitted here.

Example 1: A sorption dehumidifier is to be used to maintain indoor conditions of 73 F and 20 percent relative humidity, i.e., 24.1 grains per pound of dry air, 30 F dew point, in a room 20 ft x 30 ft x 10 ft high, having a total wall, ceiling, and floor surface area of 2200 sq ft. Outdoor design conditions are 72 F dew point (118.4 grains per pound).

Internal sources of moisture are: 4 occupants; an open natural gas burner using 15 cu ft of natural gas per hour; an open top water tank, having an area of 2 sq ft exposed surface, in which water is maintained at 87 F, with air movement over the water surface being 100 fpm. Determine the quantity and condition of the dehumidified air to be supplied to the room.

Solution: The internal moisture gain consists of items 1 to 5.

		Grains per Minute
1. From occupants:	$4 \times 1800/60 =$	120

1800 grains per person per hour is obtained from Fig. 7, Chapter 6, by interpolation between curves *C* and *D*.

2. From burned gas:	$15 \times 650/60 =$	162

1 cu ft natural gas produces approximately 650 grains of moisture.

3. From exposed water surface:	$2 \times 20 =$	40

Evaporation from water surface is assumed to be 20 grains per (minute) (square foot) at 87 F water with air movement of 100 fpm.

4. From infiltration:	$\frac{6000}{60 \times 13.56} \times (118.4 - 24.1) =$	696

One air change, 6000 cu ft, assumed per hour (see Chapter 11).

5. Moisture transmitted through room surface:

$$\frac{2200}{60} \times 3 \times (0.783 - 0.176) = 67$$

Permeability assumed to be 3 grains per (square foot) (hour) (inch Hg vapor-pressure difference on two sides of wall).

Total moisture gain from internal sources 1085

Let q be the air delivered to the room, pounds per minute. Let it be assumed for this problem that 85 percent of the air is recirculated and 15 percent is outdoor air. Enough air must be supplied to replace leakage from the system or to satisfy normal ventilating requirements for the occupants of the room as given in Chapter 6, whichever is greater. The amount is estimated from experience or obtained by test.

The humidity ratio of the mixture of recirculated and outdoor air entering the dehumidifier is then:

$$\frac{0.85q(24.1) + 0.15q(118.4)}{0.85q + 0.15q}$$

= 38.3 grains per pound entering dehumidifier.

From the manufacturer's performance data for the dehumidifier to be used it is determined that with 38.3 grains per pound of entering air the leaving condition is 6.5 grains per pound.

Effective dehumidification in the room is 24.1 — 6.5 or 17.6 grains per pound of supply air.

Then $q = \frac{1085 \text{ grains per minute}}{17.6 \text{ grains per pound}} = 61.6$ lb air per minute *minimum* that must be supplied to the room to maintain 30 F dew point.

Note that this value represents the minimum requirement for the arbitrary conditions set forth and that in practice, safety margins should be added to the outdoor air percentage value and to the calculated internal moisture gain.

VAPOR TRANSFER TO DEHUMIDIFIED SPACE

The walls enclosing a dehumidified space are subjected to a vapor-pressure differential. The pressure of the vapor outside the walls tends to force moisture through the walls into the dehumidified zone of relatively low vapor pressure. As this process can be an unnecessary load on the dehumidifying equipment, provisions should be made for keeping the vapor transfer to a minimum. Also, if the space is cooled below the ambient dew point, there is a possibility that condensation may occur within the walls, unless vapor

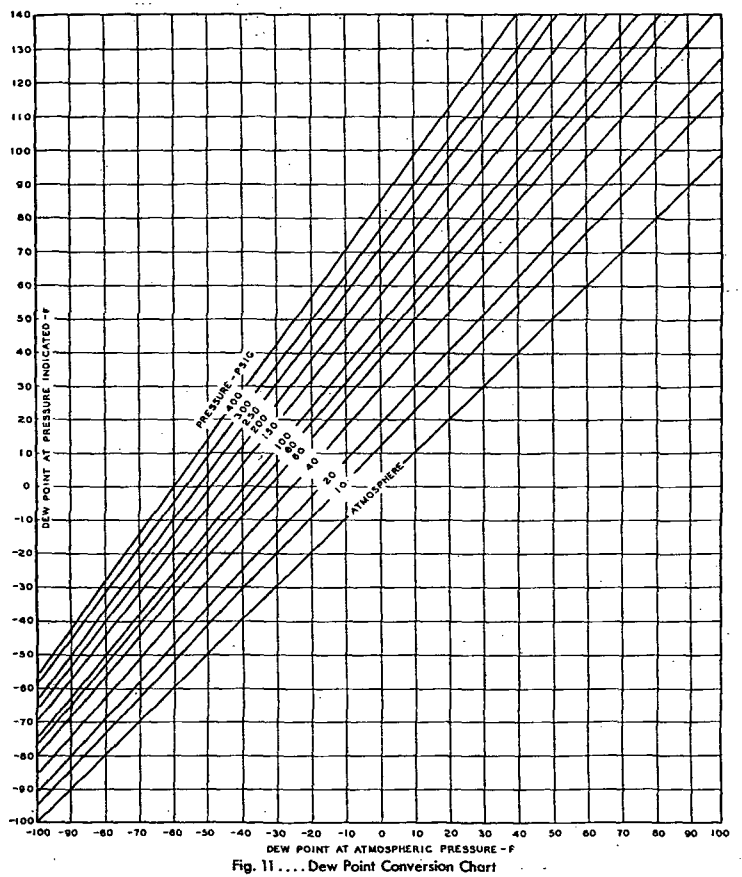

Fig. 11 .... Dew Point Conversion Chart

transfer is controlled. For these reasons a vapor barrier should be located within the wall construction as near to the high vapor-pressure side as feasible. To be effective, a barrier must be continuous and should be so located within the structure that it will be protected from rupture. (See Chapter 10 Moisture In Building Construction.)

AUTOMATIC CONTROL

Fundamentals: Types of Control Systems and Action, System Components, Controllers and Controlled Devices, Auxiliary Control Equipment; Design Coordination: Equipment Selection and Layout; Location of Controllers; Control of Steam, Water, or Air Flow; Zone Control; Control Applications: Central Fan, Temperature Control in Hot Water Systems, Zoned Steam and Water Systems, Terminal Equipment, Residential Heating and Air Conditioning

PRESENT-DAY standards of *comfort* combined with capacity and rapid response of modern heating and cooling equipment make automatic controls an essential part of heating, ventilating, and air-conditioning systems. These automatic controls respond to variables such as temperature, relative humidity, and pressure. They operate individually or in sequence to maintain the desired conditions throughout the system and in the occupied space. A factor that has made the subject of automatic control somewhat confusing has been the matter of terminology. Many different expressions or words have sometimes been used to convey a single idea or concept. This chapter, therefore, attempts to use and define the terms that are most common and suitable so that they will be readily understood. The terms and definitions used are also selected so as to conform, as nearly as possible, to automatic control terminology used by engineers in other fields of control.

PART I—FUNDAMENTALS OF AUTOMATIC CONTROL

A *control system*, Fig. 1, consists essentially of (1) a controller, (2) a controlled device, and (3) a source of energy.

A *controller* is a device which measures a variable condition such as temperature, humidity, pressure, and liquid level, and produces a suitable action or impulse for transmission to the controlled devices. Thermostats, humidistats, and pressure controllers are examples.

A *controlled device* reacts to the impulse received from a controller and varies the flow of the control agent. It may be a valve, damper, electric relay, or a motor driving a pump, fan, etc.

The *control agent* is the medium manipulated by the controlled device. It may be air or gas flowing through a damper; gas, steam, water, etc., flowing through a valve; or an electric current.

The *controlled variable* is the condition such as temperature, humidity, or pressure, being controlled.

Most control systems, of which Fig. 1 is typical, form a closed loop. That is, the controller measures and responds to changes in the controlled variable and actuates the controlled device to bring about an opposite change which is again measured by the controller. This system of transmitting information about the results of an action or operation back to its origin is known as *feedback*, and makes true automatic control possible.

An open-loop system is sometimes employed in control circuits, but it does not provide complete control. An outdoor thermostat arranged to control the flow of heat to a building in proportion to the load caused by changes in outdoor temperature is an example. This system depends for its operation on a prearranged relationship between outdoor temperature and heat input to the building, and room temperature has no effect on the controller.

As there is no feedback, the control corrects only for those disturbances of room temperature caused by changes in outdoor temperature.

TYPES OF CONTROL SYSTEMS

Control systems are divided into five main groups according to the primary source of energy:

1. A *self-contained system* combines the controller and controlled device in one unit and employs the power of the measuring system to effect the necessary corrective action. The measuring system derives its energy from the process under control without amplification by any auxiliary source of energy, and may be of the sealed-bellows or remote-bulb type as described under Types of Measuring Elements. Temperature changes at the bellows or the remote bulb result in pressure or volume changes of the enclosed media which are transmitted directly to the operating device of the valve or damper.

2. A *pneumatic system* utilizes compressed air, usually at a pressure of 15 to 25 psig, as a source of energy. This is supplied to the controller which in turn regulates the pressure supplied to the controlled device.

3. A *hydraulic system* utilizes a suitable liquid under pressure as the source of energy. The pressure often is considerably higher than in a pneumatic system, but in other respects the systems are similar. Hydraulic systems find their chief use in applications where large forces are required for operation of the controlled devices.

4. An *electric system* utilizes electric energy, either low or line voltage as the energy source. The electric energy supplied to the controlled device is regulated by the controller either directly or through relays.

5. An *electronic system* also utilizes electric energy, but employs an electronic amplifier to increase the minute voltage variations of the measuring element to values required for operation of standard electrically controlled devices. Measuring elements usually are of the resistance type, but thermocouples also are employed. Combination electronic-pneumatic systems utilize compressed air for operation of the controlled device by converting the output of the electronic amplifier into

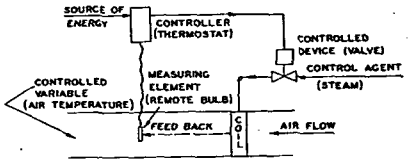

Fig. 1 .... Essentials of a Control System

suitable air-pressure changes by means of an electronic-pneumatic transducer.

TYPES OF CONTROL ACTION

Control action may be divided into five types:

1. *Two-position action*, Fig. 2, is the type in which the controlled device can be positioned only to a maximum or minimum position, or can be either *on* or *off*. A thermostat which opens and closes a valve, or starts and stops a burner, is an example.

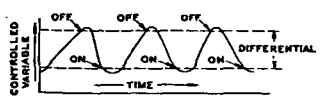

Fig. 2 .... Two-Position Control

2. *Timed two-position action* is a common variation of two-position control action in which the time of *on* periods are prematurely shortened. This type of action usually is employed only in room thermostats, and is accomplished by a heater element in the thermostat which is energized during the *on* periods. The percentage of time *on* is varied in proportion to the system load.

Controller differential applying to two-position control action, is the difference between the setting at which the controller operates to one position and the setting at which it operates to the other position. As an example, if a pressure controller starts a pump at 12 psig and stops it at 15 psig, the differential is 3 psi. It is sometimes desirable to have a controller in which the differential can be changed by manual adjustment. This is designated as an adjustable differential.

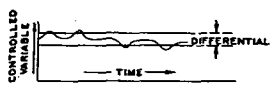

Fig. 3 .... Floating Control Showing Variations in Controlled Variable as Load Changes

3. *Floating action*, Fig. 3, is the type, as with two-position action, where the controller can perform only two operations: moving the controlled device usually at a constant rate either towards its open or its closed position. Generally there is a neutral zone between the two positions which allows the controlled device to stop at any position whenever the controlled variable is within the differential of the controller. When the controlled variable gets outside the differential of the controller, the controller moves the controlled device in the proper direction. An example of floating control is a firebox draft controller positioning a damper in the breeching of a boiler.

Fig. 4 .... Proportional Control Showing Variations in Controlled Variable as Load Changes

4. *Proportional action*, Fig. 4, is the type where the controlled device is positioned proportionately in response to slight changes in the controlled variable. It does not run through its complete stroke, as is the case with two-position control, nor does it continue to move until the change in the controlled variable resulting from that movement is felt by the controller, as is the case with floating control, but it immediately assumes a position in proportion to the system requirement.

An example of proportional control is a thermostat in a fan discharge duct actuating an automatic valve in the steam supply to a coil to regulate the air temperature leaving the coil. This control would be similar to that shown in Fig. 1.

Throttling range is the total amount of change in the controlled variable required for the controller to move the controlled device through its complete stroke, from one extreme to the other. It is often adjustable to meet job requirements.

Set point is the value at which the controller is set and represents the desired value of the controlled variable.

Control point is the actual value of the controlled variable at which the instrument is controlling. It will vary within the throttling range of the controller according to the demand on the system and other variables.

Offset is the difference between the set point and the actual control point under stable conditions. This is sometimes also called *drift*, *deviation*, or *droop*.

5. *Proportional plus automatic reset action*, Fig. 5, combines floating action with proportional action to achieve both the stability of proportional control, with a relatively wide throttling range, and the invariable control point of floating control. The system functions the same as proportional action, the automatic reset serving to shift the control point back to the set point whenever any offset occurs.

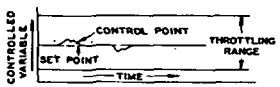

Fig. 5 .... Proportional Plus Automatic Reset Control Showing How Control Point is Returned to Set Point after a Load Change

Reset rate is the number of times per minute the proportional action is duplicated by the reset action, and usually is expressed as *repeats per minute*. The reset rate in most controllers is adjustable and must be carefully matched to the system characteristics to avoid unstable operation. Because automatic reset is necessarily slow-acting, it should be used only when load changes are of reasonably long duration and when the maximum offset resulting from proportional control alone is oustide of acceptable limits.

Figs. 4 and 5 show the results of rather abrupt demand changes, which usually result in two or three cycles before stability is restored. More gradual demand changes will result in a smoother curve.

AUTOMATIC CONTROL SYSTEM COMPONENTS

In addition to controllers and controlled devices, many control systems include auxiliary apparatus such as switches and relays of various kinds, clocks or timers, thermometers, gages, pilot lights, and other indicators for observing the operation of the system. Only those more commonly used will be described here.

Controllers

Automatic controllers have both a measuring element and a controlling element.

The *measuring element* measures changes in the controlled variable and produces a proportional effect on the controlling element. This effect usually is a change in position, force, or electrical resistance.

The *controlling element* converts the effect produced by the measuring element into an effect suitable for operation of the controlled device. (In self-contained controllers the measuring element produces a force which is directly applied to the controlled device. In pneumatic or electronic controllers the controlling element regulates the application of energy such as compressed air or electricity.)

Types of Measuring Elements

Temperature measuring elements usually consist of (1) a bimetal strip, (2) a rod and tube of dissimilar metals, (3) a sealed bellows, with or without a remote bulb, or (4) an electrical resistance.

1. A *bimetal element* is composed of two thin strips of dissimilar metals fused together. Because the two metals have different coefficients of thermal expansion, the element bends as the temperature varies and produces a change in position. Depending on the space available and the movement required, it may be in the form of a straight strip, U-shaped, or wound into a spiral. This element finds its most common application in room thermostats, but is also used in insertion and immersion thermostats.

2. A *rod-and-tube element* consists of a high-expansion metal tube inside of which is a low-expansion rod with one end attached to the rear of the tube. The tube changes length with changes in temperature, causing the free end of the rod to move. The rod-and-tube element is commonly employed on certain types of insertion and immersion thermostats.

3. A *sealed-bellows element* is either vapor-filled, gas-filled, or liquid-filled, after being evacuated of air. Changes of temperature cause changes in pressure or volume of the gas or liquid, resulting in a change in force or a movement. This element is often employed in room thermostats.

A *remote-bulb element* is a sealed bellows or diaphragm to which a bulb or capsule is attached by means of a capillary tube, the entire system being filled with vapor, gas, or liquid. Changes of temperature at the bulb result in changes of pressure or volume which are communicated to the bellows or diaphragm through the capillary tube. The remote-bulb element is useful where the temperature measuring point is remote from the desired thermostat location. It usually is provided with fittings suitable for insertion into a duct or into a pipe or tank.

4. A *resistance element* is made of wire whose electrical resistance changes with temperature changes. It is used with electronic controllers. It is available in forms suitable for measuring room temperature or for insertion into a duct or into a pipe or tank.

Humidity measuring elements are made of (1) hygroscopic organic materials or (2) an electrical resistance.

1. An *organic element* usually is made of human hair, wood, paper, or animal membrane. Changes in relative humidity cause the element to expand and contract.

2. A *resistance element*, for use with electronic controllers, frequently consists of a thin coating of hygroscopic salt on an insulating form. The resistance of the salt varies with the relative humidity.

Pressure measuring elements can be divided into one of two general classes depending upon pressure range.

1. For pressures or vacuums measured in pounds per square inch or inches of mercury, the element usually is a bellows, diaphragm, or Bourdon tube. One side of the element may be open to atmosphere in which case the element responds to pressures above or below atmospheric. A differential-pressure element has connections to both sides so that it will respond to the difference between two pressures.

2. For low ranges of pressure or vacuum which are usually measured in inches of water, such as the static pressure in an air duct, the measuring element may be an inverted bell immersed in oil, a large slack diaphragm, or a large flexible metal bellows. The element usually is of the differential type, and when employed in conjunction with orifices, Pitot tubes, and similar accessories, may be used to measure flow, velocity, or liquid level as well as static pressure.

Measuring elements for other purposes, such as flame detection or for measuring smoke density, specific gravity, CO_2, CO, etc., often are necessary for the complete control of a heating, ventilating, or air-conditioning system.

Types of Controlling Elements

Controlling elements differ because some regulate the application of pneumatic energy while others regulate the application of electrical energy. They also differ according to the type of control action produced.

An *electric controlling element* is used in several of the the common types of control action.

For *two-position control* it may simply make and break an electrical contact, to start a burner, motor, etc., or to actuate a spring-return valve or damper operator. Another type makes one contact while breaking another and is used to control unidirectional valve or damper operators. Either type may be used for timed two-position action by the addition of a small resistance heater.

For *floating control* two contacts are employed, but there is a neutral zone between the two contacts where neither is made. This type is commonly used with reversible valve or damper operators.

For *proportional control* a contact is moved across a potentiometer to vary the voltage applied to a relay. The relay controls the operation of a reversible valve or damper operator and is rebalanced as the controlled device is positioned. In another arrangement the controlling element has two contacts and a neutral zone as described for floating control and is rebalanced by a small solenoid which is energized by a variable voltage feedback from the reversible valve or damper operator which it positions.

An *electronic controlling element* consists of an electronic amplifier and an electric relay or relays. The amplifier receives the minute electrical signals from the measuring element and amplifies them sufficiently to actuate the relays. The electronic controlling element may be two-position, floating, or proportional, depending upon the amplifier and relay arrangement.

An *electronic-pneumatic controlling element* consists of an electronic amplifier and an electropneumatic relay. It may be two-position, or proportional, depending upon the amplifier and relay arrangement.

A *pneumatic controlling element* is most often of the proportional action type but may also be used for the other types of control action. It may be classified as nonrelay type and relay type.

A *nonrelay type* of pneumatic controlling element is the simplest form and employs a restricted air supply and a nozzle or control port. The measuring element varies the opening of the nozzle and the resulting variable pressure is applied to the controlled device. This type is limited to applications requiring small volumes of air.

In a *relay-type* pneumatic controlling element the relay contains both a supply and an exhaust valve usually arranged so that the exhaust valve must close before the supply valve opens. Both valves are closed except when the control pressure is required to change. The variable force for operating the valves may be supplied directly by the measuring element or it may be supplied by a diaphragm actuated by air pressure from a very small nozzle and restrictor arrangement, this air pressure being varied by the measuring element. In either case the control pressure, operating on a diaphragm within the relay, produces a force which balances the force produced by the measuring element.

Pneumatic controllers may be either direct or reverse acting.

A *direct-acting controller* increases the control air pressure as the controlled variable increases. For example, a direct-acting thermostat increases the air pressure as the temperature increases.

A *reverse-acting controller* decreases the control air pressure as the controlled variable increases. A reverse-acting

thermostat decreases the air pressure as the temperature increases.

Indicating and Recording Features

Controllers may be of the indicating or recording type.

The *nonindicating controller* is most common in heating, ventilating, and air-conditioning work, and includes all those in which the measuring element does not provide a visual indication of the *value of the controlled variable*. If an indication is desired, a separate thermometer, relative humidity indicator, pressure gage, etc., is required. With room thermostats, for example, a separate thermometer often is attached to the cover.

An *indicating controller* has a pointer added to the measuring element or attached to it by a linkage so that the value of the controlled variable is indicated on a suitable scale.

A *recording controller* is similar to an indicating controller except that the indicating pointer is replaced by a recording pen which provides a permanent record on a chart driven by a clock motor.

Proportional band is a term used in connection with indicating and recording controllers and has the same meaning as throttling range. It is usually expressed in percent of the scale or chart range of the controller.

Types of Controllers

Controllers are mainly (1) thermostats, (2) humidistats, and (3) pressure types.

1. Many thermostats are of the simple, single-purpose type, but there are *many* others for various special purposes. Various types are indicated in paragraphs (*a*) to (*k*) which follow.

a. The *room* type is designed for mounting on a wall and responds to room temperature.

b. The *insertion* type is designed for mounting on a duct with its measuring element extending into the duct.

c. The *immersion* type is designed for mounting on a pipe or tank. It has a fluid-tight connection to allow the measuring element to extend into the fluid. A separable socket or well is often used with immersion thermostats to avoid the need for draining the system when removal of the thermostat is required. Since the separable socket will reduce the response rate of the thermostat, the socket should be no heavier than necessary and should fit snugly around the element.

d. The *remote-bulb* type is designed for applications where the point of temperature measurement is at some distance from the desired thermostat location. It is often used for centralized panel mounting of the controller. The remote-bulb element may be of either the insertion or immersion type.

e. The *surface type is* designed for mounting on and measuring the temperature of a pipe or similar surface.

f. The *day-night*, or *dual* room thermostat controls at a reduced temperature at night. It may be indexed (changed from day to night operation) *individually or in groups from* a remote point by a manual or time switch. Some electric types have an individual clock and switch built into the thermostat.

g. The *pneumatic day-night* thermostat uses a two-pressure air-supply system, the two pressures often being 13 and 17 psig or 15 and 20 psig. Changing the pressure at a central point from one value to the other actuates switching devices in the thermostat and indexes them from day to night or vice versa. Supply-air mains often are divided into two or more circuits so that switching can be accomplished in various areas of the building at different times, in accordance with use. For example, a school building may have *separate circuits* for classrooms, offices and administrative areas, auditorium, and gymnasium and locker rooms.

h. The *heating-cooling* or *summer-winter* thermostat can have its action reversed and, if desired, have its set point changed by the indexing means. It is used to actuate controlled devices, such as valves or dampers, that regulate a heating source at one time and a cooling source at another time. It is often indexed in groups manually by a switch or automatically by a thermostat measuring the temperature of the control agent, the outdoor temperature, or other suitable variable.

i. The *pneumatic heating-cooling* thermostat uses a two-pressure air-supply system as described for day-night thermostats.

j. A *two-stage* thermostat is arranged to operate *in two* successive steps.

k. A *submaster* thermostat has its set point raised or lowered over a predetermined range in accordance with variations in output from a master controller. The master controller can be a thermostat, manual switch, pressure controller, or similar device. For example, a master thermostat measuring outdoor air temperature can be used to readjust a *submaster* thermostat controlling the water temperature in a heating system. Master-submaster combinations are sometimes designated as *single-cascade action*. When such action is accomplished by a single thermostat having more than one measuring element, it is known as *compensated control*.

2. *Humidistats* are of either the room or insertion type. Submaster humidistats of either type are *sometimes* used in conjunction with an outdoor master thermostat to reduce the *humidity in cold* weather and prevent condensation on windows.

A *wet-bulb* thermostat is often used for humidity control in conjunction with proper control of the dry-bulb temperature. A wick or other means for *keeping* the bulb wet, and rapid air motion to assure a true *wet-bulb measurement* are essential.

3. A *pressure* or *static-pressure* controller is made for mounting directly on a pipe or remotely on a panel or wall. A small pipe or tube may be used for transmitting the pressure signals to the instrument.

Controlled Devices

Controlled devices may be (1) automatic valves, (2) valve operators, (3) automatic dampers, and (4) damper operators. Other controlled devices include electric heaters, and motors on such equipment as fans, pumps, burners, refrigeration compressors, and similar apparatus.

1. An *automatic valve* is designed to control the flow of steam, water, gas, and other fluids and may be considered as a variable orifice which is positioned by an electric or pneumatic operator *in response to impulses from the controller*. It may be equipped with a throttling plug or v-port of special design to provide the desired flow characteristics.

Renewable composition discs are common. They are made of materials best suited to the media handled by the valve, and its temperature and pressure. For high pressures or for superheated steam, metal discs are often employed. Internal parts of valves such as the seat ring, throttling plug or v-port skirt, disc holder, and stem sometimes are made of *stainless* steel or other hard and corrosion-resistant metals for use in severe service. Automatic valves should be properly selected and sized for the specific applications. See the section on Design Coordination in this chapter for *further details*.

The functions of various types of automatic valves are as follows:

a. A *single-seated valve* is designed for tight shut-off. Appropriate disc materials for various pressure ranges and media are used.

b. A *pilot piston valve* utilizes the pressure of the control agent as an aid in operating the valve. It usually is single-seated and is used where large forces are required for valve operation.

c. A *double-seated* or *balanced valve* is designed so that *the media pressure acting against the valve disc is essentially* balanced thereby reducing the force required of the operator. It is widely used where the fluid pressure is too high to permit a single-seated valve to close. It cannot be used where *tight shut-off is required*.

d. A *three-way mixing valve* has two inlet connections and one outlet connection and a double-faced disc operating *between two seats*. It is used to mix, as required, two fluids entering the inlet connections and leaving through the common outlet.

e. A *three-way diverting valve* has one inlet connection and two outlet connections and two separate discs and seats. It is used to divert the flow to either of the outlets or to proportion the flow to both outlets.

f. A *butterfly valve* consists of a heavy ring enclosing a *disc which rotates* on an *axis* at or *near* its center, and in principle is similar to a round single-blade damper. The disc usually seats against a ring machined within the body.

2. Valve operators are of three general types:

a. A *solenoid* consists of a magnetic coil operating a movable plunger. It is used for two-position operation. The most common use of a solenoid operated valve is to control the flow of gas, water, air, and refrigerants and generally it is limited to relatively small sizes.

b. An *electric motor* operates the valve stem through a gear train and linkage. Electric motor operators are classified in three distinct types: *unidirectional*, *spring return*, or *reversible*.

Unidirectional, for two-position operation. The valve opens during one-half revolution of the output shaft and closes during the other one-half revolution. Once started, it continues until the half revolution is completed, regardless of subsequent action by the controller. Limit switches built into the operator stop the motor at the end of each stroke. If the controller has been satisfied during this interval the operator will continue to the other position.

Spring-return, for two-position operation. Electric energy drives the valve to one position and holds it. When the circuit is broken, the spring returns the valve to its normal position.

Reversible, for floating and proportional operation. The motor can run in either direction and can stop in any position. It is sometimes equipped with a return spring. For proportional control applications, a potentiometer for rebalancing the control circuit is also driven by the motor.

c. A *pneumatic operator* consists of a spring-opposed flexible diaphragm or bellows attached to the valve stem in such a way that an increase in air pressure moves the valve stem and at the same time compresses the spring. Springs of various ranges in terms of air pressure can be employed to provide sequence operation of two or more devices by proper selection or adjustment of the springs. *Springless pneumatic operators*, using two opposed diaphragms or two sides of a single diaphragm, also are used but generally are limited to special applications involving large valves or high pressures. Pneumatic operators are designed primarily for proportional control. Two-position control is accomplished by use of a two-position controller, or a two-position pneumatic relay to apply either full air pressure or no pressure to the valve operator.

Pneumatic valves and valves with *spring-return* electric operators can be classified as normally open or normally closed.

A *normally open* valve will assume an open position when all operating force is removed.

A *normally closed* valve will assume a closed position when all operating force is removed.

3. *Automatic dampers* are designed to control the flow of air or gases and function like valves in this respect. Steel blades and frames are most common, but other materials are used for special applications such as those involving corrosive fumes. Large dampers often are made in two or more sections for strength and convenience in handling, the sections being interconnected so as to operate as a unit. The damper types commonly used are:

a. Single-blade, which is generally restricted to small sizes because of the difficulty of securing proper operation with high-velocity air.

b. Multiblade or *louver* damper which has two or more blades linked together. It may be arranged for *parallel operation*, in which all blades rotate in the same direction or *opposed operation*, in which adjacent blades rotate in opposite directions and provide more linear air-flow characteristics than obtained with parallel operation.

c. Mixing dampers, composed of two sections interlinked so that one section opens as the other closes.

4. *Damper operators* of the electric type may be unidirectional, spring-return, or reversible, similar to electric-motor valve operators. Pneumatic damper operators are similar to pneumatic valve operators except that they usually have a longer stroke or the stroke is increased by means of a multiplying lever. Damper operators are mounted on the damper frame and are connected with linkage directly to a damper blade or are mounted outside the duct and connected to a crank arm attached to a shaft extension of one of the blades. On large dampers two or more operators may be required, and *usually are applied at separate* points on the damper. Normally open or normally closed operation is obtained according to the method of mounting the operator and connecting the linkage.

Auxiliary Control Equipment

In addition to the conventional controllers and controlled devices described, many control systems require auxiliary devices to perform various functions. Auxiliary controls for electric systems include:

1. *Transformers* to provide current at the required voltage.

2. *Electric relays* for control of electric heaters or to start and stop oil burners, refrigeration compressors, fans, pumps, or other apparatus for which the electrical load is too large to be handled directly by the controller. Other uses include time-delay, circuit-interlocking safety applications, and similar functions.

3. *Potentiometers* for manual positioning of proportional control devices or for remote set-point adjustment of electronic controllers.

4. *Manual switches* for manually performing a variety of operations. These may be of *two-position or multiple-position* type or may be of single or multiple-pole type.

5. *Auxiliary switches* on valve and damper operators for providing a selected sequence of operations.

Auxiliary control equipment for *pneumatic systems* includes:

1. *Air compressors and accessories*, to provide a source of air at the required pressure.

2. *Electropneumatic relays*, which are electrically actuated air valves for operating pneumatic equipment in accordance with variations in *electrical output*.

3. *Pneumatic-electric relays*, which are actuated by air pressure and make or break an electrical circuit.

4. *Pneumatic relays*, which are actuated by the pressure from a controller to perform numerous functions. They may be divided into two groups:

a. Two-position relays, which permit a controller actuating a proportional device to actuate also one or more two-position devices. They also are used in various automatic switching operations.

b. Proportional relays, which are used to reverse the action of a proportional controller, select the higher or lower of two pressures, average two or more pressures, respond to the difference between two pressures, add or subtract pressures, amplify or retard pressure changes, and perform other *similar functions*.

5. *Positioning relays*, which are devices for assuring accurate positioning of a valve or damper operator in response to changes in pressure from a controller. They are affected by the position of the operator and the pressure from the controller, and whenever the two are out of balance will change the pressure applied to the operator until balance is restored.

6. *Switching relays*, which are pneumatically operated air valves for diverting air from one circuit to another or for opening and closing air circuits.

7. *Pneumatic switches*, which are manually operated devices for diverting air from one circuit to another or for opening and closing air circuits. They may be of two-position or multiple-position type.

8. *Gradual switches*, which are proportional devices for manually varying the air pressure in a circuit.

Auxiliary control devices common to both electric and pneumatic systems include:

1. *Sequence controllers* for operating a number of electric

switches in sequence by means of a proportional electric or pneumatic operator. They are commonly used for controlling a number of steps of refrigeration capacity and may be arranged to prevent simultaneous starting of compressors and to alternate the sequence to equalize wear. They may also be used for sequence operation of electric heaters and other equipment in response to the demands of a proportional controller.

2. *Clocks or timers* for turning apparatus on and off at predetermined times, for switching control systems from day to night operation, and for other time sequence functions.

PART II—DESIGN COORDINATION

A heating or cooling system is designed to meet maximum conditions but functions at partial capacity much of the time. The ability to properly control the system at all times is one of the most important factors having to do with the design of the system and for this reason the proper use and application of controls should be considered at the time the heating or cooling system is being designed. Wherever possible the system should be designed to facilitate control operation. This section includes factors which should be considered in the design of a new heating or cooling system, or the modernization of an existing one, to enable the control system to produce the best possible results.

The design of the system and its controls should take into consideration the nature and type of the building in which it is to be used and the results it is desired to accomplish. Quality of the control equipment should be consistent with the accuracy of control required. Where results more precise than those for normal comfort applications are required, such as in certain manufacturing areas, constant temperature rooms, etc., both the air-conditioning system and the control system should be given special consideration so that the required results can be produced. Controls can be made to produce almost any degree of accuracy required, but it is useless to provide such controls unless the air-conditioning system is capable of properly responding to the demands of the controllers. For example, it is virtually impossible to maintain close control of temperature and humidity by starting and stopping a refrigeration compressor or opening and closing a refrigerant valve. It is necessary instead to employ refrigeration equipment that will permit proportional control by one of the methods discussed in Chapter 38, or to use a chilled-water system with a cooling coil or air washer that will permit proportional control. Neither is it good practice or economical to select equipment capable of producing far more precise control than the application requires, or to complicate the system to obtain special sequences or cycles of operation when not necessary. It is well to remember that the system must be adjusted and maintained in operation for many years, and that the simplest system which will produce the necessary results is usually the best.

SIZE OF CONTROLLED AREA

No individually controlled area should be excessively large because the difficulties of obtaining good distribution and of finding a representative location for the space controls become greater as the area increases. Each individually controlled area must have similar load characteristics throughout and otherwise should conform to the recommendations given in the section on Zone Control. For uniform conditions throughout the area equitable distribution must be provided by competent engineering design, careful sizing of equipment, and proper balancing of the system. The control can measure conditions only at the point where it is located, and it cannot compensate for variable conditions throughout the area caused by improper distribution or inadequate design. Areas or rooms having dissimilar load characteristics, or having different conditions to be maintained, should be individually controlled. The smaller the controlled area the better will be the control obtained and the more nearly will the system approach the optimum in performance and flexibility.

Even when individual room control is employed it often is well to consider some form of overall zone control of the whole system in accordance with the major factor influencing system load. Thus the water temperature in a hot water heating system, the steam temperature or pressure in a steam heating system, or the delivered air temperature in a central fan system may be varied inversely as the outdoor temperature varies. This obtains a fair share of the necessary control on the system as a whole, relieves the individual space controls of a part of their burden, and makes more accurate space control possible. Furthermore, modifying the basic rate of heating or cooling input to the system in accordance with system load reduces losses in the distribution system. The cost of the additional controls is often justified by the reduction in operating costs.

Where such overall system controls are employed, accurate zoning, while desirable, is not necessary. The system must always be able to satisfy the area or room having the greatest demand. The individual controls take care of the variations in demand within the area served by the system. The more accurately the system is zoned the larger will be the share of the control accomplished by the overall system controls, the smaller will be the system distribution losses, and the more accurately will the individual space controls be able to maintain the space conditions.

EQUIPMENT SELECTION AND LAYOUT

Heating and cooling coils should be carefully selected to avoid oversizing. A coil that is too large is not only more difficult to control but will increase air temperature stratification. When temperature measuring elements are to be placed between coils, ample space between the coils must be provided. The measuring element should be located as near as possible to the coil it is controlling. For example, an idle water coil interposed between a thermostat and the coil it is controlling introduces enough thermal inertia to make it difficult to produce stable control.

The elimination of stratification in an air-handling system is essential not only in producing good control but in obtaining equitable distribution of heating or cooling. Outdoor-air and return-air dampers should be arranged in such a way as to help blend the outdoor air and return air. Face dampers should be placed far enough from coils to allow for equalization of air flow over the coil surface. The controller for face and bypass dampers must be located far enough downstream so that the air has become thoroughly mixed before reaching the controller. Other sources of stratification are coils which heat or cool unevenly and coils arranged in parallel and controlled in sequence. Whenever stratification cannot be eliminated by proper design or arrangement of equipment, special baffles, mixing chambers, or other mechanical devices should be used for this purpose. If stratification still exists at a point where the measuring element of a thermostat is to be located, the use of a long averaging element, or one made up of a number of small elements, may make a suitable temperature measurement possible. This does not solve the other problems relating

to stratification which can cause discomfort or, in extreme cases, freezing of equipment.

Good air distribution and properly spaced diffusers and grilles will greatly assist in maintaining even temperatures throughout an area. A space temperature controller cannot prevent drafts. This can be accomplished only by proper attention to such factors as balancing the system, by introducing air in the correct manner, and by providing a suitable low-limit control on the delivered-air temperature. A system that employs constant air volume with variable air temperature results in more uniform distribution than one which requires variations in air volume to achieve temperature control. Varying the volume of air affects both ventilation and distribution, two factors which usually have little relation to thermal requirements. Return-air grilles usually can and should be located so as to aid both the distribution and control of the system.

A further aid to both distribution and control is the provision of adequate facilities for exhausting air from the building. The larger the percentage of outdoor air introduced the more important becomes the provision for adequate exhaust. To prevent drafts due to infiltration, it is quite common to provide for positive exhaust of less air than is brought in. On systems where the quantity of outdoor air is large but constant, this may be accomplished by use of a properly sized exhaust fan. Systems having large internal heat gains, or large solar gains, may use a variable amount of outdoor air up to 100 percent when cooling is required during cool weather. In such cases the outdoor-air quantity may be controlled from space conditions and the quantity of exhaust air may be controlled by a static-pressure controller set to maintain the space under a slight positive pressure.

LOCATION OF SPACE CONTROLLERS

Space controllers such as room thermostats must be placed where they will measure the variables they are to control and where the condition is representative of the whole area served by the controller. If the return-air duct is used to represent space conditions, the controller should be located as near the space as possible to eliminate the effect of any heat gain or loss in the duct.

Room thermostats should usually be placed in occupied areas on inside walls or columns. They should never be placed in spaces such as corridors, lobbies, and foyers unless they are used for the control of these areas only.

In a typical home which is not zoned a satisfactory location for a room thermostat can usually be found on an inside wall of the living room or dining room. It should always be located toward the center of a relatively open room situated on the coolest rather than the warmest side of the building. It should not be mounted on an outside wall or other cold surface where it is exposed to cold drafts from an outside door. Neither should it be mounted where it will be affected by direct rays of the sun, by heat from a nearby warm surface such as a chimney, pipes or ducts in the wall, or radiators, or by direct air currents from a register. The location should provide ample air circulation unimpeded by furniture or other obstructions, and should afford protection from mechanical injury.

CONTROL OF FLOW

The successful operation of practically any air-conditioning system is dependent on the proper control of flow in one form or another. The flow being controlled may be steam, water, air, or some combination thereof. In each case a controlled device is used to regulate the flow at the command of a controller. The proper design and sizing of these controlled devices, valves for steam or water, and dampers for air, are essential to obtain the desired results from the air-conditioning system.

The performance of a valve or damper is expressed by the control industry in terms of its flow characteristics as it operates through its stroke, based on a *constant pressure drop*. Three common characteristics are shown in Fig. 6 and may be defined as follows:

Quick Opening: Maximum flow is approached rapidly as the device begins to open.

Linear: Opening and flow are related in direct proportion.

Equal Percentage: Each equal increment of opening increases the flow by an equal percentage over the previous value.

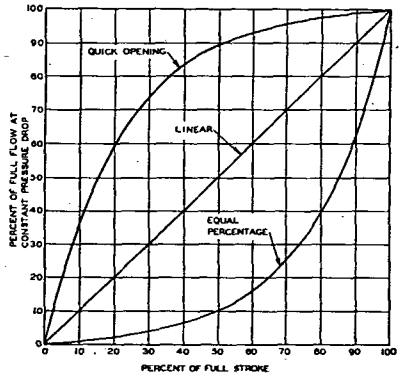

Fig. 6 .... Typical Flow Characteristics

Since the pressure drop across a valve or damper seldom remains constant as its opening changes, actual performance usually deviates from the published characteristic curve. The magnitude of the deviation is determined by the overall system design. For example, in a system arranged so that control valves or dampers can shut off all flow, the pressure drop across a controlled device increases from a minimum at design conditions to the total system pressure drop at no flow. Fig. 7 shows the extent of the resulting deviations for a valve or damper designed with a linear characteristic, when the selection is based on various percentages of the total system pressure drop. In order to approximate the designed characteristic of the valve or damper, the design pressure drop should be a reasonably large percentage of the total system pressure drop or the system should be designed and controlled in such a manner that this pressure drop remains relatively constant.

Higher pressure drops for controlled devices are obtained by using smaller sizes in conjunction with a possible increase in size of other equipment in the system. Since

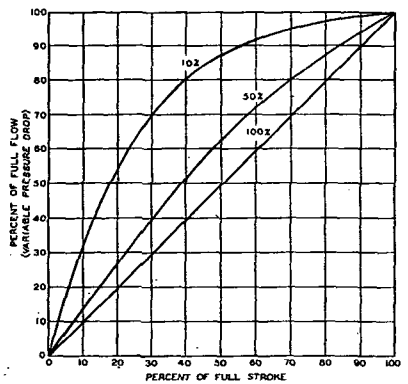

Fig. 7.... Typical Performance Curves for Linear Devices Selected at Various Percentages of Total System Pressure Drop

sizing techniques are different for steam, water, and air, each is covered separately.

THE CONTROL OF STEAM FLOW

The size of an automatic steam valve is based on the required capacity at maximum load, under the conditions which will exist at that time. Equation 52, Chapter 4, for mass flow through an orifice or nozzle can be rewritten as

$$w = CA\sqrt{P_1 - P_2} \qquad (1)$$

where

- w = the flow of steam in pounds per hour.
- A = the area of the port opening in square inches.
- P_1 = the steam supply pressure, pounds per square inch, absolute.
- P_2 = the downstream pressure, pounds per square inch, absolute.
- C = a constant for a given steam supply pressure and a given valve body.

Valves for two-position operation usually are selected of a size adequate to supply the required maximum capacity with a reasonably low pressure drop ($P_1 - P_2$). It is necessary only to be sure that the valve will close against the system pressure and will have ample capacity when fully open.

Proportional valves for steam service must be carefully sized if stable control is to be achieved. Since, in general, the tendency is to oversize such valves it should be remembered that no controller can produce its best results if handicapped by a valve which is too large. The function of the valve is to vary the value of area A in Equation 1 and it is desirable that the flow vary in proportion to the value of A. The correct maximum required capacity must first be determined. There should be no factor of safety in this determination, and it should be based on actual heating requirements rather than on the condensing capacity of the coil, since the coil may be larger than necessary. It is also necessary to base the valve size on the actual supply pressure P_1 which will exist at the valve, since this supply pressure affects both the density of the steam and the pressure drop which will be selected.

Selecting the proper pressure drop ($P_1 - P_2$) across the valve when it is wide open and is supplying the maximum steam requirement is the most important consideration in determining the valve size. For purposes of discussion it will be assumed that P_1 is constant and that the valve is supplying steam to a heating coil which has air entering at a constant temperature and velocity. Any pressure drop between the valve and the coil will be neglected so that P_2 represents the pressure in the coil. The condensing capacity of the coil varies with changing values of P_2. When the valve is fully open, P_2 assumes a value such that the capacity of the valve and the condensing rate of the coil are in balance. If this value of P_2 is relatively large, then, as the valve is partially closed, P_2 will decrease until the capacity of the valve and the condensing rate of the coil are again in balance. Reducing the value of A in Equation 1 results in an increase in the value of $\sqrt{P_1 - P_2}$ and partially offsets the effect of closing the valve. This effect is greatest when P_2 is nearly equal to P_1 and diminishes as P_2 decreases.

The minimum value which P_2 can assume is established by the return line pressure (or vacuum) of the system. However, P_2 may reach a value which results in the critical velocity through the valve before it has been reduced to its minimum value. If so, any reduction of P_2 beyond this value has no further effect on the valve capacity. The critical velocity exists when P_2 is approximately 58 percent of P_1. The undesirable effect caused by variations in P_2 can be eliminated by selecting a valve size such that P_2 is at or near its minimum value, or the value corresponding to the critical velocity, whichever is higher, when the valve is wide open.

On low-pressure steam applications it is good practice to base the valve size on a pressure differential equal to 75 or 100 percent of the gage supply pressure. When the supply pressure is high enough so P_2 at the critical velocity (58 percent of P_1) is above atmospheric pressure, the valve size can be based on a pressure differential of 42 percent of P_1 absolute. All valves of the same size do not have the same capacity for a given pressure differential. Having established the supply pressure and the pressure differential, the valve manufacturer's tables or charts should be consulted in selecting the proper size of valve for the required capacity.

It is important that the supply pressure to an automatic steam valve be constant because it is difficult for a thermostat to produce stable results if the pressure is constantly changing. This situation arises, for example, when a steam boiler is operated by a two-position pressure controller. A pressure-reducing valve, which will supply a constant pressure to the steam mains while permitting the boiler pressure to fluctuate between the limits of the pressure controller, is recommended. Lacking this, the differential of the pressure controller should be set as narrow as is consistent with efficient boiler and burner operation. On vacuum return systems the vacuum pump also should operate on a narrow differential.

The use of two automatic control valves in parallel will often provide more stable control than a single larger valve, especially on large coils or steam-to-water heat exchangers. The valves should be sized so that one valve handles about one-third of the total capacity and the other about two-thirds. They are controlled in sequence so that the small valve operates during periods of light load and the large valve begins to open only after the load exceeds the capacity of the small valve.

The steam piping from the valve to the coil inlet, and from the outlet to the trap should be the full size of the coil tapping or size specified by the manufacturer of the coil and should conform to good standard practice as illustrated in Chapter 26. It is very important that condensate be promptly drained from the coil. When the coil is at reduced pressure, as it will be much of the time, there will not be sufficient difference in pressure between the coil and the return line to obtain any lifting of the condensate.

THE CONTROL OF WATER FLOW

The capacity of a proportional valve for water service is not influenced by the supply water pressure but only by the pressure differential. This is so because water is incompressible and because the inlet pressure is not an important factor in the thermal capacity of a water system. If a certain water circuit has a total resistance of 30 psi at maximum flow, of which 1 psi is through the valve, the resistance of the rest of the circuit is 29 psi. As the valve closes and flow is stopped the resistance across the valve becomes the entire 30 psi. Thus the pressure drop across the valve increased by a ratio of 30:1 as the valve travelled from full open to full closed position. This increase in pressure drop as the valve is closed offsets partially the effect of closing the valve.

It is obviously impracticable to design a water system such that there will be no increase in pressure drop across the valve as it closes. However, it is important to design the system, including the valve, in such a manner that the ratio of this increase in pressure drop as the valve closes is kept as low as possible. Thus, if the design pressure drop across the valve is 5 psi instead of 1 psi, the ratio of increase is only 6:1 instead of 30:1 and the performance of the valve will be improved accordingly. This discussion assumes a circuit in which the entire flow is controlled by a single valve. The same reasoning will apply to the more complicated systems involving a multiplicity of parallel circuits, each having a valve. In general it can be said that the pressure drop across a water valve at full flow should be a reasonable percentage of the resistance of the circuit in which the valve controls the flow. Due consideration should be given to any resultant increase in pumping head and operating costs.

Consideration must also be given to the fact that the Btu release from the hot water coil does not vary in direct proportion to changes in flow, i.e., as flow is reduced the water temperature drop through the coil increases so that there is very little change in the total heat given off. Conversely, this is true for cold water coils. Considerable improvement in control valve operation is obtained where systems are designed for large temperature drop and valves are selected at minimum practical size. Special designs of throttling plugs in valves may further improve control.

Water circuits involving variable flow are subject to variable pressures in accordance with the pressure vs. flow characteristic of the pump. On such circuits it is desirable to provide some means of system pressure control. A bypass from supply to return is often used to accomplish this. The bypass connection either has a spring-loaded relief valve, subject to the system pressure difference, or an automatic control valve operated by a differential-pressure controller.

Another very important consideration when using hot water as the heating medium, is that the heat output of a coil is not linearly related to flow. As the flow is reduced,

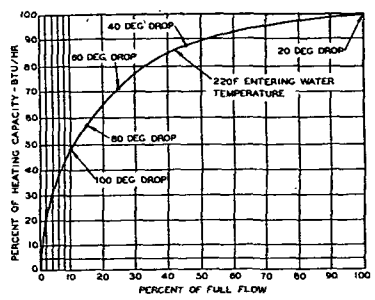

Fig. 8.... Heat Emission vs. Flow Characteristics of Typical Hot Water Heating Coil

a greater amount of heat is transferred from each gallon of water and this tends to counteract the reduction in flow. Fig. 8 shows the heat emission versus flow characteristics for a typical coil with 220 F entering water and a 20-deg design temperature drop and shows how the temperature drop increases as the flow is reduced.

To improve the coil characteristics for hot water, it is possible to design for higher water temperature drops. Selecting a temperature drop of 60 deg would require a slightly larger coil but would improve control performance and substantially lower the water requirements. This reduction in gpm also results in smaller pipe sizes, smaller control valves, and reduced pumping costs.

A properly sized control valve with equal percentage characteristics should be used to control the flow of hot water to coils for modulating service.

CONTROL OF AIR FLOW

It is common practice to size a damper to fit the duct into which it is installed. This usually results in a very low design pressure drop across the damper. It also keeps the fan horsepower requirements as low as possible. In some cases this practice results in very poor control performance. This is particularly true of dampers used to control the entire flow into a large duct, such as a static pressure damper.

For a constant pressure drop, the flow characteristic of a damper varies with the number of blades, the manner in which the blades rotate with respect to each other, and the length to width ratio of blades.[1] Dampers commonly are of the single-blade or multiblade type. The latter may have blades with either parallel or opposed operation.

When the application is such that the pressure drop across the damper increases substantially as it closes, it is preferable to use opposed blade dampers. As explained in a preceding section, Control of Flow, the changing pressure will cause a deviation from the design flow characteristic. This will change the performance from nearly equal percentage to nearly linear as shown in Fig. 9.

Even though Fig. 9 indicates good performance from an opposed blade damper under the conditions tested, it does not eliminate the need for using smaller dampers with higher design pressure drops in some applications. An extreme example is a static-pressure damper in a high-velocity system. Such a damper should not be placed in the low-

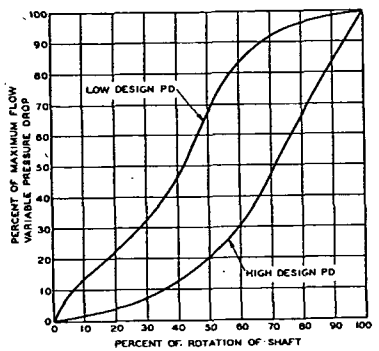

Fig. 9 .... Effect of Pressure Drop Selection on Opposed-Blade Damper Performance

velocity coil section where it would have a design pressure drop of less than 0.1 in. water, if it is expected to control with 2 to 3 in. pressure drop during periods of low flow. It should be placed in a high-velocity section where the design pressure drop will be 0.5 in. water or more, careful consideration being given to avoid excessive turbulence on either entering or leaving side of the damper.

ZONE CONTROL

Zone control for any heating, ventilating, or air-conditioning system is employed where it is desired to control, by one set of controls, the heating or cooling effect in a number of rooms or areas, having similar orientation or occupancy. For zone control to be successful the requirements must be approximately consistent throughout the extent of the zone. Whether zoning a building for heating or cooling, the following factors should be considered in determining the number and arrangement of the zones:

1. *Exposure.* Solar effect, prevailing winds, and the shelter afforded by surrounding structures affect the heat gain or loss.

2. *Occupancy.* Indoor temperature requirements for the various activities carried on in different portions of the building and the hours of occupancy of the various spaces impose definite control problems.

3. *Building Structure.* The physical characteristics of the building will influence the subdivisions of the system into zones since satisfactory temperature conditions throughout a single zone of given extent may not be obtainable equally in buildings of dissimilar types of construction. Other factors are the height of the building and its horizontal extent and form.

4. *Floors.* Even though several floors have the same wall exposure, it is advisable to have separate zones on the lowest and highest floors due to variations of basement or ground floor requirements and the effect of roof exposure. It is also desirable to have a separate zone or zones for the intermediate floors.

The initial investment will often influence the decision as to the final number of zones to be employed. In larger buildings accepted practice is to have at least one zone for each exposure. Each exposure may require subdivision vertically into two or more zones for the higher structures. Also, the presence of two or more wings having the same general exposure may suggest the desirability of more restrictive zoning. When the street floor or any other portion of the building is used for public occupancy or activities which differ from those carried on in the remainder of the building, it is desirable to provide separate thermostats and controls for each individual area.

Zone controls alone may not provide satisfactory temperature conditions in all rooms or areas within the zone because occupancy, lighting load, space arrangements, and similar factors cannot always be predicted with accuracy. A combination of zone controls with individual room control in critical areas may be necessary to achieve complete satisfaction.

INDIVIDUAL ROOM CONTROL

The ideal temperature control system for any building is one that promotes maintenance of the desired temperature in every room at all times regardless of location and occupancy. Individual room temperature control is desirable for securing proper thermal environment in schools, hospitals, and offices.

Control of the temperature in each room, or possibly of adjacent rooms having the same orientation (as in an apartment), overcomes many of the problems encountered when attempting to regulate the temperature of a building as a whole or of large areas or zones. Each individual thermostat controls the heat input to its particular space regardless of occupancy or exposure to sun and wind. The advantage of individual room control is in fuel economy and comfort for the occupants. Each room should have a thermostat that controls valves or dampers on all the controllable sources of heating and cooling. One such uncontrolled source may prevent proper operation of the control system.

PART III—CONTROL APPLICATIONS

Applications of controls to systems or apparatus of a general nature will be found in this section. Applications pertaining to specific systems or apparatus will be found in the chapters covering these subjects. The application of controls may conveniently be considered for the three divisions of a system indicated in Fig. 10: (1) *primary source apparatus*, (2) *distribution system*, and (3) *terminal equipment*.

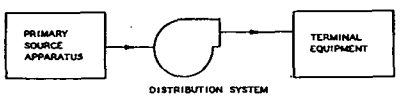

Fig. 10 .... Three General Divisions of Control Applications

PRIMARY SOURCE APPARATUS

The control of *primary source apparatus* is described in the following chapters: Chapter 18, Warm Air Heating Systems, Chapter 34, Automatic Fuel-burning Equipment, Chapter 39, The Heat Pump, and Chapter 38, Refrigeration. The second and third divisions are considered in this section.

DISTRIBUTION SYSTEMS

The control of distribution systems is discussed separately for central fan systems, hot water systems, zoned steam systems, and zoned hot water systems, due to the difference in these systems.

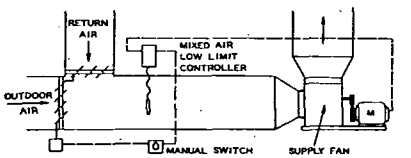

Fig. 11 .... Manual Adjustment of Outdoor-Air Quantity With Low-Limit Control of Mixture Temperature

CENTRAL FAN SYSTEMS

Refer to Chapter 19 for additional material on control for a typical central fan system.

Since there are numerous control combinations that can be employed with central fan systems, the following sections will deal with only a few of the typical combinations for controlling outdoor- and return-air dampers, preheat coils, heating coils, cooling coils, and humidity control. The complete control system is obtained by combining the selected method for each item into an integrated set of controls. Proper consideration must be given to the interrelation of the several parts and the sequence of operation, etc.

Outdoor-Air Damper Control

Outdoor air for ventilation is usually controlled by a damper arrangement providing a homogeneous mixture of outdoor air and recirculated air. Outdoor air to meet minimum ventilation requirements should be available whenever the fan is running and is usually provided in one of the following ways:

a. By a minimum outdoor-air damper which is fully open when the fan is started. A maximum outdoor-air damper may also be provided if additional outdoor air for natural cooling is desired.

b. By an outdoor-air damper which opens to a minimum position when the fan is started. Additional outdoor air is provided by further opening of the damper under automatic control.

Recirculated-air and exhaust-air dampers are synchronized to operate with the outdoor-air dampers. Mechanical interconnections are preferable but separate operators on each of the dampers can be used when mechanical interconnections are impractical. In most arrangements provisions are made to prevent admission of more than the minimum outdoor air required for ventilation both during heating operation and when the outdoor-air temperature is too high to provide some natural cooling. Provisions should also be made to close the outdoor-air and exhaust-air dampers and open the return-air damper whenever the fan is stopped.

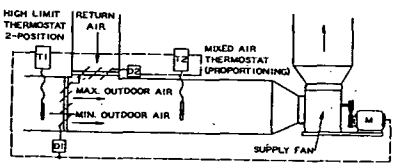

Fig. 12 .... All-Season Ventilation Control With Fixed Minimum Outdoor Air Plus Additional Outdoor Air When Practicable

Fig. 11 shows a system having manual adjustment for maximum outdoor air and having an optional, but very desirable, mixed-air controller. This controller overrides the manual switch whenever the mixed-air temperature drops below its set point. This provides for a minimum mixed-air temperature for safety of downstream equipment. Whenever the fan motor is stopped the outdoor-air and exhaust-air dampers close while the return-air damper opens.

Fig. 12 shows an all-season ventilation control system with a fixed minimum quantity of outdoor air and automatic control of maximum outdoor- and return-air dampers. This arrangement is sometimes referred to as an economizer control of outdoor air. With outdoor-air temperatures below the set point of the summer controller, the mixed-air controller positions the outdoor- and return-air dampers. When outdoor-air temperature rises to the set point of the outdoor high-limit controller, usually about 70 F, the maximum outdoor-air damper is closed and the return-air damper opened. The minimum quantity of outdoor air is assured by the separate minimum outdoor-air damper. Both outdoor-air dampers are closed and the return-air damper opened whenever the fan motor is stopped. By adding a thermostat in the conditioned space or in the return-air duct the opening of the maximum outdoor-air damper can be limited to only the desired minimum quantity of outdoor air until the space heating requirements are satisfied. This feature is desirable for quick warm-up during winter heating.

Preheater Coil Control

The function of a preheater is to temper the outdoor air to prevent the possibility of freezing beyond the coil. Care must be taken to avoid freezing in the coil itself. The proper selection, installation, and sizing of steam traps are very important to assure rapid elimination of condensate to prevent freezing. Other important considerations are vacuum breakers to insure condensate removal, provisions for rapid air elimination from coil, and the use of vertical rather than horizontal tubes wherever possible.

Fig. 13 shows a simple application of an outdoor thermostat usually set for 35 F controlling the preheat coil valve. Careful sizing of the coil is very important with this type of control. The temperature rise through the coil should be limited to a maximum of 30 deg when the entering air is 35 F. A higher temperature rise will very likely cause overheating of the space. If more than a 30-deg temperature rise is needed then multiple coils should be used and their control valves operated in sequence at selected outdoor temperatures.

Fig. 14 offers a method of control which reduces the

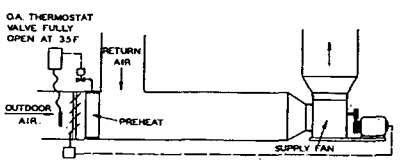

Fig. 13 .... Control of Preheat Coil From Outdoor Air

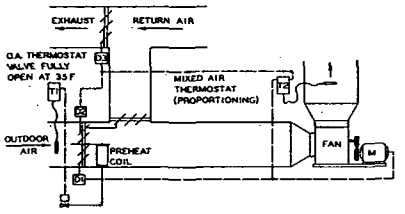

Fig. 14 .... Control of Preheat Coil From Outdoor Air With Damper Control From Mixed Air

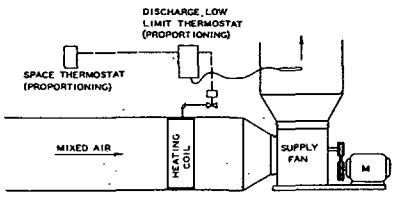

Fig. 16 .... Control of Heating Coil From Space and Discharge Air Using Valve

overheating problem outlined for Fig. 13. Here a mixed-air thermostat operates an outdoor-air bypass damper in conjunction with the exhaust- and return-air dampers. The use of bypassed outdoor air makes it possible to control the mixed-air temperature without endangering the preheat coil. A minimum quantity of outdoor air is assured by use of a two-position face damper on the coil.

Steam-distributing type coils can be controlled by a proportional-type thermostat set for 55 F or higher and located downstream from the coil to operate a valve in the steam supply line. Where a temperature rise of more than 30 deg is required, two or more coils in series should be used, each having a separate valve. This arrangement is shown in Fig. 15. The valves should be arranged to operate in sequence, with the valve on the upstream coil *opening first*.

Hot water preheat coils should be controlled by face and bypass dampers operated by a thermostat downstream from the coil, with continuous water circulation when the outdoor air is below freezing. A pressure switch to stop the fan in case of pump failure is often employed. Further freeze protection can be accomplished by a thermostat in the coil outlet arranged to stop the fan if the water temperature drops to 35 F. In all applications where face and bypass dampers are used, precautionary measures must be taken to prevent stratification of the mixture beyond the coil. One method is to locate the bypass damper above the face damper so that the cooler bypassed air will tend to drop while the warmer air through the face damper tends to rise thereby mixing the air by gravity.

Heating Coil Control

Heating coils when used for tempering air for ventilation can be controlled by a proportional type of insertion thermostat, preferably located in the fan discharge where the air is usually least stratified. This thermostat operates the heating coil valve or valves, or face and bypass dampers, to maintain a constant discharge air temperature. When face and bypass dampers are used it is good practice to have a valve on the coil which closes as the face damper closes to prevent overheating due to radiation from the coil, damper leakage, or escape of heat from the coil.

Fig. 16 shows a typical control arrangement for a heating coil when the fan system is used for heating as well as for ventilation. Here a room or a return-air thermostat controls the heating coil valve until the space temperature is satisfied. A discharge duct thermostat then assumes control of the valve to maintain the desired minimum air discharge temperature. With this system no portion of the air entering the coil should be less than 32 F.

Fig. 17 shows an arrangement using face and bypass dampers on the heating coil and two-position control of the valve. It should be noted that without a low-limit controller the air entering temperature must be the desired minimum discharge air temperature.

Fig. 18 offers a typical water coil control application. The room or the return-air duct thermostat operates the three-way mixing valve until the space temperature is satisfied. The discharge duct thermostat then takes over the valve control to maintain the desired minimum air discharge temperature.

Cooling and Dehumidification Coil Controls

Dehumidification by condensation is so closely related to sensible cooling that it is convenient to discuss them together. Three typical applications of controls are discussed.

Direct-Expansion Systems. A thermostat measuring the space temperature may be used to open and close a solenoid refrigerant valve on the coil inlet; control the starting

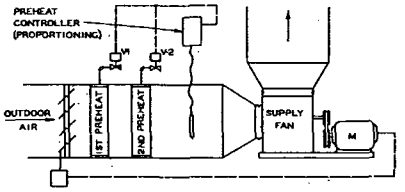

Fig. 15 .... Proportional Control of Two Preheat Coils in Sequence

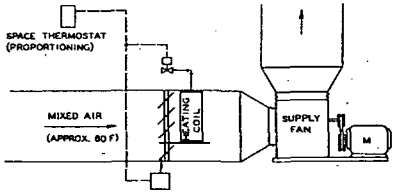

Fig. 17 .... Control of Heating Coil From Space Temperature Using Valve and Face and Bypass Dampers

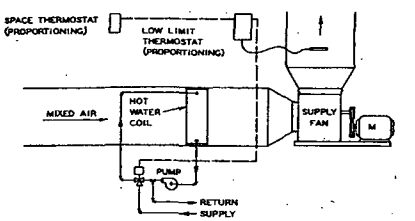

Fig. 18 .... Control of Hot Water Coil From Space and Discharge Air Using Mixing Valve.

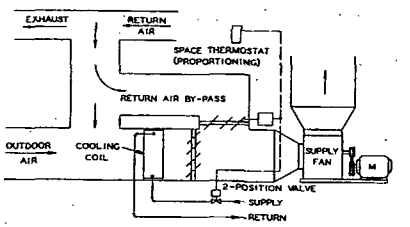

Fig. 20 .... Control of Chilled Water Coil From Space Temperature Using Return Bypass Damper and Valve

and stopping of one or more refrigerating compressors, or otherwise control the compressor capacity; position face and bypass dampers, or a return-air bypass damper, in combination with the opening and closing of the refrigerant coil valve or the starting and stopping of the compressor; or control a back pressure regulating valve with proportional action. The positive opening and closing of the refrigerant valve or the starting and stopping of the refrigeration compressor will result in wide variations in discharge temperature and dehumidification. When such variations are objectionable, it is desirable to employ proportional damper controls or proportional control of refrigerant flow in conjunction with refrigeration equipment capacity controls as discussed in Chapter 38.

Chilled-Water and Brine Coils. A thermostat measuring the space temperature may be used to control a valve on the inlet or outlet of the cooling coil; control a three-way mixing valve; position face and bypass dampers at the coil; or position a return-air bypass damper. An apparatus dew-point thermostat may also be used to control the cooling coil valve. When cooling capacity is controlled only by a dry-bulb thermostat the amount of dehumidification will vary with the sensible cooling demand. When independent dehumidification is required it is necessary to employ some form of reheat.

Fig. 19 shows a simple arrangement where chilled water is supplied to the coil at a constant temperature and the water volume through the coil is varied. The space or return-air thermostat modulates the three-way valve to *increase or decrease the volume of water through the coil.* Although this arrangement provides constant flow through the chiller, it should be noted that throttling of chilled water to the coil causes higher coil temperatures with light sensible cooling loads which may result in unsatisfactory humidity conditions.

Fig. 20 shows a control system using two-position control of a cold water coil valve and modulating control of a return-air bypass damper. Here the cooled air through the coil is mixed with bypassed return air to satisfy the space thermostat demands. When the return-air bypass damper is fully opened the water valve can be closed. It is often desirable to omit the valve control and instead maintain a constant flow of chilled water through the coil. This provides some dehumidification with light sensible cooling loads.

Air Washers. Since the air leaving an efficient washer is practically saturated, the temperature of the spray water will *determine the dew-point temperature of the air leaving* the washer. With this condition it is possible to maintain very accurate dew-point temperatures and consequently accurate relative humidities under a given ratio of sensible-to-latent heat gain in the conditioned space, provided the space dry-bulb temperature is accurately controlled. In general, the water pump operates continuously and a thermostat measuring the dew-point temperature is used to position a three-way valve to mix refrigerated water with bypassed washer water. To compensate for variations in latent load, a humidistat measuring the space relative humidity may be employed as a master controller to readjust the set point of a dew-point submaster controller.

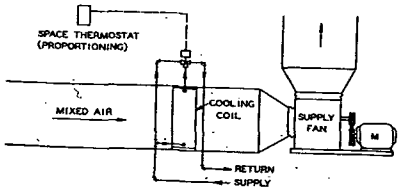

Fig. 19 .... Control of Chilled, Water Coil From Space Temperature Using Mixing Valve

Humidity Controls

Fig. 21 shows a simple method of humidity control employing a room or a return-air duct humidistat to control a valve supplying steam to an evaporator pan type humidifier. Additional control provides for closing the valve

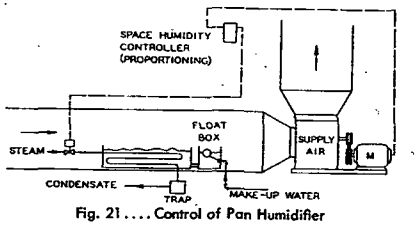

Fig. 21 .... Control of Pan Humidifier

when the fan is stopped. This prevents evaporation of water which might later condense in the ductwork and cause damage. Since untreated city water is evaporated there are none of the objectionable odors usually caused by chemically treated boiler water. Such odors often are noticeable with steam jet humidifiers.

Control of steam jet humidifiers is the same as for pan humidifiers.

Control of atomizing water spray humidifiers also is the same as for pan humidifiers except that two-position valve action must be employed. This action is necessary in order to obtain efficient atomization.

Fig. 22 shows an example of winter dew-point control of an air washer humidifier. A space or return-air humidistat readjusts the set point of the dew-point controller to compensate for latent load changes. If the latent load of the space is constant then the humidistat can be omitted in which case the dew-point controller would control at a constant set point. The dew-point controller increases the temperature first by closing the maximum outdoor-air damper and then by gradually opening the water heater valve.

Static-Pressure Control

Since fans are selected to produce the desired results for a certain system characteristic, any change in the system characteristic will change the output of the fan. Such changes occur, for example, on single-duct systems in which the volume of air delivered is varied and in double-duct systems where quantities of air are shifted from one duct to the other to obtain final space control. System characteristics may also change when the relative quantities of outdoor air and recirculated air are varied, when exhaust fans are run intermittently, and for other reasons. Such changes result in a changing static pressure in the system, a changing noise level, and changing velocities at air outlets which upset the air-flow patterns.

Static-pressure control of some form is usually required on such systems, and is accomplished by a static-pressure controller measuring the pressure at a selected point in the system with respect to an atmospheric reference point or some other point inside the building. It can be used to actuate a damper operator on fan inlet vanes, on a multiblade damper on the suction or discharge side of the fan, or on a damper in a bypass connection between the fan discharge and the fan suction.

Fig. 23 shows a simple method of static-pressure control. Here a differential-pressure controller measures the static pressure in the supply duct in relation to some reference space such as outdoors. With increase in duct static pressure due to throttling of space volume control dampers the controller throttles the static-pressure damper proportionately. For controlling system static pressure, louver dampers may be installed on either the suction or discharge side of the fan or fan inlet vanes may be employed. To control static pressures in various sections of a distribution system, louver dampers are installed in the inlets to the various sections, with separate static-pressure controllers for each section. Measuring tubes must be located within the system or section at a point where constant pressures are most desirable.

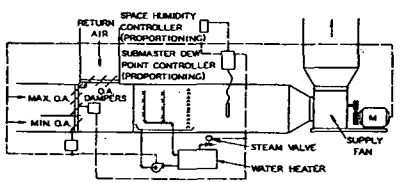

Fig. 22 .... Control of Air Washer Humidifier With Submaster Dew-Point Controller

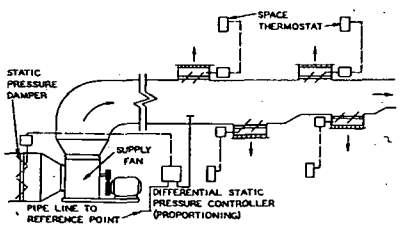

Fig. 23 .... Static-Pressure Control in Variable Volume System

Control of a Typical Central Fan System

Fig. 24 shows an example of control arrangement using some of the system components previously described and referred to in Part II of this chapter under Design Coordination. The controls can be pneumatic, electric, or electronic.

When the fan is started relay *E-1*, actuated by the fan-motor starter, opens outdoor-air damper *D-1*, places humidistat *H* in service, and allows insertion thermostat *T-1* to operate preheat coil valve *V-1*, maximum outdoor-air damper *D-2*, return-air damper *D-3*, and exhaust damper *D-4*. When the fan stops, *E-1* is de-energized thereby closing dampers *D-1*, *D-2*, and *D-4* while opening *D-3*. Humidifier valve *V-4* is closed and preheat valve *V-1* is opened.

The sequence of operation described will in general also apply to high-pressure fan systems except that it is considered desirable to open the outdoor-air damper before starting the fan. With this arrangement, a manual switch operates damper *D-1*. An auxiliary switch mounted on the damper starts the fan when the damper is *fully* open. It also stops the fan when the damper *starts* to close.

Insertion thermostat *T-1* maintains a temperature of 55 F at the preheat coil discharge by operating preheat coil valve *V-1*. This serves as a low limit for the fan discharge temperature during heating operation. When *V-1* is closed, thermostat *T-1* then gradually opens maximum outdoor-air damper *D-2* and closes return-air damper *D-3* proportionately. At 55 F outdoor temperature *D-2* is wide open and *D-3* is closed. Exhaust-air damper *D-4* opens and closes in synchronization with *D-2*. At about 70 F outdoors, when the outdoor air is no longer useful for natural cooling, *T-2* closes *D-2* and *D-4* and opens *D-3*.

Reheater coil valve *V-3* is controlled by submaster thermostat *T-3* in the fan discharge. This thermostat is automatically readjusted over an appropriate range of temperature by thermostat *T-4* so that the discharge temperature matches the space requirements. When the space temperature tends to rise above a predetermined value, *T-3* has been readjusted downward far enough to keep reheat valve *V-3* closed. *T-4* then controls cooling coil valve *V-2* directly to maintain the desired space temperature.

Humidistat *H* operates humidifier valve *V-4* to maintain the desired humidity in the conditioned space. It is usually adjusted to maintain 30 to 40 percent relative humidity, and therefore keeps the humidifier off during cooling operation when the humidity is higher.

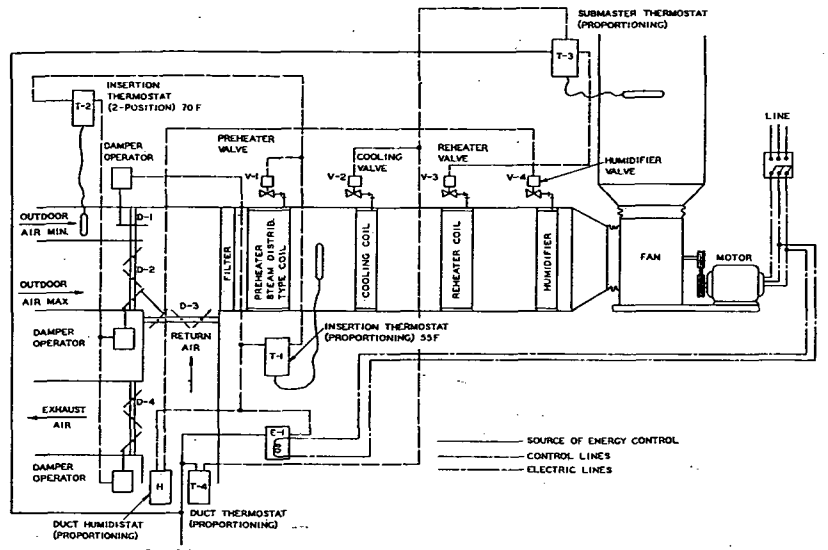

Fig. 24 .... Control Diagram for a Typical Central Fan Air-conditioning System

TEMPERATURE CONTROL IN HOT WATER SYSTEMS

Hot water heating systems permit use of relatively simple automatic temperature control for the purpose of reducing operating costs and providing comfortable temperatures. On installations not requiring different supply-water temperatures simultaneously and where the boiler is not used to heat domestic hot water, outdoor reset control of the supply-water temperature may be obtained by direct control of the burner from a thermostat that is located in the boiler water and is reset in accordance with outdoor temperatures. A seperate high limit control should be provided.

In systems using converters for a hot water supply, a controlling thermostat actuated by the leaving water temperature modulates the heat source to the converter. The set point of this supply-water thermostat can be readjusted in accordance with outdoor temperature.

In some systems a boiler or converter supplies water at a constant temperature, and three-way mixing valves are used to supply water at different temperatures for various uses or to multiple zones. In these cases, a three-way mixing valve under control of a thermostat in the valve discharge blends boiler water with return water to provide supply water at the desired temperature. The control setting of this thermostat in the valve discharge can be reset in accordance with outdoor temperatures.

On systems using outdoor-reset supply water and lowered night or week-end temperatures, provision should be made for warmup on restoration to day or normal operation. This can be accomplished by a program control, a warmup space thermostat, or some similar means of providing higher than normal water temperatures during the warmup period.

A measure of control can also be accomplished by use of a room thermostat to operate the burner. This type of control is applicable only to residences or very small commercial installations, where there is no great difference in heating requirement throughout the building. Where a difference in heating requirements throughout the building does exist, it is advisable to control the supply-water temperature with provision for automatic control or manual adjustment of heating unit output in individual spaces.

Economical zone control can be obtained by separate return or supply piping for zones, with a zone thermostat to operate zone pumps or automatic valves. The piping for each zone should be isolated to avoid a common return line, because in many cases the return water from one zone is warmer than required for the supply water to another zone.

The control of air-handling units in a hot water heating system requires careful consideration. Where the piping required is within economical limits, it is advisable to use a three-way mixing valve and a pump in the coil circuit (see Fig. 19, Chapter 28) to achieve control. This arrangement provides a constant flow to the coil while the temperature of the water to the coil is varied by changing the mixture of supply water and return water. If impracticable to use separate three-way valves and pumps for each coil, it is necessary when varying the flow to a hot water coil to use control valves with plugs or discs designed for close control of flow. They should also be sized accurately for the flow required by the coil at a pressure drop as large as the pump and the piping system will permit. Face and bypass dampers to vary the flow of air over a coil with constant water flow can be used in the control of air-handling units.

Precautions should be taken to prevent the freezing of water in a hot water heating system whenever design outdoor temperatures are lower than approximately 20 F, particularly if the system is to be operated on an intermittent basis as in schools where normal operation is not required on Saturdays or Sundays or during vacation periods. In selecting a means of freeze protection, consideration should be given to the type of system as well as outdoor temperature. For instance, an air-handling unit to heat outdoor air must have the coil protected for 32 F, whereas supply mains and radiation usually are not subjected to freezing temperatures until the outdoor temperature drops considerably below 32 F for extended periods. Intake dampers on air-handling units that heat outdoor air should be interlocked with the fan motor so as to close whenever the fan is not running. Provision should be made to close the outdoor-air intake and/or stop fan operation if the water circulating in the coil drops below a safe temperature level. The possibility of water freezing in the mains can be minimized by using an outdoor thermostat to provide continuous circulation of the water whenever the outdoor temperature drops below approximately 30 F. Another arrangement uses an interval timer and outdoor thermostat to provide intermittent cycling of the circulating pump whenever the outdoor temperature drops below some predetermined temperature. A thermostat in the return water at the boiler can be used to start the burner or other heat source if the temperature of the return water drops to about 40 F. See Chapter 43 for general information on controls.

ZONE CONTROL OF STEAM AND WATER SYSTEMS

This section is concerned with zone controls for steam or hot water heating systems. Refer to Part II of this chapter for a general discussion of zoning.

Most zone control systems are designed to supply heat to a zone at a rate equal to the heat loss. This rate of heat input may be established by room thermostats, by controllers responsive to outdoor conditions, or by a combination of both. The outdoor controller responds to temperature and may respond to solar radiation and wind velocity and direction. Features which may be added to the basic zone control system include:

1. Means for automatically or manually varying the heat input to the zone to compensate for variations in internal heat gain. The automatic arrangement requires a thermostat at a representative location within the zone. The manual arrangement usually consists of a switch located where convenient.

2. Means for maintaining a lowered economy temperature or shutting off the heat completely at night or at other times when the zone is unoccupied. This may be accomplished manually or by means of a clock.

3. An arrangement providing rapid warm-up following a period at the nonoccupancy temperature. During this warm-up period full heat may be admitted to the system or the heat input may be controlled at a higher-than-normal rate. The warm-up may be accomplished by a manual switch or may be part of the clock program. A warm-up thermostat located within the zone may be arranged to terminate the warm-up period independently of the switch or clock when the zone approaches the desired occupancy temperature.

4. A manual switch to provide full heat or no heat independently of other controls and to permit manual selection of the various clock functions.

5. Means for shutting off the heat completely when the outdoor temperature reaches a point where heat no longer is needed.

6. A high-limit thermostat in the zone to shut off the heat completely when the zone becomes overheated.

Steam: Zone Distribution

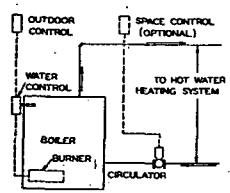
In *continuous-flow steam systems* the quantity of steam supplied to the zone is varied in accordance with the demands of the control system. To obtain equalized distribution of the steam, metering orifices are generally required on the inlets to all radiators or convectors. Supplementary controls for low heat output are often desirable. The following two arrangements are common:

1. Varying the difference in pressure between the supply and return which results in partially filling the heating units in accordance with demand. This method can be used on atmospheric or vacuum return systems.

2. Varying the pressure in the system while maintaining a constant differential pressure between the supply and return. This results in the heating units being filled with steam at a temperature which is proportional to demand. A vacuum pump maintaining a vacuum slightly below the supply pressure is required, and vacuums as high as 20 in. Hg during mild heating weather are common.

In *intermittent systems* steam at full pressure is supplied intermittently to the zone, the length of the *on* and *off* periods being varied in accordance with the demands of the control system. Two common arrangements are:

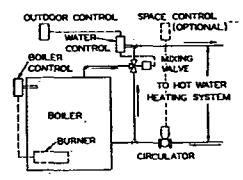
1. A timing device controlled by an outdoor thermostatic element. This can be used to vary the on-off periods of boiler operation or the opening and closing of a steam valve as a function of outdoor temperature.



2. A control responding to an outdoor element and an element attached to a radiator or convector. This control varies the length and frequency of the on-off intervals in such a way that the radiator or convector temperature is varied in accordance with outdoor temperature.

For proper operation of zone control equipment the heating system must be carefully designed and installed, and maintained in good operating condition. Vents, traps, vacuum pumps, and valves must be given a careful inspection and repaired or replaced when required. Piping must be of adequate size, graded, and dripped. Return piping must be vented and any pockets or lifts removed.

Water: Zone Distribution



A common method of obtaining zone control of hot water systems consists of varying the temperature of water supplied to the zone inversely as the outdoor temperature varies. This may be accomplished by a submaster thermostat in the zone supply line readjusted by an outdoor master thermostat, or by a single controller having one

measuring element in the supply line and another compensating element outdoors. On single-zone installations the controller may actuate the burner directly as shown in Fig. 25. If the boiler is also used for domestic hot water the controls may be arranged as in Fig. 26. In this case the boiler is controlled at a fixed temperature and the zone controller is arranged to operate a valve to proportion hot water from the boiler with cooler return water to obtain the desired zone water temperature. On multiple-zone installations the boiler usually is controlled at a fixed temperature, and each zone is controlled by a separate valve and outdoor compensated controller. Each zone should be equipped with a separate pump because in many cases the

(Limit and primary controls not shown)

Fig. 25 .... Control of Hot Water Heating Without Domestic Hot Water Service

(Limit and primary controls not shown)

Fig. 26 .... Control of Hot Water Heating With Provisions for Domestic Water Heating

return water from some zones is warmer than the required supply water for other zones. By using individual zone pumps the returns can be separated and thus prevent overheating that would otherwise occur.

To compensate for variations in internal load, the action of the zone control may be modified by a room thermostat in each zone which either starts and stops the zone pump, modifies the relationship between outdoor temperature and water temperature, or operates an automatic valve in the zone supply or return line. Each zone may be further subdivided by providing a separate thermostat and valve for each subdivision.

Another zone control method for hot water systems consists of maintaining a constant water temperature and varying the volume of water supplied to the zone by means of a room thermostat which either starts and stops the zone pump or operates a two-position valve in the zone supply or return line.

Whenever flow control valves are employed in water circuits it is necessary to employ a relief valve or pressure-regulating valve in a bypass connection around the pump.

TERMINAL EQUIPMENT

Control applications to the following types of terminal equipment are described in their respective chapters:

Radiant Panels—Warm Air Ceiling Panels, Chapter 18
—Hot Water Panels, Chapter 30
—Electric, Chapter 30 and 17
Snow Melting, Chapter 49
Unit Heaters, Chapter 15
Unit Ventilators, Chapter 15
Unit Air Coolers, Chapter 16
Induction Units, Chapter 19
Dual-Duct Mixing Units, Chapter 19
Room Fan-Coil Units, Chapter 19
Reheat Coils for Individual Spaces, Chapter 19

Classroom Heating and Cooling Units

Controls for winter heating and ventilating are essentially the same as for classroom unit ventilators as described in Chapter 15, Unit Ventilators and Unit Heaters, except that face and bypass dampers are usually added. The supply hot water temperature should be varied inversely with outdoor temperature for best results. The space thermostat operates the face and bypass dampers, coil valve, and the outdoor- and return-air dampers.

When the system water is changed from hot to chilled water the controls are reversed. For summer cooling the outdoor-air damper opens to a fixed position to admit the required percentage of outdoor air when the fan motor is started. The space thermostat is now reverse-acting and operates only the face and bypass dampers at the cooling coil while the valve remains open.

Radiators and Convectors

When individual room control is used each radiator and convector is equipped with an automatic control valve. Depending upon the size of the room one thermostat may control one or several valves in unison.

Volume Damper or Single-Duct Units

When individual room control is used each volume damper is equipped with an operator. Often several air outlets are supplied through one damper. The damper operation is usually controlled by a room-type thermostat. The volume damper is usually set to provide for minimum ventilation requirements regardless of thermostat demand. When the air-supply system is used for heating as well as cooling it is necessary to use a heating-cooling thermostat.

RESIDENTIAL HEATING AND AIR CONDITIONING

The control equipment function in the residence may vary from the regulation of a coal-fired heating plant to the completely automatic control of a year-around heating and cooling system. Regardless of the type of heating or air-conditioning system used, the control system should be selected carefully to insure safety and comfort of the occupants as well as economy of operation.

The simplest type of domestic control is one in which the room thermostat starts and stops the burner, as described in the preceding section. It may be used on gravity or forced-warm air, hot water or steam systems. In forced

warm air or forced hot water systems the fan or circulator usually is controlled by a thermostat in the furnace or boiler and runs whenever the air or water temperature is above a minimum value, as discussed in Chapter 26. If straight two-position control is used for this application, the *on* and *off* periods are relatively long and there is a tendency towards cold drafts on the floor during off periods. If timed two-position control is used, the burner may be cycled (started and stopped) often enough to provide results very comparable to proportioning control. The heat input to the home is proportioned continuously to the heat loss from the home. The fan of a forced warm air system or the circulator of a forced hot water system may be run almost continuously, thus minimizing the possibility of cold drafts.

Proportional control is used on residential applications when provisions are made for it in the design of the system. Face and bypass dampers on warm air systems, throttling valves on steam systems and three-way mixing valves on hot water systems are typical examples of controlled devices which permit proportional control. With these arrangements the burner usually is controlled by a thermostat in the furnace or boiler. Proportional control will permit nearly continuous circulation of warm air or hot water, thus reducing cold drafts.

Automatic night set-back through the use of a day-night type room thermostat is a refinement frequently added to residential control systems. Though opinions vary regarding the amount of fuel that can be saved by automatic night set-back, tests made both in the warm air heating research residence and the I = B = R research home at the University of Illinois indicate that, on thermostatically controlled systems, a possible fuel saving of from 7 to 10 percent may be obtained by reducing the house temperature 6 to 10 F from about 10:00 p.m. to 5:30 a.m.

It is often desirable to divide the house into two or more zones for greater accuracy of control and comfort. Each zone may then be maintained individually at the desired temperature level. The division into zones should be based upon exposure or occupancy; the most common division is usually found to be (1) the living section such as living room, dining room, den; (2) the sleeping section; (3) the service section such as kitchen, pantry, servants' quarters; and (4) recreational areas.

Further discussion of zone control principles has been given in Part II of this chapter.

Year-round residential air-conditioning systems which provide for heating in winter and cooling in summer should be given the same consideration in selecting the control system as required for commercial air-conditioning systems. See Chapter 19. The basic principles are the same and the final results must provide for the comfort of the occupants. A reduction in investment for automatic controls may result in wasteful operation of the system and discomfort for the occupants.

Special thermostats have been designed to take care of the year-round residential air-conditioning systems. These thermostats offer manual, semi-automatic, and automatic change-over from heating to cooling as selected by the unit manufacturer. Generally speaking, the heating unit is controlled by timed two-position action and the cooling unit by straight two-position action. Some form of humidity control may be added.

When an *add-on* unit is installed to obtain a year-round air-conditioning system by change of a straight heating system, it may be controlled separately or integrated with the heating control system. However it is accomplished, the control system should be simple enough for the user to understand how to operate it effectively.

INSTRUMENTS AND MEASUREMENTS

Temperature Measurement, Pressure Measurement, Air-Flow Measurement, Air Change Measurement, Measurement of Air Currents, Humidity Measurement, Measurement of Mean Radiant Temperature, Heat Transfer Through Building Materials, Combustion Analysis, Smoke Density Measurements, Sound and Vibration Measurements, Determination of Air Contaminants

HEATING and air-conditioning engineers and technicians require instruments for both laboratory and field use. Somewhat more precision is attainable and essential in the laboratory, where research and development are undertaken, than in the field, where acceptance and adjustment tests are conducted. The purpose of this chapter is to describe briefly some of the more important instruments, and to outline their uses and characteristics.

TEMPERATURE MEASUREMENT[1, 2]

Thermometers

Any device capable of indicating temperature is a thermometer, but in common usage the term *thermometer* without qualification has come to signify the ordinary liquid-in-glass temperature indicating device. Mercury-filled thermometers have a useful range from −40 F, the freezing point of mercury, to about 1000 F, at or near which the glass usually softens. Lower temperatures can be measured with alcohol-filled thermometers for which the range is about −94 F to +248 F. The better thermometers have their scales, either Fahrenheit or Centigrade, etched with acid into the glass which forms their stems.

Thermometers are calibrated during manufacture for at least two temperatures, frequently the freezing and boiling points of water, and the space between the calibration points is then divided into the desired scale divisions. The probable error for etched stem thermometers is plus or minus one scale division. For precise work, recalibration is frequently necessary to determine the proper corrections to be applied to the scale readings.

Liquid-in-glass thermometers are calibrated by the manufacturer for either complete or partial stem immersion. If a thermometer which has been calibrated for complete immersion is used at partial immersion, that is, with a portion of the liquid column at a temperature different from that of the bath, an *emergent stem correction* should be made. This correction may be calculated by Equation 1:

$$\text{Stem correction} = Kn\,(t_b - t_s) \qquad (1)$$

where

K = the differential expansion coefficient of the mercury or other liquid in the glass. K may be taken as 0.00016 for Centigrade mercurial thermometers and 0.00009 for Fahrenheit mercurial thermometers. For values of K for other liquids and for specific glasses, see Reference 1.

n = the number of degrees of the liquid column emergent from the bath.

t_b = the temperature of the bath.

t_s = the average temperature of the emergent liquid column of n degrees.

A thermometer can be appreciably affected by radiation from surrounding surfaces. If the temperature to be measured is approximately the same as that of the surrounding surfaces, radiation effects may usually be ignored. If the temperature being measured differs considerably from that of the surroundings, steps should be taken to minimize the effect of radiation.[3] This is usually accomplished either by shielding or by aspiration. Shielding is accomplished by placing highly reflective surfaces between the thermometer bulb and the surrounding surfaces. However, this must be done in such a way that air movement around the bulb is not appreciably restricted.[4] Improper shielding may increase rather than decrease errors. Aspiration is accomplished by drawing a high-velocity stream of air or gas over the bulb of the thermometer.

Industrial-type thermometers are available for permanent installation in pipes or ducts. These instruments are fitted with metal guards to prevent breakage, and are useful for many purposes. However, the considerable heat capacity and conductance of the guards or shields may introduce errors.

To prevent errors in temperature measurements, ample time should be allowed for the thermometer to attain temperature equilibrium with the surrounding fluid. In reading a thermometer, the eye should be at the same level as the top of the liquid column to avoid parallax.

Thermocouples

When two wires made of dissimilar metals are joined by soldering, welding, or merely by twisting, a thermocouple or thermo-junction is formed. An electromotive force, which depends upon the temperature of the junction, is found to exist between the wires. When the wires are joined at two points a thermocouple circuit is formed. If one junction is kept at a temperature different from the other, an electric current flows through the circuit due to the difference in emf developed by the two junctions. This phenomenon is employed for temperature measurements in thermocouple systems, one junction being ordinarily kept at a constant temperature, as in an ice bath, while the other junction is placed at a point at which it is desired to observe the temperature. In practice it is desirable to utilize emf to indicate temperature because, at small or zero current flow, the resistance of the circuit is unimportant. A high resistance millivolt meter is useful in some cases but the potentiometer yields better results. In the potentiometer the electromotive force generated by the thermo-

couples is balanced against an electromotive force from the battery so that observations are made with no flow of current through the thermocouple circuit. A conventional arrangement is illustrated in Fig. 1. The thermocouple leads *A-B* are so connected that their polarity opposes that of battery *C*. *If the position of E on the graduated slide wire rheostat DF* is adjusted until galvanometer *G* shows no current flowing, resistance *DE* will indicate directly the voltage generated by the thermocouple. In order to calibrate the instrument, switch *S* is thrown over to the standard cell circuit while rheostat *R* is adjusted so that the galvanometer shows zero current. Battery *C* then exerts the known voltage of the standard cell at *DH*.

The act of adjusting rheostat *D-F* (Fig. 1) for zero current flow is known as balancing the potentiometer. Automatic self-

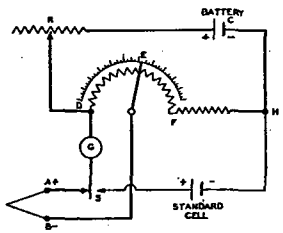

Fig. 1.... Basic Circuit and Connections for Thermocouple and Potentiometer

balancing instruments of both the indicating and recording types are on the market. They usually contain an automatically compensating cold junction to avoid the use of an ice bath, and special thermocouple wire is furnished with them from the factory.

The choice of materials for thermocouple wire is determined by the temperature to be measured, the protection from corrosion afforded the couple, and the precision and service life required. In general, copper vs. constantan is suitable for temperatures up to 700 F, iron vs. constantan up to 1500 F, and chromel vs. alumel up to 2200 F. Higher temperatures require the use of noble metal thermocouples (platinum vs. platinum-rhodium). In addition to the higher initial cost of a noble metal couple, it does not develop as high an emf as the base metal couples do. Impurities make large differences in the performance of thermocouple wires and for this reason calibration of samples from each spool of wire is essential for precise work. Data on wire can usually be obtained from the manufacturer.

With a suitable potentiometer, small wires serve as well for thermocouples as large ones, and the fineness of the wires is limited only by consideration of mechanical strength and convenience in handling. Small couples respond more promptly to changes in temperature and are less affected by radiation than large ones. Heavy gage couples, however, are necessary for high temperature work where corrosion of the wire is a problem. For use in heated air or gases, thermocouples are often shielded,[8] as are thermometers, and aspirated thermocouples are sometimes used. An arrangement has been described for avoiding error due to radiation. It involves the use of several thermocouples of different wire sizes, the true temperature being estimated by extrapolation of readings to zero diameter.[8]

By the use of thermocouples, temperatures at remote points may be indicated or recorded on conveniently located instruments, and temperatures may be obtained within thin materials, narrow spaces, or otherwise inaccessible locations.

Thermocouples in series, with every alternate junction maintained at a common temperature, will produce an emf which, when divided by the number of couples, gives the average emf corresponding to the true average temperature. This series arrangement of thermocouples, often called a thermopile, can have extreme sensitivity and is useful in detecting very small changes in temperature.

Thermocouples in parallel, having the similar metals of a number of couples connected together and run to a common cold junction, will cause an indication on a potentiometer which is the true average emf only if the electrical resistances of the parallel circuits are the same.[8, 9]

The thermocouple is particularly useful in determining a surface temperature. It may be attached to a metal surface in any of several ways. For permanent installations, soldering, brazing, or peening may be desirable. A small hole is drilled for the peening operation; the thermocouple is inserted and the metal is peened to retain it. The fact that the thermocouple is in electric contact with the surface is unimportant in usual circuits. For temporary arrangements, couples may be attached by means of surgical or cellophane tape. For boiler or furnace surfaces, furnace cement serves very well. To minimize the possibility of error due to heat conduction along the wires, a surface thermocouple should be made of fine wires, and the wires should be held in close contact with the surface for an inch or so from the junction. Electrical insulation between the wires must be perfect except at the junction.

Resistance Thermometers

Resistance thermometers depend for their operation upon the change of electric resistance of metal with change in temperature. The resistance generally increases with rising temperature. Their use largely parallels that of thermocouples, although readings tend to be unstable above 950 F. Two-lead temperature elements are not recommended, since they do not permit correction for lead resistance. Three leads to each resistor are necessary to obtain consistent readings.

A typical circuit used by several manufacturers is shown in Fig. 2. In this design a differential galvanometer is used, in

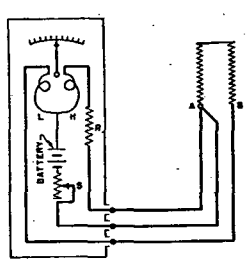

Fig. 2.... Typical Resistance Thermometer Circuit and Connections

which coils *L* and *H* exert opposing forces on the indicating needle. Coil *L* is in series with the thermometer resistance *AB*, and coil *H* is in series with the constant resistance *R*. As the temperature falls, the resistance of *AB* decreases allowing more current to flow through coil *L* than through coil *H*. This causes an increase in the force exerted by coil *L*, pulling the needle down to a lower reading. Likewise, as the temperature rises the resistance of *AB* increases, causing less current to flow through coil *L* than through coil *H*. This forces the indicating needle to a higher reading. Rheostat *S* must be adjusted occasionally to maintain a constant flow of current.

As compared to the thermocouple, the resistance thermometer does not require a cold junction, and it can be simply scaled for more accurate measurements; but, generally because of its construction it is more costly and is apt to have considerable lag. It gives best results when used to measure steady or slowly changing temperature. For accurate results the entire thermometer coil must be exposed to the temperature to be measured.

Pyrometers

The pyrometer is the usual instrument for measuring high temperatures such as those of incandescent bodies or furnace interiors. There are two types. In the radiation pyrometer the radiant energy from an observed surface falls on a thermopile, and the emf generated by the pile, measured by a galvanometer or potentiometer, is an index of the surface temperature. With the optical pyrometer a narrow spectral band, usually red, emitted by the surface, is matched visually with the filament of a special electric lamp. The emf necessary to cause the filament to match the surface in brightness is the index of the temperature of the surface. Pyrometers are calibrated by means of various metals with known melting or freezing points. Portable as well as laboratory models are manufactured.

Color Indicating Crayons

Crayons are available, the marks of which change color or melt at specified temperatures. Such crayons have been sold in boxes covering the range from about 100 F to about 800 F in 100 deg steps, with a precision of some 10 deg. They are a rough but convenient means of determining temperatures, and of locating isothermal lines on surfaces below red heat.

PRESSURE MEASUREMENT

Pressure Gages

The Bourdon is the most common type of pressure gage, and its appearance probably is familiar to anyone having an acquaintance with power plants or laboratories. The essential element of such a gage is the Bourdon tube, a metal tube of oval cross-section curved along its length to *form an almost complete circle. One end is closed* and the other is connected to the vessel in which the pressure is to be measured. With an increase of pressure, the tube tends to straighten, and vice versa. The resulting motion of the closed end is communicated by suitable linkages to a needle moving over a graduated dial. If the range is above about 20 psi, such gages are usually calibrated by means of a *dead weight tester*, whereby known pressures are produced in a fluid by imposing known weights on a *piston of known area. Suction gages and pressure gages* with ranges below about 20 psi are ordinarily calibrated against mercury manometers. Gages are commonly set to read accurately at or near the pressure of probable use. Gages of several different types or qualities are available on the market.[8]

Manometers

The manometer is a simple and useful means for measuring partial vacuum and low pressure. It is, moreover, a primary instrument; it does not require calibration, and it is often used as a standard for the calibration of other instruments. It is so universally used that both the inch of water and the inch of mercury have become accepted units of pressure measurement. In its simplest form, the manometer consists of a U-shaped glass tube partially filled with a liquid. A difference in height of the two fluid columns denotes a difference in pressure in the two legs, which is proportional to the difference in height.

For converting manometer readings into other pressure units, certain proposed standard factors are applicable for precise work. These are based on a standard gravitational acceleration of 32.1740 ft per (sec) (sec) and are as follows:

1 Standard Atmosphere = 14.696 lb per sq in. = 29.921 in. mercury at 32 F = 33.96 ft water column at 68 F

For most ordinary purposes, the following figures are of ample accuracy:

1 Atmosphere = 14.7 lb per sq in. = 29.9 in. mercury = 34.0 ft (408 in.) water column

Manometer tubes should be chemically clean. The bore is not important, except insofar as it affects the meniscus through wetting or surface tension. Bores of at least 3/16 in. for rough, and ½ in. for more precise, measurements are recommended. Liquids other than water are sometimes used for low-pressure measurement and, when this is done, the readings must be corrected for the density of the fluid.

For measuring pressure differences of a few inches of water, or less, U-gages are often set at an angle for scale amplification. In many gages of this type, commonly termed draft gages or inclined manometers, only one tube of small bore is used and the other leg is replaced by a reservoir. The scale is calibrated to read in inches of water, and it is necessary to use a fluid having the same gravity as that for which the gage was originally calibrated, or to apply a correction if another fluid is used. Such gages may be checked one against another. For more accurate calibration the gage may be checked against a micromanometer or a calibrating device known as a hook gage.[10] The accuracy of a draft gage is dependent on the slope of a tube, and consequently the base of the gage must be leveled carefully. It is not desirable to use a slope of less than 1 in 10. Where pressures are read under extreme conditions of temperature, and calibration is possible only at normal temperature, it is necessary to correct for the change in density of the liquid in the manometer.[11] For measuring low-pressure differences to within 0.001 in. of water, very sensitive micromanometers are available, such as the Illinois or Wahlen,[12] *and the Emswiler.*[13] *Various instrument manufacturers* are also prepared to furnish accurate micromanometers.

Barometer

The simplest and earliest type of barometer consists of a glass tube somewhat more than 30 in. long filled with

mercury, and inverted in a cup partially filled with mercury. The height of the mercury column in the tube above the mercury surface in the cup is a measure of the existing atmospheric pressure, except for the slight pressure of the mercury vapor in the space above the mercury in the tube. This can ordinarily be ignored.

Elaborate mercury barometers, fitted with vernier scales, are available. For precise work, corrections must be made for the thermal expansion of the mercury and of the scales.[14] The instruments are usually calibrated for 32 F mercury and 62 F scale temperature, and the correction C to be subtracted from the observed barometer's height is obtained by means of Equation 2.

$$C = \frac{h(t - 28.630)}{(1.1123t - 10978)} \qquad (2)$$

where

C = correction to be subtracted, inches of mercury.
h = observed height, inches of mercury.
t = observed temperature of the barometer, Fahrenheit degrees.

Standard atmospheric pressure at sea level is 29.921 in. Hg, and since normal atmospheric pressure decreases about 0.01 in. Hg for each 10 ft increase in elevation, it is important to make a correction if the elevation of the barometer is not that of the test apparatus. In many cases the barometric reading may be obtained from a nearby Weather Bureau Station, in which case inquiry should be made as to whether the value is for *station* or *sea level* pressure.

Atmospheric pressure may also be measured by an *aneroid barometer* which is easily portable. In this type, variations in atmospheric pressure deflect the thin surface of a sealed diaphragm capsule. Most commercially available aneroid barometers are not as accurate as the mercurial type, and the best require occasional recalibration. Open-scale aneroid barometers are more expensive than common mercurial barometers.

Most of the pressure gages used in engineering work indicate gage pressures, that is, the difference between the pressure being measured and the atmospheric pressure. Such pressures are called gage pressures. Absolute pressure may be obtained by adding barometric pressure and gage pressure algebraically.

AIR-FLOW MEASUREMENT

The theory of various means for measuring the flow of fluids is discussed in Chapter 4 Fluid Flow. Heating and air-conditioning engineers are called upon to measure the flow of air more often than that of other gases, and usually the air is measured at or near atmospheric pressure. Under this condition, the air can be treated substantially as an incompressible fluid which implies that simplified formulas can be used with sufficient accuracy for the solution of many problems.[15]

The Pitot Tube

The Pitot tube, used in conjunction with a suitable manometer, provides a simple method of determining the air velocity in a duct. The construction of a Standard Pitot Tube,[11] and the method of connecting it to a draft gage is shown in Fig. 3. The equation for determining the air velocity from the measured velocity pressure is as follows:

$$V = 1096.5 \sqrt{\frac{h_w}{\rho}} \qquad (3)$$

where

V = velocity, feet per minute.
h_w = velocity pressure (Pitot tube manometer reading), inches of water.
ρ = density of air, pounds per cubic foot.

Since the velocity in a duct is seldom uniform across any section, and since a Pitot tube reading indicates a velocity at only one location, a *traverse* is usually made to determine the average velocity so that the flow can be computed. In general, the velocity is lowest near the edges

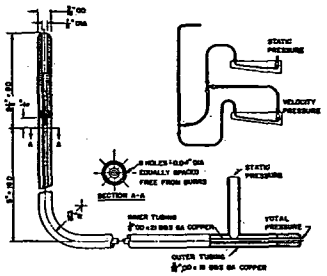

Fig. 3 .... Standard Pitot Tube

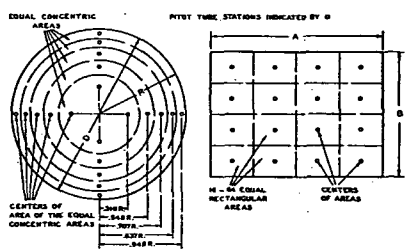

Fig. 4 .... Pitot Tube Traverse for Round and Rectangular Ducts

or corners, and greatest at or near the center. Suggested Pitot tube locations for traversing round and rectangular ducts are shown in Fig. 4. In round ducts not less than 20 readings should be taken along two diameters at centers of equal areas as shown. In rectangular ducts the readings should be taken in the center of equal areas over the cross-section of the duct. The number of spaces should not be less than 16, and need not be more than 64. When less than 64 are taken, the number of equal spaces should be such

that the centers of the areas are not more than 6 in. apart. In determining the average velocity in the duct from the readings given, the calculated individual velocities or the square roots of the velocity heads must be averaged. It is incorrect to use the average velocity head for this purpose.

Pulsating or disturbed flow will give erroneous results and therefore, if possible, the Pitot tube should be located at least 7½ diameters downstream from a disturbance such as that caused by a turn. Straightening vanes[11] located 1½ duct diameters ahead of the Pitot tube will serve to improve the precision of the measurements.

The type of manometer to be used with a Pitot tube depends upon the magnitude of the velocity pressure being measured and the accuracy desired. At velocities greater than 1500 feet per minute, a draft gage of appropriate range is usually satisfactory. If the Pitot tube is being used to measure low air velocities, a precision manometer of some type is essential.

Many forms of Pitot tubes, other than the one described, have been used and calibrated.[16] A double-ended tube,[17] one end pointing downstream, and one upstream, is sometimes used for low velocities, but it should be carefully calibrated for accurate results. A special form of this tube design consists of two straight ⅛-in. tubes soldered together, closed at the end, and with a 0.04 in. hole in each tube opposite the line of contact. This tube is useful in exploring velocities in exhaust inlets, such as hoods placed around grinding wheels. To meet special conditions, different sized Pitot tubes which are geometrically similar to the standard tube can be used.

Orifices and Nozzles

Application of the Pitot tube is often inconvenient when velocities are low, because the resultant velocity pressures become so small that extraordinary means are necessary for measuring them. In addition, velocity surveys of the whole cross-sectional area of a duct are inexpedient when numerous test runs are in prospect. Chiefly for these reasons orifices are used in many test and research applications.

Plate or square-edge orifices[18, 19] are simple to construct and convenient to use. They may be mounted between flanges, and a set of orifices of different sizes may be made readily interchangeable to measure a wide range of air-flow rates. The proportions of standard orifices and nozzles are given in Chapter 4.

Several standard arrangements of pressure taps for use with orifices are described in Chapter 4. Where velocities are low or where flow is free of large eddies and parallel to the walls of the duct, a drilled hole cleared of burrs and at a right angle to the stream is satisfactory.[20] For higher velocities it is common practice to provide four or more holes around the periphery of the duct and connect them into a manifold.

To determine air flow by means of an orifice or nozzle, the pressure drop across the device is measured. The flow rate may then be calculated by means of the equation,

$$Q = 1096.5\, K A_2 \sqrt{\frac{h}{\rho}} \qquad (4)$$

where

Q = air flow, cubic feet per minute.
A_2 = area of the orifice or nozzle, square feet.
h = pressure drop across orifice or nozzle, inches of water.
ρ = density of air, pounds per cubic foot.
K = orifice or nozzle coefficient.

The discharge coefficient K for an orifice is approximately 0.60, and for a nozzle is approximately 0.95. Correct values of K for various diameter ratios, pressure tap locations, and Reynolds numbers are given in Chapter 4. In some instances nozzles are used in multiple so that the capacity of the testing equipment can be changed by shutting off the flow through one or more nozzles. An apparatus designed for testing the air flow and capacity of air-conditioning equipment is described by Wile[21] in an article in which pertinent information on nozzle discharge coefficients, Reynolds numbers, and the resistance of perforated plates is also presented. Such apparatus in some laboratories is commonly referred to as a *code tester*.

The Venturi meter is like the nozzle, except for the addition of a downstream transition section that reduces the pressure drop through the measuring apparatus.

In some cases air flow through a heater coil or heating unit may be estimated by computation from the heat given up by the coil, and the temperature rise (measured by thermocouples) of the air passing through. It is essential to have a uniform flow over the entire inlet and outlet of the heater at the planes of temperature measurement, and temperatures must be taken at enough points to provide a good average.

Propeller or Revolving Vane Anemometer

The propeller or revolving vane anemometer consists of a light revolving wind-driven wheel connected through a gear train to a set of recording dials that read the linear feet of air passing in a measured length of time. It is made in various sizes, 3 in., 4 in., and 6 in. being most common. Each instrument requires individual calibration. At low velocities the friction drag of the mechanism is considerable. In order to compensate for this, a gear train that overspeeds is commonly used. For this reason the correction is often additive at the lower range and subtractive at the upper range, with the least correction in the middle range of velocities. Most of these are not sensitive enough for use below 200 fpm.

Deflecting Vane Anemometer

The deflecting vane anemometer consists of a pivoted vane enclosed in a case. Air exerts a pressure on the vane as it passes through the instrument from an upstream to a downstream opening. The movement of the vane is resisted by a hair spring and a damping magnet. The instrument gives instantaneous readings of directional velocities on an indicating scale. With fluctuating velocities, it is necessary to average visually the swings of the needle to obtain average velocities. This instrument is very useful for studying motion of the air in a room,[22] and in locating objectionable drafts. Various attachments are available, such as the double tube arrangement for determining velocities in ducts, and a device for measuring static pressures. Each instrument, and the attachments for it, must receive individual calibration. For determining average velocity in a duct, it is necessary to *traverse* the duct as is done when using the Pitot tube.

Thermal Anemometers

If a suitable sensing element is heated electrically at a fixed rate and exposed to an air stream, the temperature

difference between the element and the stream becomes a measure of velocity by calibration. In the *hot-wire anemometer*, a very fine heated wire is employed as a resistance-thermometer element whose temperature may be determined accurately.[23, 24, 25] In the *heated-bulb thermometer* type, a heating wire is wound around the bulb of a mercury-in-glass thermometer, and the temperature difference between this thermometer and a similar unheated one serves as an index of air speed.[26] The *heated-thermocouple anemometer* is calibrated to give velocity in terms of the differential *emf* between heated and unheated thermo-junctions exposed to an air stream.[25, 27] Combined measurements of air temperature and velocity are particularly useful for air distribution studies, and automatic recording potentiometers or resistance-thermometer devices facilitate spatial traverses. A correct calibration of thermal anemometers requires consideration of the effects of temperature, humidity, and pressure upon the air properties which influence convective heat transfer.[27] With sensing elements of simple shapes for which convection data are known, thermal anemometers may be designed, both thermally and electrically, for desired characteristics. Directional sensitivity is controllable. Thermal anemometers are convenient and practical for low velocities.

Cup Anemometer

The cup-type anemometer is almost universally used for measuring wind speeds. It consists of three or four hemispherical cups mounted radially from a vertical shaft. Wind from any point of the compass will cause the cups and shaft to rotate. The instrument is usually so constructed that wind speeds may be recorded or indicated electrically at some remote point.

Measurement of Velocities at Inlets and Outlets of Ducts

In the field it is often desirable to make volume measurements at the face of the supply openings. For accuracy, the instrument and its application should be checked on a similar approach and grille in the laboratory before use in the field.

Tests have shown that the propeller-type anemometer can be used successfully on most of the common types of supply grilles.[28, 29] The core area is divided into equal squares, and the anemometer is held against the face of the grille for the same length of time in each. To obtain the air volume in cubic feet per minute, the average corrected velocity in feet per minute thus obtained is multiplied by the average of the gross and net free area of the grille (core) in square feet.

On exhaust openings, the anemometer traverse is made as described previously. The air volume may be determined by multiplying the corrected velocity in feet per minute by the gross core area of the grille in square feet, and by a coefficient for average conditions of 0.85.[29]

When a propeller-type anemometer is held in a stream of varying velocities, it tends to indicate higher than the true average, that is, the speed of the propeller is nearer to the top velocity in its area than it is to the minimum velocity. This is the main reason for the large difference in ratings of unit ventilators by the anemometer method, and by air volume measurements in a duct approach to the inlet.[21]

Deflecting vane anemometers can be also used within their range at the face of supply grilles when properly applied. In principle, it is a case of finding the velocity at many points, and using the average thus found with the correct discharge area at that cross-section. The deflecting vane anemometer equipped with a jet on the end of a rubber tube has been found especially convenient and accurate on supply grilles.[21] On modern air conditioning grilles, the core area is used without a correction coefficient when the jet is held one inch away from the face of the grille. At this distance, the constriction due to the thin bars has disappeared, since the small air jets have reunited and the air stream has not yet spread beyond the core dimensions. With deflecting grilles the exploring jet should be turned to the angle giving a maximum reading. With suitable traversing tips and calibration, this instrument may also be used on exhaust grilles if proper grille factors are applied.[29] Those contemplating such measurements should consult the references cited.

MEASUREMENT OF AIR CURRENTS

The measurement of air current velocities within an enclosed space is usually a tedious undertaking. However, useful data can be obtained with any of several instruments now available, if they are maintained in calibration, and the user understands their operation and limitations.[30] Thermal-type anemometers, when calibrated for low air velocities, are well suited for this service.

The Kata Thermometer

Another instrument useful for studying air currents in free spaces is the Kata thermometer. This is essentially an alcohol thermometer with a very large bulb, and with only two scale divisions etched on its stem. On the *Low Kata* these divisions are 95 and 100 F; on the *High Kata* they are 125 and 130 F. In use, the instrument is heated, usually in a water bath, until the alcohol has risen sufficiently above the upper calibration on the stem. It is then thoroughly dried, and placed at the point at which the air velocity is to be measured. The time in seconds required for the temperature to drop from the upper to the lower scale division is observed. From this cooling time and the calibration factor inscribed on each Kata thermometer, the air velocity can be calculated or determined from a chart. The Kata thermometer is also used in determining the cooling power of the atmosphere, since it loses heat by radiation and convection when dry, and by radiation, convection, and evaporation when the bulb is equipped with a wetted cloth covering.[31] To minimize the effect of radiation, the Kata thermometer is also made with a silvered bulb.

Smoke is a qualitative tool which is very useful in studying air movements. Satisfactory smoke can be obtained from titanium tetrachloride (which, however, is very irritating to nasal membranes) or by mixing potassium chlorate and powdered sugar (a nonirritating smoke) and firing the mixture with a match. This latter process evolves considerable heat, and it should be confined in a pan away from flammable materials. The titanium tetrachloride smoke lends itself to spot determinations, particularly for leakage through casings and ducts, as it can be easily handled in a small pistol-like ejector. The fumes of aqua ammonia and of sulfuric acid, if permitted to mix, form a white precipitate which is useful for some purposes. Two bottles, one containing ammonia water and the other acid, are connected to a common nozzle by means of rubber tubing. Air is forced over the surfaces of the liquids in the bottles by means of a syringe, and the two streams, upon mixing at the nozzle, form a white cloud.

A satisfactory test smoke may also be made by bubbling an air stream through ammonium hydroxide and then through muriatic acid.[32] Smoke tubes, smoke candles, and smoke bombs are available for studying airflow patterns.

Infiltration or Air Change Measurement

The total air leakage into an existing building caused by wind and temperature difference forces can be determined with considerable accuracy by determining the decrease in concentration of a tracer gas. Hydrogen and helium have both been used rather successfully as tracer gases in conjunction with a sensitive thermal conductivity comparator.[33, 34] About one percent of tracer gas by volume is introduced into the room or building, and the tracer gas is thoroughly mixed with the air. The decrease in concentration of the tracer gas is observed at regular time intervals with a thermal conductivity meter as infiltration dilutes the mixture. The following formula is used to calculate the infiltration from the observed concentration measurements:

$$C = C_o e^{-\frac{kt}{v}} \tag{5}$$

where

C_o = initial tracer gas concentration, percent.
C = concentration of tracer gas after t minutes, percent.
v = volume of room or building, cubic feet.
k = infiltration rate, cubic feet per minute.
e = 2.718.

Closets and cupboards should be left open during such infiltration tests so the entire space will have the same rate of change of tracer-gas concentration.

HUMIDITY MEASUREMENT

Psychrometers

Any instrument capable of measuring the humidity or hygrometric state of the air is a hygrometer. A psychrometer is a particular kind of hygrometer which consists of two mercury thermometers, one of which has a cloth wick or *sock* applied to its bulb. For use, the wick is wetted with distilled water and ventilated with air moving at a recommended rate of 900 fpm or more, relative to the instrument.[35] In the simpler and more common type, known as the sling psychrometer, the two thermometers are mounted side by side on a frame fitted with a handle by which the device can be whirled through the air. The motion is arrested for reading the thermometers, and continued until the thermometer readings become steady. Due to evaporation, the wet-bulb thermometer will indicate a lower temperature than the dry-bulb thermometer, and the difference is known as the wet-bulb depression. Charts and tables are available showing the relation between the thermometer readings and the humidity.[35, 36, 41] Data are usually based on a total pressure of one standard atmosphere. For precise work, a correction is necessary for barometric pressure and is usually made by multiplying the observed relative humidity by the ratio of the observed to the standard atmospheric pressure.

For air temperatures below 32 F, the water on the wick may either freeze or supercool, and its state must be known and a proper table or chart used, since the wet-bulb temperature is different for ice and for water. Some operators remove the wick from the wet-bulb for freezing conditions and dip the bulb in water a few times, allowing the water to freeze on the bulb between dips and to form a film of ice. Since wet-bulb depression is slight at low temperatures, precise temperature readings are essential.

In the ventilated or aspirated psychrometer, the thermometers remain stationary, and a small fan or blower or a syringe is used to move the air across the thermometer bulbs. Various designs have been employed in the laboratories, and several commercial models are available.

The Dew-Point Hygrometer

In the usual form of these instruments, means are provided for cooling, and observing the temperature of, a surface which is exposed to air. The temperature at which visible condensation occurs on the surface is considered the dew point of the air. With the dew-point temperature known, the relative humidity and other properties of the air can be determined from tables and charts (See Chapter 3). A bright surface or metallic mirror is usually employed to improve the visibility of the dew deposit, and various means are used to cool the mirror from the back, including evaporation of ether or another refrigerant, or a stream of air passed through dry ice. Dew-point temperatures, in some cases, are observed by means of thermometers in fluids in contact with the back of the mirror, but in modern instruments thermocouples are used, and are soldered or welded to the mirror itself. The dew-point apparatus is not so commonly used as the psychrometer, probably because it is less convenient. It is usable, however, for higher temperatures than the wet- and dry-bulb psychrometer, and should be considered for dew points near or above the boiling point, as in the case of flue gases. Special apparatus for high precision has been constructed, in which the photronic cell and a light source are used for dew or frost detection instead of visual inspection.

Organic Hygrometers

Many organic materials change in dimensions with changes in humidity and this action has been utilized in a number of simple and effective humidity indicators, recorders, and controllers. See also Chapter 43 Automatic Control. Motion caused by the changes in dimension, through a suitable linkage, causes a pointer to move across an indicating dial, moving a pen across a recording chart, or actuating a pneumatic or electric control mechanism.

Common organic materials employed are human hair, animal membrane, animal horn, wood, and paper. Unfortunately, although the field has been well explored, no organic material has been found which can be relied upon to consistently reproduce its action over an extended period of time. Such devices require initial calibration and frequent recalibration or setting, especially if they are exposed to extremes of either high or low humidity. In spite of this they are highly useful because they read directly in terms of humidity, they are simple and inexpensive by comparison with most other types, and the inconvenience of recalibration is often less than that of providing distilled water and servicing the wicks of wet- and dry-bulb psychrometers.

Electrolytic Hygrometers

The dampness, and therefore the electrical resistance of a salt film, varies with the humidity of the atmosphere to

which the film is exposed, and at least two types of instruments based on this fact have been developed. The Dunmore hygrometer was originally designed for use in radiosondes or small balloons, and means were devised whereby the device transmits humidity data back to earth in the form of a radio signal. In the more usual form, this hygrometer consists of a dual winding of small wire on a nonconducting tube. The whole is coated with an electrolytic film, usually containing a salt such as lithium chloride, which forms an electric connection between the windings. Means are provided for determining the electrical resistance of the film, which is an indication of the humidity. In the radio-sonde, variations in the resistance of the film affect the frequency of an oscillating circuit. These hygrometers are usually calibrated by comparison with a wet- and dry-bulb psychrometer. For calibration for some purposes, particularly for use at subzero temperatures, means have been provided for producing atmospheres of known humidity.[42] Advantages of instruments of this type for some scientific and industrial purposes are becoming apparent, and some forms of them are on the market.

The Weaver-type hygrometer is particularly useful for determining the humidity of air or other gas in pipes or closed vessels at various pressures and temperatures. It consists of a threaded plug carrying a central electrode insulated from the plug, except for a gelatinous electrolytic film. The film is exposed to the air or gas from the pipe or vessel, and provision is made for determining its electrical resistance. The hygrometer, or detector, is mounted in a manifold equipped with valves whereby the film can be alternately exposed to the test gas, and to a standard gas having a known absolute humidity. The pressure of the standard gas is varied until contact with it establishes the same resistance in the film as the test gas, and the humidity of the test gas is then determined by computation based on the gas laws.

Chemical Hygrometry

The humidity of an atmosphere can be measured directly by extracting and weighing the water vapor from a known sample. For precise laboratory work, powerful desiccants such as a sulfuric acid and phosphorus pentoxide are used for the extraction process, while for some purposes, calcium chloride, lithium chloride, or silica gel are satisfactory. Freezing the water vapor out of a measured stream of air or gas with solid carbon dioxide, and weighing the resulting ice, is a similar operation. A thermal conductivity method for gas analysis can be used for temperatures above 212 F, or for very low humidities.[43]

MEASUREMENT OF MEAN RADIANT TEMPERATURE

Because if its effect on human comfort, it is sometimes desirable to measure the radiation exchange between a person and his surroundings. The radiant environment of a space is usually expressed in terms of its mean radiant temperature (MRT), which is defined in Chapter 1.

The Vernon globe thermometer[44, 45] is commonly used to measure mean radiant temperature. This instrument consists of a 6-in. diameter hollow copper sphere coated with flat black paint and having a thermocouple or thermometer bulb at its center. The temperature assumed by the globe at equilibrium is the result of a balance between the heat gained or lost by radiation and the loss or gain by convection. In terms of heat-transfer relationships:

$$T_r^4 = T_g^4 + 0.103 \times 10^9 \sqrt{V}\,(t_g - t_a) \qquad (8)$$

where

T_r = mean radiant temperature, Fahrenheit absolute (black-body equivalent).
T_g = globe temperature, Fahrenheit absolute.
V = air velocity, feet per minute.
t_g, t_a = globe ambient air temperature, Fahrenheit.

It will be noted from the above equation that the air temperature and the air velocity around the globe must also be determined. It is the velocity measurement which presents the greatest problem in the use of the globe thermometer.

A *two-sphere radiometer*[46] has recently been developed which may be used for the measurement of MRT. This instrument utilizes two spheres approximately 2 in. in diameter, one of which is gold-plated, and the other black. The two spheres are heated electrically to the same temperature, thus eliminating differences in convection. The difference in energy required by the two spheres to maintain temperature equilibrium is measured, and from this difference, the MRT of the space may be calculated.

Several instruments have been developed to evaluate the combined effect of radiation and convection on human comfort. Among these are the eupatheoscope[47] and the thermal integrator.[48, 49]

HEAT TRANSFER THROUGH BUILDING MATERIALS

Thermal Conductivity

The thermal conductivity (k value) of an insulation, as defined in Chapter 9, is a unit heat-transfer factor. Practically universally accepted for the conductivity determination of flat insulation is the guarded hot plate, which is described in ASTM test method C-177.[50] In its simplest form it consists of an electrically heated plate and two water-cooled plates. Two identical specimens or slabs of a material are required for a test, and one is mounted on each side of the hot plate. A cold plate is then pressed against the outside of each specimen by a clamp screw. The heated plate is divided into two portions: the central or measuring section, and the outer or guard section. During tests the two sections are maintained as nearly as possible at the same temperature. The purpose of the guard section is to minimize errors due to edge effects. The electric energy required to heat the measuring section is carefully observed and converted to Btu per hour. From this heat quantity, the area of the test section, the temperature gradient, and the specimen thickness, the thermal conductivity of the material can be calculated. Hot plate apparatus accommodating specimens on the order of one foot square and an inch or more thick is common. The apparatus at the National Bureau of Standards takes specimens 8-in. square, while plates as large as 3-ft square have been used. The thermal conductivity of cylindrical or pipe insulation (Chapter 27) is determined in a similar manner except that an equivalent thickness must be calculated to account for the cylindrical shape.[51]

Recently there has been considerable development of transient state conductivity apparatus utilizing a slender probe.[52, 53, 54, 55] These instruments are commercially available and have the advantages of rapidity and requiring a small test specimen. While useful as research and development tools, the probe has not been generally accepted as have the guarded hot plate and pipe insulation apparatus.

Wall Conductances

The thermal conductances (C values) of many walls can be satisfactorily estimated from the conductivities of their components and their dimensions, but some walls are complicated by the inclusion of metal, for instance, and tests for conductance are required. The apparatus is required to accommodate large specimens representing actual construction. The guarded hot box apparatus was developed for this purpose. Test specimens for the apparatus at the National Bureau of Standards are 5 ft long and 8 ft high, while others require different sizes, some larger, others smaller.

The guarded hot box is described in the *ASTM Standard Test Code for Built-up Sections* C-236-54T.[56] The apparatus consists essentially of three boxes: a cold box, cooled by a refrigerating machine; a hot box, heated electrically; and a metering box also heated electrically. Each box has an open side to be placed against the specimen. The cold box is clamped against one side of the specimen, and the hot box against the other. The hot box encloses the metering box and is kept at the same temperature to minimize heat exchanges to or from the metering box, except through the specimen. The electric energy necessary to heat the metering box is measured, converted to Btu per hour, and divided by the area and the temperature difference through the wall, from surface to surface, to yield the conductance of the wall. The transmittance or U value of the wall is then computed by means of the surface coefficients from Chapter 9.

A heat-flow meter is sometimes useful for measuring steady heat flow through a wall or other building member.[57, 58, 59] In essence, this meter consists of a plate or slab of material of known thermal resistance having attached thermocouples on both sides. For use, the device is pressed against or cemented to the wall to be tested. At steady state, the temperature difference through the slab, measured with the thermocouples, with the known thermal resistance of the slab, indicates the heat flow through the slab and hence, through the wall covered by it. For best results, such meters are calibrated by means of a guarded hot plate or other suitable apparatus. The chief precaution is to assure that the heat flow is steady at the time of measurement.

COMBUSTION ANALYSIS

There are two approaches to the problem of measuring the capacities of fuel-burning devices, such as boilers and furnaces. The direct or calorimetric test consists in measuring the change in enthalpy or heat content of the fluid, air or water, heated by the device and multiplying by the flow rate in pounds per hour to arrive at the capacity in Btu per hour.[60] The indirect test consists in determining the heat lost in the flue gases and deducting it from the heat evolved by combustion of the fuel.[61] A heat balance consists in the simultaneous application of both tests to the same device. The indirect test almost invariably indicates the greater capacity, and the difference is credited to radiation from the boiler or furnace casing and *unaccounted for loss.*

In the case of some small equipment, the expense of the direct test is not considered justifiable, and the indirect test is relied upon with an arbitrary *radiation and unaccounted for* factor.[62]

Flue-Gas Analysis

The Orsat apparatus is commonly used for analyzing flue gases. In its ordinary form, it consists of three pipettes and a means for isolating a sample of flue gas in a graduate. After measuring, the sample is expelled from the graduate into the first pipette where the carbon dioxide is extracted by potassium hydroxide. The sample is then remeasured and successively passed into the second and third pipettes, where the oxygen and the carbon monoxide are respectively extracted by potassium pyrogallate and cuprous chloride.

For field testing and burner adjustment, simpler portable devices are available for carbon dioxide determination only. From curves, based on typical hydrogen content of several common fuels, efficiencies may be estimated from the carbon dioxide value obtained. More elaborate laboratory equipment is sometimes provided for precise determination of carbon monoxide content by burning the carbon monoxide to carbon dioxide in presence of a catalyst.[63, 64] In large plants, carbon dioxide recorders are used to obtain a continuous indication of the plant's efficiency.[65, 66]

SMOKE DENSITY MEASUREMENTS

Ringelmann charts are widely used for evaluating the density of smoke discharged from chimneys or stacks, and smoke ordinances are based on them in some cities. Each chart is composed of a series of crossed black lines on white paper which, at a distance of about 50 ft, is visually compared with the smoke under observation. Four charts are used with different degrees of blackness as shown in Table 1. The smoke density is specified by Ringelmann numbers from 1 to 4.

Table 1.... Ringelmann Smoke Chart Spacings

Number of Card	Thickness of Lines, mm	Distance in Clear Between Lines, mm
1	1.0	9.0
2	2.3	7.7
3	3.7	6.3
4	5.5	4.5

The photoelectric cell is used in some apparatus developed for smoke density recording in large plants. The same device is included in the testing equipment for domestic oil burners described in *National Bureau of Standards, Commercial Standard* CS75-42.[67] Under Laboratory Tests this publication contains the following section: "Smoke Determination.—After combustion has reached equilibrium, the amount of smoke in the flue gases, when viewed lengthwise through 4 feet of the smoke pipe in accordance with the *Underwriters' Laboratories, Inc., Standard for Domestic Oil Burners* (Subject 296), March 1934 and subsequent revisions, shall not reduce the output of a standard photoelectric cell from 9 microamperes, with a clear smoke pipe, to less than 8 microamperes." The Commercial Standard also requires that during a test after installation, the burner shall operate without visible smoke at the chimney top.

A method of evaluating smoke produced by pot-type oil

burners was developed for the Institute of Cooking and Heating Appliance Manufacturers by R. N. St. John. A glass rod is interposed between a light source and a photosensitive cell, both before and after being exposed to the flue gases from a heating device. The diminution of the light transmitted by the rod, due to the deposit of soot on its surface, causes a reduction in the cell emf which is taken as an index of the concentration of smoke in the flue gases. A description of the method is contained in *National Bureau of Standards Commercial Standard* CS104-46.[68]

DETERMINATION OF AIR CONTAMINANTS

Two measures of air dustiness are in use: particles per unit volume of air, and weight per unit volume of air. A comparative method consists in drawing known samples of air through a known area of filter cloth or paper, and comparing the density of the resulting spots with blackness charts or with spots from other sources.

For counting, particles are captured in a device such as the Smith-Greenburg impinger, the Owens jet dust counter, or in an electrostatic or a thermal precipitation device designed for the purpose.[69] Counting is done with a microscope, and the method yields important results when the nature or constituents of the dust are of interest.

For a weight determination, a known volume of air is drawn through a porous crucible or thimble, and the weight gained by the thimble during the operation is the weight of the dust captured from the air sample.[69] For precise work, the thimble must be dried in a desiccating chamber before weighing each time.

At the National Bureau of Standards a test method was developed for interested Government agencies, under which measured samples of the uncleaned air and of the air cleaned by a device under test are passed through filter papers.[69] The ratio of the flow rates through the two filter papers is adjusted during successive tests, until the resulting dust spots approach equality in density as shown by a photometer. The ratio of the flow rates is then indicative of the effectiveness of the cleaner in arresting dust. A statement of an air cleaner's efficiency by any test method, is meaningless unless the test dust is specified. Other instruments for determining gaseous and particulate air contaminants are described in industrial hygiene literature.[68, 69, 70]

SOUND AND VIBRATION MEASUREMENTS[71, 72, 73, 74, 75]

The measurement, analysis, and ultimate control of noise in air-conditioning systems is becoming increasingly important. The sound-level meter is the basic instrument used in acoustic measurements. While a crystal-type microphone is usually supplied with the meter, dynamic and condenser-type microphones can also be used. The dynamic type is employed when the microphone and sound-level meter are separated by a long cable. The condenser microphone is stable and has a flat response. Crystal microphones are stable and sensitive, but require a temperature correction when connected to the sound-level meter through a long cable.

In the refined art of acoustics, the overall or total sound level is of little value. Loudness and annoyance as interpreted by the ear are a function of frequency as well as sound level. The effective rating and control of noise must, therefore, involve the measurement of frequency distribution. The octave-band analyzer, which divides the noise spectrum into eight frequency bands, is most commonly used in conjunction with the sound-level meter. A number of the criteria that have been developed for environmental noise levels are based on octave bands. Narrow-band filters are also available, and impact noise analyzers can be used to measure transient noise levels such as those produced by drop-forge hammers.

Electronic instruments are available for measuring the frequency, amplitude, and acceleration of a vibrating mass. Vibration meters are usually portable, self-contained, and direct reading.

CHAPTER 45

MOTORS AND MOTOR CONTROLS

Fundamentals of Motor Selection; Alternating-Current Motors, Types and Control Equipment; Motor Rating; Functions of Motor Control Equipment; Glossary of Motor Terms, Enclosures, Speed Classification and Mounting

THE electric motor, available in many different types suitable for various services, is now the most widely used form of motive power. The equipment for starting, controlling, and protecting these motors varies with the type and with the functions it is desired to attain. Motors are divided into two general classifications, *alternating-current* or *direct-current*, depending on the power source to be used.

FUNDAMENTALS OF MOTOR SELECTION

The following characteristics of the *power supply* should be determined: (1) whether current is alternating or direct, (2) voltage, (3) alternating-current phase, (4) alternating-current frequency, (5) voltage regulation, (6) continuity of power.

1. *A-C vs. D-C Systems*. For most applications, a-c supply is satisfactory since suitable performance can usually be obtained with a-c motors and control. Where special characteristics, such as an extra wide speed range and severe accelerating or reversing duty are involved, conversion by means of motor generator sets, by rectifiers, or in special cases by converters, may be justified.

2. *Voltage*. Standard conditions of voltage and frequency are the values listed on the name plate of the motor. Reasonable horsepower design limits are given in Table 1. Power lines are often given voltage ratings known as *nominal system voltages* which are numerically slightly different from the standardized motor voltages.

3. *Phases*. Three-phase power supply is most desirable, but only single-phase is offered for most residential and rural districts.

4. *Frequency*. Sixty-cycle systems predominate in the United States. In foreign countries, 50-cycle systems are common and nominal system voltages are frequently different.

5. *Voltage Regulation*. The voltage regulation of the power supply should be known in order to select motors which will deliver sufficient torque even with the probable drop in voltage, to start and carry the load. All induction motor torques and synchronous-motor starting and pull-in torques vary as the square of the voltage.

6. *Continuity of Power*. Dips in voltage from switching or other line disturbances may necessitate time-delay undervoltage protection, and, in case of synchronous-motors, high torque designs and resynchronizing control. Sustained low voltage may necessitate higher torque motors.

The following characteristics of the *driven machine* should be determined: (1) mechanical arrangement including position of motor and shaft, portability desired, drive connection, and space limitations; (2) speed range desired; (3) horsepower requirement; (4) torque; (5) inertia; and (6) frequency of starting.

1. *Mechanical Arrangement*. Arrangement of the driven machine usually determines whether a *horizontal* or *vertical* motor is needed. Horizontal motors are more generally available and less expensive; most grease-lubricated ball-bearing motors will operate in either position. Fractional-horsepower waste-packed sleeve-bearing motors are satisfactory for short periods of vertical operation where no thrust is involved.

If shaft is *tilted* for momentary operation, special construction of bearing housings will be required for oil-ring-lubricated sleeve-bearing motors, to avoid loss of lubricant. In case of long periods of tilted operation, bearings suitable for end thrust may be necessary. Ball-bearing motors with grease lubrication are suitable for tilted operation.

Most motors are suitable for mounting with base above a horizontal shaft or to one side of the shaft, provided the end shields are rearranged. If, during operation, the angle of the motor (with regard to the horizontal shaft) changes more than 10 or 12 deg, a ball-bearing motor will usually be required. Sleeve-bearing motors are also applicable within the angle given if modified oil gages are provided.

On portable machines, motors of greater compactness and less weight than standard may be required, and special bearing construction may be needed, except for ball-bearing motors. Direct connection should always be considered where machine speed coincides with available motor speed.

Maintenance, efficiency, power factor, space, and initial cost, will determine the choice between *direct connection* and other methods, such as *belt*, *chain*, or *gear* drive. When direct connection is possible (where parts of the driven machine, such as shaft or bearings, are common with the motor structure) a *built-in* construction may be advantageous.

Belt Drive. Diameters and widths of pulleys or sheaves and center distances are factors in determining motor-bearing pressures and shaft deflection. Flat belts should not run at greater speeds than about 5000 fpm. Application of flat belting to vertical-shaft motors is difficult.

Chain Drive. The chain manufacturer should be consulted so that the best drive on a basis of quietness and economy of operation may be selected.

Gear Drive. Compactness and arrangement of drive often indicate *gear motors*, which are obtainable in a variety of mechanical constructions with speed ratios of 3 to 1 upwards, and are generally limited to about 75 hp maximum. Where the pinion of ordinary spur gearing is mounted on the motor shaft, two-bearing motors are limited in horsepower ratings. Maximum pitch-line speed with steel pinions is about 1400 fpm.

The selection of the motor part of a *gear motor* is the same as for a conventional motor.

Space limitations may affect the choice of motor and require (*a*) built-in construction; (*b*) a gear motor; (*c*) forced

Table 1 . . . . Reasonable Horsepower Design Limits for Standard Motor Voltages

Power Supply	Standard Motor Voltage	Suggested Minimum Horsepower	Suggested Maximum Horsepower
Alternating 1-phase	115	None	1
	230	None	15
Alternating 3-phase	110	None	15
	220	None	200
	440–550	1	1000
	2300	50	6000
	4000	100	7500
	4600	250	8000
	6600	400	None

ventilation using an external blower; or (*d*) a small frame with Class B or H insulation permitting higher temperature rise.

2. *Speed Range.* Where more than one speed or a range of speeds is required, one of the motor types listed in Table 2 may be applicable, depending upon the power supply and the speed range required.

3. *Horsepower Requirement.* The horsepower required by the driven machine determines the motor rating. Where the load varies with time, a horsepower vs. time curve will permit determination of the peak horsepower required. The calculation of the root-mean-square (*rms*) horsepower indicates the proper motor rating from a heating standpoint. In case of extremely large variations in load, or where shutdown, accelerating, or decelerating periods constitute a large portion of the cycle, the rms horsepower may not give a true indication of the equivalent continuous load. The motor manufacturer should, therefore, be consulted.

Where the load is maintained at a constant value for an extended period (varying from 15 min to 2 hr, depending on the size), the horsepower rating required will usually not be less than this constant value, regardless of other parts of the cycle.

If the driven machine is to operate at more than one speed, the horsepower required at each speed must be determined.

4. *Torque.* The torque required to operate the driven machine at every moment between initial breakaway and final shutdown is important in determining the type of motor. A torque-speed curve is desirable and sometimes essential.

The *starting torque* or breakaway torque required by the driven machine may be as low as 10 percent, as in the case of medium-sized centrifugal pumps, or as high as 225 to 250 percent of full-load torque, as in the case of a loaded reciprocating two-cylinder compressor. The breakaway torque may vary greatly at different times because of frequency of start, temperature changes, type and amount of lubricant, etc. The motor torque available at the shaft must be well above the torque required by the driven machine, taking into consideration these variables as well as the possibility of low voltage and the type of starter used.

The torque required after breakaway for *acceleration to full speed* varies with different driven machines, remaining at a rather high value throughout acceleration for such machines as loaded compressors and plunger pumps. The torque delivered by the motor must at all points, up to full speed, be in excess of the torque required by the driven machine. The greater this excess torque, the faster will be the acceleration. The approximate time required for acceleration from rest to full speed is:

$$\text{Time in seconds} = (\text{rpm}) \times WR^2 \div (T \times 308) \qquad (1)$$

where

(rpm) = full-load speed in revolutions per minute.
T = average torque available for acceleration, foot-pound.
WR^2 = inertia of rotating parts, pound-foot square.

If the time to accelerate on full voltage is greater than about 20 sec, special motors or starters may be required to avoid overheating.

5. *Inertia of Driven Machine.* The inertia or flywheel effect WR^2 of the rotating parts of the driven machine affects the accelerating time and, therefore, the heating of motors and control, particularly where reversing duty or frequent starting is involved.

Where synchronous motors are applied, the WR^2 must be known, since the pull-in torque required of this motor varies approximately as the square root of the total WR^2 of motor and load.

The WR^2 of a rotating member of the driven machine which operates at a speed different from that of the motor may be converted to an equivalent value at the motor shaft by multiplying by

$$[(\text{rpm of rotating member}) \div (\text{rpm of motor})]^2 \qquad (2)$$

6. *Frequency of Starting.* The frequency of starting the driven machine affects the motor and control by increasing their heating, particularly where accelerating time is prolonged by high WR^2 and high load torques. In general, driven machines starting more than 4 to 6 times per hour may require special motors and control.

Table 2 . . . . Speed Ranges for Various Types of Motors

Power Supply	Type	Speed Range
Single-Phase a-c	* Brush-shifting repulsion motor	3:1
	* Capacitor motor with tapped winding	2:1
	Multi-speed capacitor motor	2 or 3 fixed speeds
Poly-phase a-c	Multi-speed squirrel-cage	2, 3, or 4 fixed speeds
	* Wound-rotor motor	2:1
	* 2-speed wound-rotor motor	4:1
	Brush-shifting shunt motor	20:1
	* Brush-shifting series motor	3:1
	Squirrel-cage motors with variable frequency supply	Very wide range
	Motor-Generator Set—D-C Drive Motor	Very wide range
	Rectifiers—D-C Drive Motor	Very wide range
d-c	Shunt-wound standard *constant-speed* motor with field control	2:1 in some cases
	* D-C motor with armature control	Wide
	Adjustable-speed motor	From 3:1 to 6:1
	Shunt motor with adjustable-voltage supply	Very wide

* Speed regulation relatively wide. Unsuitable for some loads.

ALTERNATING-CURRENT MOTORS

Alternating-current motors are divided into two main classifications: *polyphase* and *single-phase* (see Table 3), according to the type of power supply. They are further subdivided by type of motor winding.

When polyphase power is available it is usually found more economical to apply polyphase motors in preference to single-phase motors. A typical 5 hp, 1200 rpm capacitor-start induction-run single-phase motor, for instance, will cost approximately twice as much as the corresponding three-phase *Design B* squirrel-cage motor. In addition, the polyphase motor has the advantage of higher efficiency.

Polyphase Motors

The three types of polyphase motors are: *squirrel-cage induction* motors, *wound-rotor induction* motors, and *synchronous* motors.

Squirrel-cage motors are specified by NEMA standards providing a variety of speed and torque characteristics. *Design A* motors provide normal starting torque at starting current in excess of *Design B* motors, and are suitable for constant speed application to equipment such as fans and blowers. *Design B* motors provide normal starting torque with NEMA starting current values shown in Table 4, which are acceptable by many power companies for full voltage starting. They are used for the same type of application as *Design A*. *Design C* motors provide high starting torque with starting current same as *Design B*, and are used on compressors started without unloaders, and on reciprocating pumps. *Design D* motors have high slip* and are used with flywheels for widely pulsating loads on equipment such as reciprocating compressors and pumps where other motors would draw high peak currents. *Design F* motors have low starting current and low torques. They are used on power systems of limited capacity. Careful application must be made since the low breakdown torque provides only limited safety margin for overload or low voltage conditions. A drop in voltage, for instance, could cause the motor to stall.

Figs. 1 and 2 illustrate the characteristics of squirrel-cage motors. The motor operates under load from near synchronous speed at light load to about 95 percent synchronous speed at full load. Overloads decrease the speed further until the maximum torque point is reached. If the load torque exceeds this point the motor will stall. The motor torque varies as the square of the voltage. If the voltage drops 10 percent, the motor torque will be only 81 percent of rated value. Both power factor and efficiency are improved if the motor is operating as near rated load as possible. In addition, as shown in Fig. 2, power factor and efficiency are better for higher speed motors.

Hermetically-enclosed polyphase a-c motors are now quite generally used with large centrifugal compressors. The motors are built into the compressors and are cooled by circulation of refrigerant through the motor windings or by circulation of condenser cooling water through the motor housing. In either case, the cooling is excellent and the motor can deliver more power than if it were air-cooled.

Wound-rotor motors are used for applications requiring high starting torque at low starting current, because a wound-rotor motor with its controller and resistance can develop full load torque when starting with about full load current. For comparison, a squirrel-cage motor would require from 3 to 5 times as much current to develop full load torque at starting. The wound-rotor motor is also used for varying speed service to drive fans, blowers, and other continuous duty apparatus.

The addition of resistance to the secondary winding of the wound-rotor motor changes the speed torque characteristics. The motor speed, with the resistance added, is dependent on load, and consequently, the motor has very poor speed regulation when secondary resistance is added to reduce the speed

*Refer to Glossary at end of chapter.

	Split phase	Constant and adjustable	Normal	Normal	Fractional	(a) Fans (b) pumps and compressors (d) fans—direct

to values below 50 percent. Fig. 3 illustrates the characteristics of wound-rotor motors.

Synchronous motors are used for continuous duty applications at constant speed where efficiency and power factor are important. Another advantage of these motors is that of lower initial cost in large sizes and for low speeds when compared with squirrel-cage type motors.

The outstanding advantage of the synchronous motor is that its power factor can be changed to compensate for the low power factor of other drives in the same location. Lagging power factor is an inherent characteristic of all induction apparatus, such as induction motors and neon signs. Unless synchronous motors or capacitors are installed, the plant power factor may be comparatively low. This does not

Table 3 .... Classificatiom of Motors (Continued)

	Type	Speed Characteristics	Full Voltage		HP Range	Application See Footnotes (a) to (e)
			Starting Torque	Starting Current		
	Adjustable Speed Drives					
Polyphase a-c	Squirrel-cage high slip. Transformer adjustment	Variable	Normal	Normal	Medium Small	(a) Fans
	Squirrel-cage separate winding or regrouped poles	Constant multi-speed	Normal or high	Normal or low	All	(a) Fans (b) pumps and (c) compressors
	Wound rotor	Variable	High (with secondary control)	Low	All	(a) Fans (b) centrifugal pumps and compressors
Single-phase a-c	Repulsion	Variable	High	Normal	Low and Fractional	(a) Fans, centrifugal pumps (b) compressors
	Capacitor low torque tapped winding	Variable two speed	Low	Normal	Fractional	(d) Fans, direct

a. Drives having medium or low starting torque and inertia WR^2 such as fans and centrifugal pumps or reciprocating pumps and compressors started unloaded.
b. Drives having high starting torques, such as reciprocating pumps and compressors started loaded.
c. Similar to (a) except where frequent or hard starting (large WR^2) requires a higher starting and accelerating torque. d. Fans direct connected. e. Stoker drives.
f. Torque depends on hp rating and speed. See *NEMA Standard* MG1-4.10 on Motors and Generators.

Table 4 .... Locked-rotor Current of Three-phase, 60-cycle Motors at 220 Volts [a, b]

HP	Design B, C, and D Amperes	Design F Amperes	HP	Design B, C, and D Amperes	Design F Amperes
1 or less	24[c]	..	30	435	270
1½	35	..	40	580	360
2	45	..	50	725	450
3	60	..	60	870	540
5	90	..	75	1085	675
7½	120	..	100	1450	900
10	150	..	125	1815	1125
15	220	..	150	2170	1350
20	290	..	200	2900	1800
25	365	..			

[a] The locked-rotor current of three-phase, 60-cycle, constant-speed, induction motors, measured with rated voltage and frequency impressed and with rotor locked, shall not exceed the tabulated values.
[b] Locked-rotor current at other voltages shall be inversely proportional to the voltage.
[c] For 1 hp or less the value is given per hp.

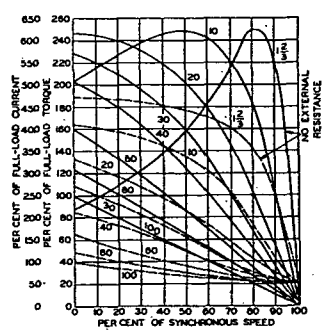

Fig. 3 .... Speed-Torque Speed-Current Characteristics of Wound-rotor Motors

necessarily mean that corrective equipment must always be installed, but in most cases it is desirable to determine what advantages may be gained by improving the power factor. With purchased power, if the rates include a clause embodying a penalty for low power factor, or a bonus for high power factor, the saving in power costs may often make a very good return on the investment required for the corrective equipment.

Synchronous motors are used to drive fans, blowers, pumps, compressors, and other applications. Compressor applications having a high peak torque require the use of flywheels to smooth out power peaks, and should always be referred to the electrical manufacturer for recommendations.

Synchronous motors are provided with built-in damper windings on the rotor and operate during the starting period similarly to squirrel-cage motors. After the motor is nearly up to speed, field excitation is applied and the motor draws into step at synchronous speed. After excitation is applied, the motor runs at exactly constant speed and will remain at this speed until a load approaching the pull-out load is reached, whereupon the motor pulls out of synchronism and stops.

In applying synchronous motors, consideration must be given to the torque the motor can develop on pull-in, that is, at the instant when field excitation is applied. Table 5 shows typical application requirements of synchronous motor drives, listing starting, pull-in, and pull-out torques.

Multi-Speed motors provide flexibility in many types of drives. Synchronous motors can be furnished only with a 2 to 1 ratio in speed, single-winding. Squirrel-cage induction motors may be 2-, 3-, or 4-speed. Two-speed induction motors are usually of single-winding type, having a 2 to 1 speed ratio such as 600 rpm and 1200 rpm, or may be double-winding. Three-speed induction motors are always two-winding, and four-speed motors are usually two-winding with a 2 to 1 speed ratio in each winding. Motors can be provided in constant torque, varying torque, or constant horsepower ratings. The constant horsepower type of motor is considerably larger than the constant torque motor, due to the fact that the same horsepower must be developed at either reduced speed or high speed.

In selecting two-speed motors for fan, pump, blower, or compressor applications, it is usually found that two-winding motors are more expensive than the single-winding type. The control cost for two-speed, two-winding motors, however, is more economical, and therefore the combined price of both motor and control for the two-winding motor is only slightly higher. Because of the improved performance of the two-winding motors, and because of the factor of safety provided by two independent windings, the increased cost is frequently worth the difference.

Single-phase Motors

Single-phase induction motors have auxiliary windings or devices for starting, and are classified by the method used.

Capacitor-start motors develop high starting torque in fractional horsepower ratings, and moderate starting torque in larger ratings. They are used for constant speed drive such as fans, blowers, and centrifugal pumps. During the starting period, a winding with a capacitor in series is connected to the motor circuit and when the motor comes up to speed, a centrifugal switch cuts the capacitor and second winding out of the circuit.

Two-value-capacitor motors develop high starting torque employing a starting capacitor and a running capacitor. The starting capacitor gives high starting ability, but is suited for short time operation only, and is cut out for the running condition by a centrifugal switch. The running capacitor gives high efficiency at full speed. These motors are used on compressors, reciprocating pumps, and similar equipment which may start under heavy load.

Permanent-split-capacitor motors have low starting torque and are ideally suited for small fan drives. Operation is similar to the capacitor-start motor, except that the capacitor is not cut out when running.

Repulsion-start Induction-run motors develop high starting torque. The motors have a wound rotor connected to a commutator for starting. A centrifugal switch shorts the commutator bars when the motor comes up to speed to obtain a winding approximately like the squirrel-cage in its function.

Repulsion-start Induction-run motors are suitable for applications, such as industrial compressors, requiring high breakaway torque, and where commutator and brush noise are not factors.

Split-phase motors have a high-resistance auxiliary winding which is in the circuit during starting, but is disconnected through the action of a centrifugal switch as the motor comes up to speed. Under running conditions it operates as a single-phase induction motor with one winding in the circuit. These units are available for the small horsepower ratings, and when equipped with a high-slip rotor, may be used for adjustable varying speeds through line-voltage control. The motors are ideally suited for fan duty.

Speed-torque characteristics of single-phase motors are shown in Fig. 4.

Full-voltage starting of single-phase motors is general practice, but since most of these motors are connected to secondary distribution systems located in light-load density areas, power companies check carefully the starting currents in order to prevent objectionable voltage dips. This is particularly important for motors started frequently, such as those controlled by pressure or temperature-sensitive devices and applied to refrigerators, stokers, oil burners, and water pumps.

The report of a joint committee of AIEC-EEI-NEMA recommended three application rules taking into account the greater annoyances resulting from frequent motor starting during lighting hours against infrequent starting at any time. Table 6 shows typical applications of these rules which are becoming widely accepted for full-voltage starting. Rules 1 and 2 apply to general use.

Rule 1 limits the locked-rotor current to 20 amp at 115 volts, and 25 amp at 230 volts when automatically controlled (usually frequently started) motors are used. Rule 2 permits twice these values when manually controlled (usually infrequent starting) motors are used. Rule 3 applies to special conditions where larger currents may be allowed above Rules 1 and 2 upon approval of the electric company.

Hermetically-enclosed single-phase a-c motors are widely used in appliances such as domestic and commercial refrigerators, room air conditioners, beverage coolers, freezer chests, and water coolers. In such appliances, the motors are sealed inside the compressor, and the gas and oil circulate freely within and around the motor. Centrifugal starting switches are not used on such motors because any arcing in the gas and oil atmosphere would be detrimental, and also because the units are permanently sealed and cannot be serviced or repaired in the field. In place of a centrifugal switch, an external relay is used to start hermetically-enclosed motors.

Hermetically-enclosed motors for refrigeration compressors will, in the future, have the horsepower rating eliminated. The full-load current is to be the operating current in amperes, when the compressor is delivering rated output. The motors for hermetically-enclosed service are usually of the

Table 5 .... Typical Application Requirements of Synchronous Motor Drives Showing Starting, Pull-In, and Pull-Out Torques

	Application	Method of Connecting Motor to Load	Starting Conditions	Torques			Remarks
				Starting	Pull-In	Pull-Out	
Fans	Exhaust and ventilating	Coupled or belted	Usually loaded	50	60–125	150	WR^2 of fan must be considered
Blowers	Cycloidal positive	Coupled or engine type	Unloaded	40–60	40–60	150	Two-speed motors sometimes used
	Blowing engines reciprocating	Engine-type	Unloaded	40	40–60	150	
	Turbo high speed	Direct connected or step up gear	Unloaded (intake closed)	30	50	150	WR^2 of blower must be considered
Compressors	Air	Engine-type	Unloaded	40	30	150	Flywheel effect important
	Ammonia and ammonia booster	High speed—belted Low speed—engine-type occasionally coupled	Unloaded (by bypass)	40	30	150	Flywheel effect important
	Freon	High speed—belted Low speed—engine	Unloaded (by bypass)	45	50	150	Flywheel effect important
	Gas reciprocating	High speed—belted Low speed—engine	Unloaded (by bypass)	40	30	150	Flywheel effect important

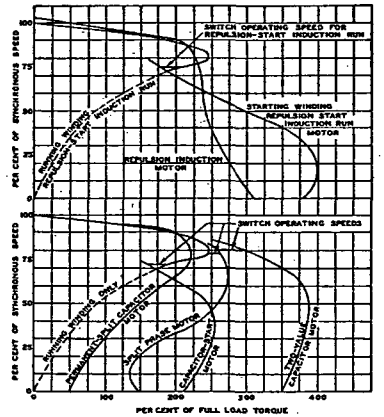

Fig. 4 .... Speed Torque Characteristics of Single-phase Motors

Table 6 .... Recommended Single-Phase Motor Ratings for Full-voltage Starting

HP Rating	Locked-rotor Current[a] at 25 C Amperes		General Use (Rules 1 & 2)		Special Conditions (with Utility Permission) (Rule 3)	
	115 V	230 V	115 V	230 V	115 V	230 V
1/20	20	10	A-M	A-M	A-M	A-M
1/8	20	10	A-M	A-M	A-M	A-M
1/6	20	10	A-M	A-M	A-M	A-M
1/4	23	11.5	A-M	A-M	A-M	A-M
1/3	31	15.5	M	A-M	A-M	A-M
1/2	45	22.5	M	A-M	A-M	A-M
3/4	61	30.5		M	A-M	A-M
1	70	35		M	A-M	A-M
1 1/2		40		M		A-M
2		50		M		A-M
3		70				A-M
5		100				A-M

A refers to automatically controlled devices.
M refers to manually controlled devices.
[a] These values of Locked-rotor current are the same as the NEMA standard for single phase Design M motors.

split-phase type or of the capacitor-start (or two-value capacitor) type.

For starting the split-phase type of motor, two methods are generally acceptable. In one method a thermally-operated time delay is used. When the motor is started, a contact which is normally closed applies power to the starting winding. A thermal element which controls these contacts is in series with the motor and carries line current. Due to the current flow through this element, it is heated until, after a definite period of time, it is warmed sufficiently to open the contacts and remove power from the starting winding. The running current then heats the element enough to keep the contacts open. The setting of the time for the starting contacts to open is determined by tests on the system components, i.e., the relay, the motor, and the compressor, and is based on a prediction of the amount of time delay required to bring the motor up to speed.

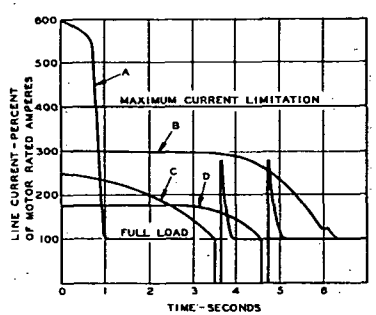
The second method of starting split-phase motors utilizes a series-coil or current-operated relay. This device is affected indirectly by motor speed.

In this type of connection, a relay coil carries the line current going to the motor. When the motor is started, the inrush current to the running winding, passing through the relay coil, causes the contacts to close, and applies power to the starting winding. As the motor comes up to speed, the current decreases until at a definite calibrated value of current corresponding to a preselected speed, the magnetic force of the coil diminishes to a point which allows the contacts to open to remove power from the starting winding.

Capacitor-start and *two-value-capacitor hermetically-sealed* motors are usually started with a voltage-type relay. In this method of starting the relay coil is connected in parallel with the starting winding. When power is applied to the line, the relay does not operate because it is calibrated to operate on a higher voltage. As the motor comes up to speed, the voltage across the starting winding and relay coil increases in proportion to the motor speed. At a definite voltage corresponding to a preselected speed, the relay operates and opens its contacts, thereby opening the starting-winding circuit. The relay then keeps these contacts open because there is sufficient voltage induced in the starting winding, when the motor is running, to hold the relay in the open contact position.

CONTROL FOR ALTERNATING-CURRENT MOTORS

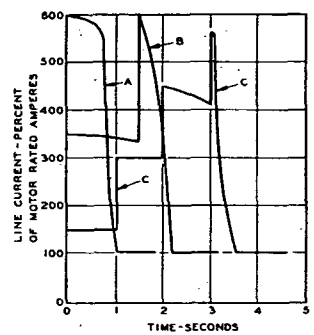
Squirrel-cage motors are usually started at line voltage where power company limitations permit. In sizes up to 5 hp at 220 volts, or 7½ hp at 440 volts, polyphase motors may be started by means of manual switches having overload current elements for motor protection. In larger ratings a linestarter is usually provided with either an additional safety switch or circuit breaker for disconnecting and short-circuit protection. Reduced-voltage starting may be used when the current inrush on full voltage exceeds the limitations set by the power company. The magnitude of this inrush current is entirely independent of the load on the motor, and is the same whether the motor is lightly loaded or heavily loaded.



Restrictions on starting current may limit the maximum current inrush or may limit the increments of current inrush which may be drawn on each step. Table 7 shows a comparison of the various methods of reduced-voltage starting. The choice may depend upon the limitation to be met. Fig. 5 shows examples for maximum current limitations. Fig. 6 shows examples for increment limitations. The increment starters would not be satisfactory for meeting maximum current limitations as they exceed the maximum value before the motor reaches full speed. Both Curves *B* and *C* of Fig. 6 would be satisfactory if the increment limitation were 400 percent but only the starter illustrated by Curve *C* would meet a limitation of 200 percent increments.

Table 7 . . . . Comparison of Squirrel-Cage and Synchronous Motor Starting Methods

Type of Starter	Percent of Motor Rated Values		
	Voltage	Starting Torque	Line Current
Full Voltage Starter	100	100	100
Autotransformer			
80 percent tap	80	64	68
65 percent tap	65	42	46
50 percent tap	50	25	30
Resistor, single step	80	64	80
Reactor			
50 percent tap	50	25	50
45 percent tap	45	20	45
37.5 percent tap	37.5	14	37.5
Part Winding	60*	50*	60*
Star-delta	58	33	33



* Varies with portion of winding used.

When increment starters are used, the motor may not develop enough torque to start until the last step. Fig. 6 shows that with the resistor step starter the motor does not start until Step 3 or after 2 seconds on Curve *C*. Part-winding motors may start and then stall at about half speed until the second step which applies full torque.

Curve A—Full Voltage Starter
Curve B—Part Winding Starter
Curve C—4-Step Resister Increment Starter

Fig. 6 . . . . Starters for Increment Limitations

The load inertia WK² may also affect the selection of reduced current starting method since the reduced torques may not be sufficient to accelerate the load without overheating the motor or in the case of synchronous motors, may not reach sufficient speed to pull into synchronous speed. In these cases the solution may be to use the wound-rotor induction motor or some means of reducing the load such as suction dampers on compressors. Fig. 7 illustrates recommended control practice for squirrel-cage motors.

Wound-rotor motors require control of both primary and secondary circuits. The primary* control may be the same as for squirrel-cage motors, manual or magnetic, at full voltage. Secondary* control provides means of varying secondary resistance for starting and speed control. The secondary controller should be specified for starting duty only, or for speed regulating duty. If the secondary controller is to be used for speed-regulating duty, the percent speed reduction, the number of speed control points, and the type of load (variable or constant torque) should be specified. Fig. 8 illustrates recommended control practice for wound-rotor motors.

Arrangements 2, 3, 4, and 5 Provide Automatic Push-button Starting.

Fig. 7 . . . . Recommended Controls for Squirrel-Cage Motors

Synchronous motor starters should provide pull-out protection, automatic synchronization or automatic stopping of the motor after pull-out, and assurance of complete starting sequence, as well as overload and low-voltage protection. The control may be either magnetic or semi-magnetic at full or reduced voltage. Semi-magnetic starters provide automatic field control, but require hand operation for closing the line contactors to start and transfer to full voltage.

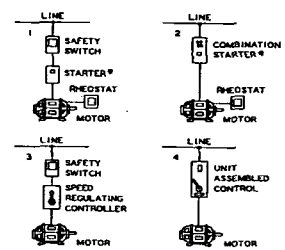

Fig. 8 . . . . Recommended Controls for Wound-Rotor Motors

In applying reduced-voltage starters to synchronous motors it should be remembered that, since these motors are started on damper windings and function during the acceleration period similarly to squirrel-cage motors, the starting torque varies as the square of the applied voltage. Consideration should be given to insure development of sufficient motor torque to accelerate the load.

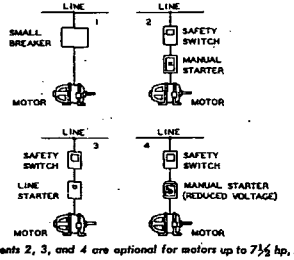
Multi-speed control may be either manual or magnetic, and at full or reduced voltage. When using automatic magnetic control with two-, three-, and four-speed separate winding or consequent-pole motors, control may be obtained from a remote point by means of a push button master switch. The various speeds of the motor are obtained from the master switch by simply depressing the correct push button. This is known as selective speed control. It is commonly used in the smaller theater installations where the fan and motor are located backstage and the speed control is located in the lobby.

Multi-speed motor controllers may be provided with compelling relays which make is necessary for the operator to press the first speed button before regulating the motor to the desired speed. This ensures that the motor is always started at low speed before adjusting to a higher speed.

Timing relays which provide for automatic acceleration may be used for control. With this feature the motor will always start at low speed and automatically accelerate to the desired speed. Decelerating relays may be used to reduce the shock effect of the braking action on the motor and drive when the speed is reduced from a higher to a lower speed.

Single-phase motor control usually consists only of an across-the-line starter, either manual or magnetic. In some

*Refer to Glossary at end of chapter.



cases it is desirable also to provide a disconnect switch. Fig. 9 illustrates the recommended controls.

MOTOR RATING

The rating of an electric motor depends upon the total temperature which the motor attains under operating conditions. This total temperature depends on both the ambient temperature and the temperature rise of the motor. As motor temperature rise is in turn determined by the ability of the motor to dissipate heat, circulation to the motor should not be restricted. Improper selection of motors with regard to temperature ratings may result in high motor operating temperatures and accompanying reduction in motor life.

FUNCTIONS OF CONTROL EQUIPMENT FOR MOTORS

In general, control equipment for all types of motors should provide (1) means of disconnecting the motor and controller from the power supply, (2) means for starting the motor, (3) overload protection for the motor, (4) protection against low voltage, and (5) means for varying the motor speed.

Arrangements 2, 3, and 4 are optional for motors up to 7½ hp, 220 volts.

Fig. 9 . . . . Recommended Controls for Single-Phase Motors

Full-voltage starting for motors is preferable because of its lower first cost and simplicity of control. Except for d-c machines, most motors are mechanically and electrically designed for full-voltage starting. The starting inrush current, however, is limited in many cases by regulations of power companies because of the voltage fluctuations which may be caused by heavy current surges. It is therefore often necessary to reduce the starting current below that obtained by across-the-line starting. The power supplier should be consulted to determine the allowable inrush current for any given location.

The choice between full-voltage and reduced-voltage starting is governed almost entirely by inrush current limitations. The starting torque of all motors varies with the starting current, and it is therefore necessary to insure that the motor is supplied with sufficient current to develop enough torque to accelerate the load.

In present practice overload protection of motors is obtained by use of thermal-overload inverse-time-limit type protection. The usual setting of such protection devices is not to exceed 125 percent of rated full load current for open 40 C deg rise motors, and not to exceed 115 percent of rated full-load current for all other motors, the element tripping after a definite interval of time. The *National Electrical Code* requires the addition of fuses or circuit breakers to protect the overload elements from severe short-circuit currents.

Two types of protection are available against low voltage at the motor terminals. One type, called low-voltage release, permits the motor line contactor to drop out on low voltage and to close again when the voltage returns to normal, thereby restarting the motor when the abnormal condition is ended. The second type, called low-voltage protection, causes the motor line contactor to drop out on low voltage, but prevents restarting when the voltage returns to normal except by the action of an operator. This latter type of protection is desirable where it is necessary for the operator to make initial starting adjustments on the machine.

Manual control for an alternating- or a direct-current motor is usually located near the motor. When so located an operator must be present to start and stop or change the speed of the motor by operating the control mechanism. Manual control is sometimes employed only as a device to give overload protection, and another device is employed to start and stop the motor. Manual control is used particularly on small motors which operate unit heaters, small blowers, and room coolers in an air-conditioning system. In other cases manual control in the form of drums, when used with multi-speed motors, is used only as a speed setting device, while the *starting and stopping functions operate automatically* through thermostats and pressure switches.

Because of the increasing complexity of air-conditioning systems, the equipment is operated preferably by automatic control, and less dependence is placed on manual operation and regulation.

Automatic control of motor starters may be accomplished by the use of remote push button stations, by a thermostat, float switch, pressure regulator, or other similar pilot devices. An added advantage of automatic control is that the main wiring for the starter may be installed near the motor, while the starter may be operated by a remote control device.

GLOSSARY

General Definitions

NEMA is the abbreviation for the National Electrical Manufacturers Association.

AEIC is the abbreviation for the Association of Edison Illuminating Companies.

EEI is the abbreviation for the Edison Electric Institute.

Speed Regulation (d-c motors) is the change in speed between no load and full load, expressed in percent of full-load speed; for example, a motor having a no-load speed of 1200 rpm and a full-load speed of 1140 rpm would have a speed regulation of 5.26 percent.

Slip (a-c induction motors) is the difference between the motor speed and synchronous speed expressed in percent of synchronous speed, e.g., a 1200-rpm motor operating at 1140 rpm would have a slip of 5 percent.

Torque is an expression of the turning effort developed by the motor at the shaft, and is usually expressed in ounce-feet for fractional horsepower motors, and in pound-feet for motors of larger ratings.

Primary is the term usually applied to the high voltage or line side of a transformer or motor. In the case of the wound rotor motor the primary is the stator winding.

Secondary is the term usually applied to the low voltage or load side of a transformer or motor. In the case of the wound rotor motor the secondary is the rotor winding.

NEMA Classification by Mechanical Protection and Method of Cooling

These classifications are from NEMA publications MGI-1.20 and MGI-1.21.

Open Machine

An open machine is one having ventilating openings which permit passage of external cooling air over and around the windings of the machine.

a. *Drip-proof Machine.* An open machine in which the ventilating openings are so constructed that drops of liquid or solid particles falling on the machine at any angle not greater than 15 degrees from the vertical cannot enter the machine either directly or by striking and running along a horizontal or inwardly inclined surface of the machine.

b. *Splash-proof Machine.* An open machine in which the ventilating openings are so constructed that drops of liquid or solid particles falling on the machine or coming towards it in a straight line at any angle not greater than 100 degrees from the vertical cannot enter the machine either directly or by striking and running along a surface of the machine.

c. *Semi-guarded Machine.* An open machine in which part of the ventilating openings in the machine, usually in the top half, are guarded as in the case of a "guarded machine" but the others are left open.

d. *Guarded Machine.* An open machine in which all openings giving direct access to live or rotating parts (except smooth shafts) are limited in size by the design of the structural parts or by screens, grilles, expanded metal, etc., to prevent accidental contact with such parts. Such openings shall not permit the passage of a cylindrical rod ½ inch in diameter, except that, where the distance from the guard to the live or rotating parts is more than 4 inches, they shall not permit the passage of a cylindrical rod ¾ inch in diameter.

e. *Drip-proof Fully Guarded Machine.* A drip-proof machine whose ventilating openings are guarded in accordance with paragraph d.

f. *Open Externally-ventilated Machine.* A machine ventilated by means of a separate motor-driven blower mounted on the machine enclosure. Mechanical protection may be as defined in paragraphs a to e, inclusive.

g. *Open Pipe-ventilated Machine.* An open machine except that openings for the admission of the ventilating air are so arranged that inlet ducts or pipes can be connected to them. This air may be circulated by means integral with the machine or by means external to and not a part of the machine. In the latter case, this machine is sometimes known as separately- or forced-ventilated machine. Enclosures may be as defined in par. a to e, inclusive.

h. *Weather-protected Machine. Type I*—A. An open machine with its ventilating passages so constructed as to minimize the entrance of rain, snow and air-borne particles to the electric parts and having its ventilated openings so constructed as to prevent the passage of a cylindrical rod ¾ in. in diameter.

Type II—A machine having, in addition to the enclosure defined for a weather-protected Type I machine, its ventilating passages at both intake and discharge so arranged that high-velocity air and air-borne particles blown into the machine by storms or high winds can be discharged without entering the internal ventilating passages leading directly to the electric parts of the machine itself. The normal path of the ventilating air which enters the electric parts of the machine shall be so arranged by baffling or separate housings as to provide at least three abrupt changes in direction, none of which shall be less than 90 deg. In addition, an area of low velocity not exceeding 600 fpm shall be provided in the intake air path to minimize the possibility of moisture or dirt being carried into the electric parts of the machine.

Totally-enclosed Machine

A totally-enclosed machine is one so enclosed as to prevent the free exchange of air between the inside and the outside of the case but not sufficiently enclosed to be termed air-tight.

a. *Totally-enclosed Nonventilated Machine.* A totally-enclosed machine which is not equipped for cooling by means external to the enclosing parts.

b. *Totally-enclosed Fan-cooled Machine.* A totally-enclosed machine equipped for exterior cooling by means of a fan or fans integral with the machine but external to the enclosing parts.

c. *Explosion-proof Machine.* A totally-enclosed machine whose enclosure is designed and constructed to withstand an explosion of a specified gas or vapor which may occur within it and to prevent the ignition of the specified gas or vapor surrounding the machine by sparks, flashes or explosions of the specified gas or vapor which may occur within the machine casing.

Note—See National Electrical Code Article 500—For Hazardous Locations, Class I, Groups A, B, C or D.

d. *Dust-ignition-proof Machine.* A totally-enclosed machine whose enclosure is designed and constructed in a manner which will exclude ignitable amounts of dust or amounts which might affect performance or rating, and which will not permit arcs, sparks, or heat otherwise generated or liberated inside of the enclosure to cause ignition of exterior accumulations or atmospheric suspensions of a specific dust on or in the vicinity of the enclosure.

Note I—Successful operation of this type of machine requires avoidance of overheating from such causes as excessive overloads, stalling or accumulation of excessive quantities of dust on the machine.

Note II—See National Electrical Code Article 500—For Hazardous Locations, Class II, Groups E, F or G.

e. *Water-proof Machine.* A totally-enclosed machine so constructed that it will exclude water applied in the form of a stream from a hose, except that leakage may occur around the shaft provided it is prevented from entering the oil reservoir and provision is made for automatically draining the machine. The means for automatic draining may be a check valve or a tapped hole at the lowest part of the frame which will serve for application of a drain pipe.

Note—A common form of test for a water-proof machine is to play on the machine a stream of water from a hose with a one-inch nozzle delivering at least 65 gpm from a distance of about 10 ft, from any direction, and for a period of not less than 5 min.

f. *Totally-enclosed Pipe-ventilated Machine.* A totally-enclosed pipe-ventilated machine is a totally-enclosed machine except for openings so arranged that inlet and outlet ducts or pipes may be connected to them for the admission and discharge of the ventilating air. This air may be circulated by means integral with the machine or by means external to and not a part of the machine. In the latter case, these machines shall be known as separately- or forced-ventilated machines.

g. *Totally-enclosed Water-cooled Machine.* A totally-enclosed machine which is cooled by circulating water, the water or water conductors coming in direct contact with the machine parts.

h. *Totally-enclosed Water-air-cooled Machine.* A totally-enclosed machine which is cooled by circulating air which, in turn, is cooled by circulating water. It is provided with a water-cooled heat exchanger for cooling the ventilating air and a fan or fans, integral with the rotor shaft or separate, for circulating the ventilating air.

i. *Totally-enclosed Air-to-air cooled Machine.* A totally-enclosed machine which is cooled by circulating the internal air through a heat exchanger which, in turn, is cooled by circulating external air. It is provided with an air-to-air heat exchanger for cooling the ventilating air and a fan or fans, integral with the rotor shaft or separate, for circulating the internal air and a separate fan for circulating the external air.

j. *Totally-enclosed, Fan-cooled Guarded Machine.* A totally-enclosed, fan-cooled machine in which all openings giving direct access to the fan are limited in size by the design of the structural parts or by screens, grilles, expanded metal, etc., to prevent accidental contact with the fan. Such openings shall not permit the passage of a cylindrical rod ½ in. in diameter except that,

where the distance from the guard to the fan is more than 4 in., they shall not permit the passage of a cylindrical rod ¾ in. in diameter.

Motor Speed Classifications

A Constant-speed motor is one in which the speed remains practically constant with changes in load; e.g., a d-c shunt-wound motor or a-c squirrel-cage motor with low slip.

A Varying-speed motor is one in which the speed varies with the load, usually decreasing when the load increases; e.g., a d-c series motor or an induction motor with large slip.

An Adjustable-varying-speed motor is one in which the speed can be adjusted gradually, but when once adjusted for a given load will vary in considerable degree with change in load; e.g., a shunt-wound d-c motor adjusted by armature resistance control.

An Adjustable-speed motor is one in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load; e.g., a d-c shunt motor with field-resistance control. The standard ratings for open-type, adjustable-speed motors, having a speed range of 3 to 1 and greater are in accordance with the following:

(1) A standard continuous horsepower rating at 150 percent of minimum speed with a temperature rise of 40 C.

(2) The next higher standard continuous horsepower rating at 3 times minimum speed with a temperature rise of 40 C.

(3) Between 150 percent of minimum speed and 3 times minimum speed, the standard continuous horsepower rating with a temperature rise of 40 C will vary with the speed along a straight line connecting these two horsepower ratings. No further increase in horsepower is recognized above 3 times minimum speed.

(4) Below 150 percent of minimum speed the lower continuous horsepower rating (see preceding item 1) will apply with a temperature rise of 50 C.

Example: 20/25 hp, 400 to 1600 rpm. This motor may be rated 20 hp, 40 C at 600 rpm and 25 hp, 40 C from 1200 to 1600 rpm. Between 600 and 1200 rpm the rated horsepower increases directly with speed from 20 to 25 hp.

(5) Motors may also be rated 1 hour with temperature rise of 50 C with the higher horsepower rating (see preceding item 2) throughout the entire speed range.

Example: 20/25 hp, 400 to 1600 rpm. This motor may be rated 25 hp, 50 C 400/1600 rpm; 1 hour.

Mechanical Modifications

Vertical Mountings are available for such applications as pumps and agitators. This type of application may require a special umbrella-type hood to protect against dripping liquids.

Flanged Mountings are available for use where motors are built in as part of machines. Motors may also be supplied with flush plate mountings, suitable for close coupled pump and similar applications.

CHAPTER 46

RESIDENTIAL SUMMER AIR CONDITIONING

Consumer Requirements, Equipment Capacity Selection, Types of Equipment, Types of Systems, Gas Year-round Air Conditioners, Location of Cooling Equipment, Noise, Air Distribution Methods, Operating Costs, Effects on Future House Design

SUMMER air conditioning in residences has become a major factor in the air-conditioning field and has created a heavy interest among home-owners, builders, architects and business men. Residential cooling, particularly for the small home, received its initial impetus when equipment specifically designed for such purposes became available in the 1930's.

The first installations were made by using commercial and industrial methods as the estimating basis and did not prove as satisfactory as the installer or designer desired. Actually, the difference between estimating the residential summer air-conditioning and commercial summer air-conditioning loads is in the design temperature differences used, the type of internal load in the conditioned area, and the method of calculating equipment size.

CONSUMER REQUIREMENTS

Present practice is to design residential summer air conditioning on the basis of an 80 F indoor temperature. In using this basis it is assumed that the home owner will operate the system continuously with a thermostat setting of 75 or 76 F and thereby take advantage of the thermal storage in the house and household furnishings to reduce the peak temperatures. The preference of the individual home owner must, however, be considered in selecting the design indoor temperature and may require that a temperature lower than 80 F be selected. Analog computed studies and field investigations[1] have apparently demonstrated the adequacy of the 80 F indoor temperature as a basis for equipment selection procedure.

To ensure comfort, it is essential that the proposed operation and performance of the system be explained to the user in advance. Usually the greatest degree of comfort can be obtained by keeping the house closed and operating with a fixed thermostat setting throughout the cooling season. In some climates the opening of the house to utilize *night-air cooling* creates humidity difficulties that take several hours to overcome during the following day. The use of *night-air cooling* may lead to unsatisfactory conditions when the equipment is not turned on again sufficiently early the next day. It will also allow unfiltered air to enter the house thus reducing the cleanliness advantage of air conditioning.

EQUIPMENT CAPACITY SELECTION

There are two industry-accepted methods of calculating residential cooling loads. These are as given in Manual 11, *Summer Air Conditioning*, of the National Warm Air Heating and Air Conditioning Association and Standard 610-56, *Application Engineering Standard for Year-Round Residential Air-Conditioning* published by the Air Conditioning and Refrigeration Institute. Published procedures of reliable manufacturers when used in conjunction with their equipment are also adequate.

Both of the industry methods mentioned employ cooling load factors for the various components of the load that are averaged over a peak period of several hours and thereby make allowance for thermal storage effects. They avoid the possibility of pyramiding non-concurrent, instantaneous peak loads.

With most methods it is possible to select the desired design indoor-outdoor temperature difference, using 80 F or the user's preference for the indoor temperature, and the commonly used outdoor temperature for the area as listed in Chapter 13.

Design methods which average load conditions for a period in excess of 12 hr have not been accepted by the industry committees. Such methods require the introduction of factors that are not at present considered to be adequately substantiated by mathematical analysis or to be justified by the thermal storage effects of a typical residence.

The contractor should avoid any capacity selection procedure based on a rule of thumb such as *10 average windows or doors per ton* or *500 sq ft of floor area per ton*. Insulation, glass areas, shading effects, and solar orientation must be given careful consideration by using an accurate, step-by-step procedure for estimating the load.

In residences, peak lighting loads will not usually occur during the period of greatest load from outdoor temperature and solar conditions. Unlike summer air conditioning in commercial or industrial establishments where internal heat producing sources may be a major portion of the load, internal loads in residences may generally be neglected except under the most unusual circumstances.

The heat and moisture introduced by a clothes dryer or water heater should be vented to outdoors. Heat introduced by the kitchen range should be discharged through an exhaust fan. These are major internal loads that must be taken into account if adequate venting is not to be provided.

The load calculation method presented in Chapter 13 is not recommended for residences where it has been found[2] to result in oversizing because internal loads that are generally a prime consideration in commercial applications are not generally significant in residences. Furthermore the method outlined in Chapter 13 gives an instantaneous peak load without consideration of residential usage and heat storage effects applied in the ARI and NWAH & ACA load calculation procedure. Oversizing is objectionable from at least two viewpoints: (1) it increases the capacity and consequently the

cost of the equipment installed, and (2) it results in less desirable humidity conditions within the residence because of the increased size.

TYPES OF EQUIPMENT

Low Side

Three types of low side equipment (the equipment that actually removes the heat from the conditioned space) have been developed for residential work as follows: (1) refrigerated coils, (2) chilled-water coils, and (3) water-cooled coils.

The first and most commonly used method of absorbing heat from the conditioned air is to use direct evaporation of the refrigerant in a coil with the air to be conditioned passing over the outside of the coil surface. The heat is passed directly from the air into the refrigerant for removal. This requires the use of an air distribution system and, although generally most economical in new construction, may present costly problems in modernization work where ductwork is not installed.

In a chilled-water system, water is circulated through a closed circuit containing two coils. In one coil the water removes heat and moisture from the air in the conditioned space. In the other coil (water chiller) the heat is removed from the water by mechanical refrigeration. This type of system is called a duplex system in that the heat is picked up by chilled water and later removed from the water by means of a refrigeration system.

The water-cooled coil using water directly from city mains or wells is the simplest type of installation but, because of limitations imposed by the capacity, cost, or temperature of the available water supply, its use is not generally practicable. Cold water is circulated directly through the coil while air from the conditioned space is passed over the coil to remove heat and moisture. After the water has passed through the coil, it is wasted. To operate satisfactorily, an installation of this type requires water of sufficiently low temperature to chill the air enough to remove the desired amounts of heat and moisture. Where a large supply of cool water is obtainable, the water-cooled coil will operate with satisfactory results. As a general rule a water-cooled coil should not be used unless there is a supply of 52 F or colder water at the peak of the cooling season and in sufficient quantities to take care of the cooling load with a temperature rise of no more than 10 deg. Where water is not obtainable in sufficient quantities or at the required temperatures, it is necessary to chill the water to the desired temperature by using mechanical refrigeration.

High Side

The high side of a conditioning system, the section of equipment that removes the heat from the refrigerant and reclaims the refrigerant for further use in the system may be either the air or water-cooled type. The air-cooled high side is so constructed that the heat is removed from the compressed or hot refrigerant by passing it into a cooling coil over which outside air (air taken from outside the conditioned area and returned to outside of the conditioned area) is circulated.

The major advantage of air-cooled equipment is that no water is required to accomplish the removal of heat from the refrigerant and only an electrical supply is needed. The disadvantage is that operating pressures are higher because of the inability to cool the refrigerant as much by air as by water. This results in an increase in electrical input to the compressor motor.

Water-cooled equipment can be of two types. In one type the water drawn from a well or from city mains is passed through the condenser of the high side and is allowed to flow to a drain, swimming pool, a wetted roof, or to other means of disposal. Where the water supply is sufficient and at low cost, this type of water-cooled unit is the better type installation because of lower equipment cost, lower operating costs and quieter operation. In a second type, if water is in short supply or is expensive, about 95 percent of the cooling water can be reclaimed by evaporating sufficient water to rid the remaining water of the heat picked up in the condensing unit. This can be done by the use of an evaporative condenser or a cooling tower described in Chapters 38 and 40.

TYPES OF SYSTEMS

The present generally accepted method of cooling residences is to employ a central system. The main components of the central plant for year-round air-conditioning systems may be obtained in factory-made assemblies providing matched components for both winter and summer conditioning functions or they may be obtained in one or more separate parts and combined on the job into an integrated system. Summer conditioning equipment may be obtained separately and added to existing heating systems or may be installed independently of any heating system. Cooling coils may be used in conjunction with warm-air furnaces and duct systems, or chillers may be combined with boilers to provide hot and cold water for circulation to room units as required. Refer to other Chapters 15, 16, 19, 42, and 43 for information on specific system components.

Self-contained room coolers, which are discussed in Chapter 16, are used for room or spot cooling and are not generally used to cool an entire residence. Their application and use is not to be considered further, but it may be noted that when only a portion of a residence is cooled the load calculation methods currently used in the industry for central residential systems are not applicable. Refer to Chapter 13 when calculating the load for such applications.

In some areas there is little or no need for heating but there is a distinct need for summer cooling. Both air- and water-cooled package cooling units are available for such installations, ranging in size from one ton to at least 15 tons capacity. To install these units it is only necessary to make plumbing and electrical connections and add the duct work required to convey air to and from the conditioned space. These units can also be used to provide central air conditioning for residences

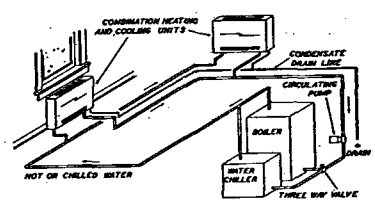


Fig. 1 . . . . Combination Summer Air-Conditioning and Hot Water Heating System

having heating systems which do not contain provision for attaching summer cooling equipment.

Year-round air conditioners require less space than a separate heating plant plus a separate summer conditioner. Usually the heating and cooling portions of a year-round air conditioner operate independently of each other. The air circulated by the fan passes through the cooling or heating portion of the equipment, only one of which is in operation at any one time.

Air conditioning can be installed in homes having a hot-water heating system by use of either of the following:

1. *Room units resembling convectors and containing* both heating and cooling coils. These units are used in place of the conventional radiator or convector. They can be installed in all rooms of the house to provide complete summer cooling, or they can be used in only one or two rooms. This arrangement is shown in Fig. 1.

2. A *split system*. The cooling coil is located in a duct through which air from the rooms is circulated, cooled, and returned to the rooms. Another coil in the same duct can be used for winter heating, or conventional radiators, convectors, or panels can be used to bring heat to the rooms.

When the cooling equipment to be used in houses equipped with forced-circulation hot water heating is of the type which produces chilled water, it may be located in the basement or utility room near the boiler. In most of such systems it is then possible, with the addition of suitable valves, to use the same piping system for circulation of heated water in winter and chilled water in summer. The piping must be insulated to prevent sweating when circulating chilled water.

GAS YEAR-ROUND AIR CONDITIONERS

Gas-fired year-around air conditioners, based on the absorption cycle are available in sizes suitable for residential use and small commercial applications.

The conditioners are built in 3½ ton and 5 ton sizes with heating capacities appropriate for various climates. The 3½ ton and one model of the 5 ton units have heating inputs of 120,000 Btuh. This makes them suitable for homes having design heat losses up to 76,800 Btuh. The other 5 ton model has an input of 180,000 Btuh making it suitable for homes having design heat losses up to 115,200 Btuh.

General Description

The principal components of the gas-fired year-round air conditioner are an absorption unit, a gas burner, a centrifugal fan for air circulation, a filter section, and controls. The gas flame supplies the heat to actuate the absorption unit which provides heating in winter and cooling in summer.

The entire unit operates under a vacuum at all times. The absolute pressure within the generator and condenser on cooling cycle is of the order of 2 to 2½ in. Hg (50 to 60 mm) absolute pressure. The pressure within the cooling coil and absorber is between 0.25 to 0.3 in. Hg (6 to 9 mm) pressure. On the heating cycle, since the same coil is used for both heating and cooling, the absolute pressure is on the order of 14 in. Hg (350 mm) or about ½ atmosphere.

Heating Cycle

The gas flame, when applied to the generator of the absorption unit in winter, boils the solution. The water vapor which is thus produced goes directly (bypasses the condenser) to the single coil over which air is passed by the blower. The heat is taken from the water vapor, and the water is returned to the generator by gravity to be used again.

Cooling Cycle

The gas flame, when applied to the generator of the absorption unit, boils the solution. The water vapor which is thus produced goes to the condenser where this vapor is condensed. It then flows into the single coil (which is the evaporator on the cooling cycle). The air being cooled and dehumidified is blown over this coil. The water vapor (through the process of absorption) is returned to the liquid state and flows by gravity to the generator to be used again. The refrigeration unit is factory-sealed and contains a solution of lithium bromide and water which acts as the absorbent, water vapor being the refrigerant. Circulation of these fluids in the system is accomplished by differences in temperature and height of liquid columns, without moving parts.

Control System

Manual switches permit the owner to select heating or cooling, constant or automatic fan operation, and turn the system *on or off*. For protection of the unit a generator limit switch and a cooling circuit preventive control switch are provided. The former protects the generator from excessive input and is preset to operate at safe temperature levels both on the heating and cooling cycles. The preventive control switch keeps the unit from serving as a heating plant if the condensing water were cut off. Another protective device used in the year-round gas air conditioner is the low temperature control which prevents the unit from freezing as a result of improper equipment operation.

A fan delay control delays fan operation until the heating coil has reached 140 F so as to prevent cold air circulation when heat is desired.

LOCATION OF COOLING EQUIPMENT

The preferred location for summer cooling equipment will depend upon the type. In a combination self-contained unit, the location will depend upon accessibility to the duct system, the fuel supply, the chimney, and the electrical supply. Too often, a heating or cooling unit is located by giving consideration to installation only, without considering the usability of the basement. This may result in breaking up the basement area to such an extent that it becomes practically useless for other purposes. In a remote type combination unit, consideration must be given to the location of the condensing unit, whether it is located in the basement area or whether the unit is located in a remote area such as the garage breezeway. Preferences of the family and their habits of living must be given consideration so as to keep all space as useful as possible and still locate the equipment in such a place that it can do its intended job and be accessible.

NOISE

One of the prime problems with residential air-conditioning installations is the operating noise level. Almost any degree of quietness in an installation can be had for a price. However, the numerical standards for describing sound levels have little meaning for the average person. It is difficult to ascertain from the prospective user in advance of installation just what sound levels will be acceptable and to describe what sound levels will result from any particular arrangement.

Motors and motor drives, compressor, blower, pumps if

any, and flowing air and liquids are potential sources of noise and vibration. The first, and frequently the least expensive and most effective measure in noise reduction, is to put distance between the noise and the listener. Installations of cooling equipment in basements, crawl spaces, utility rooms or attached garages are preferable to those in alcoves or closets adjacent to bedrooms and living rooms. Mounting of units on concrete floors is preferred. Further steps which may be taken to achieve an acceptable low noise level are as follows:

1. Minimize the production of noise and vibration. Use only true, concentric pulleys with smooth belts at the proper tension and use properly balanced blower wheels and other rotating parts, operated at the minimum practical speed. Provide an adequate duct system which promotes smooth air flow at reasonable velocity and is sufficiently rigid in construction so that it does not vibrate unduly.

2. Prevent the transmission of noise and vibration to the house structure and to ducts and piping. Use properly loaded isolation mounts for compressors, even when on concrete floors, and provide vibration isolators on blowers and refrigerant lines and vibration loops in the refrigerant system. Install flexible connections between the cooling unit and the ductwork.

3. Control airborne noise with sound-absorbing material or other acoustical treatment. Install sound-absorbing material within ductwork and, where practicable, use one or more elbows between the equipment and the registers or grilles.

AIR DISTRIBUTION METHODS

Systems should be designed and installed by competent engineers in accordance with authoritative information such as given in the design manuals of the Air-Conditioning and Refrigeration Institute[6] and the National Warm Air Heating and Air Conditioning Association.[4] The sizes of the ducts of year-round air-conditioning systems are often larger than those of equivalent winter heating systems since large quantities of cool air, at 55 F to 65 F, must be circulated through them.

Several manufacturers have developed reliable methods of duct design. Such methods should be used when recommended, since they take into account the specific air-flow and static pressure characteristics of the systems to which they apply. They should, however, be applied with caution to systems and equipment other than those for which they were developed.

Cooled air admitted to rooms from ducts through supply outlets is from 15 F to 25 F colder, and therefore heavier, than the air in the room, and has a natural tendency to drop toward the floor. Unless the supply outlets are properly selected, located, and adjusted, the air distribution is likely to result in a low velocity of cool air falling on the occupants or a high velocity stream of cool air striking a wall or other obstruction and deflecting on the occupants. A further complication is introduced when the same outlets are used for heating in which case the delivered air at temperatures considerably above room temperature has a tendency to rise.

Where cooling is installed with ducts and air outlets that serve the cooling function only, the practice and experience of comfort air conditioning for offices and commercial buildings apply directly to residential installation. Although cooling and heating by means of the same ductwork and air outlets has been common practice in commercial and industrial applications, greater care must be taken in residential applications. It has been found that low air-flow rates (much lower than would be used for cooling systems) are desirable for warm air heating systems.[5] It is therefore recommended that, in a residence located in a moderate or cold climate, provision be made for different air-flow rates for summer and winter. In warmer climates, however, where air conditioning is the primary consideration, the summer air-flow rate may be used the year around.

The registers may be placed either in the high side-wall or in the perimeter location. For the high side-wall applications, it is necessary that the deflection of the air be different for summer than it is for winter to prevent the jet from dropping into the living zone (60 in. above the floor and below) where the velocity should be not greater than 35 fpm. For registers located at the perimeter of the residence,[5] it is not necessary to change the deflection from summer to winter.

The air distribution system should be designed for the largest air-flow rate that is to be used, as outlined in *Manual* 9 of the National Warm Air Heating and Air Conditioning Association. For small-pipe perimeter systems, it is necessary to have more outlets than for the larger duct systems. In some applications, it may be necessary to close off some registers during the winter so that adequate register air velocities will be obtained. These registers would then be opened during the summer to give a sufficient number of outlets.

Recent investigations have shown[7] that the use of perimeter-duct systems for air conditioning gives excellent results, and that objectionable air motion does not occur within the living zone except in the immediate vicinity of the registers. Care must be taken, however, to use only registers or diffusers that are specifically designed for perimeter application. This is necessary to permit the introduction of the air into the room in a pattern that does not cause drafts. Floor diffusers which distribute the air in a fan-shaped pattern along the wall or low side-wall diffusers which blanket the wall are recommended. For supply-air temperatures not more than 15 deg below room-air temperatures, diffuser face velocities of 500 fpm are recommended.[5] For supply-air temperatures 20 deg below room-air temperature, the diffuser face velocity should not be less than 700 fpm.

Many registers designed for outside wall application may not be satisfactory for cooling when applied to low-velocity systems because the cool air is apt to remain at the floor.

Ceiling diffusers may also be used, but they may lead to difficulty during the heating season if the warm air remains at the ceiling, resulting in cold floors.

High return locations at inside walls are very effective with outside wall or floor perimeter distribution systems for both the heating and cooling season. In multi-story or split-level dwellings there should be a minimum of one return on each level with a high central return on the upper level to minimize the effects of hot air rising through halls and stairways to upper levels. With ceiling or high-inside-wall distribution, the returns should be located on the outside walls under windows for best results.

CONTROLS

Control devices and systems and their application in residential air conditioning are discussed in Chapter 43, Automatic Control.

OPERATING COSTS

The operating cost of residential cooling equipment during a particular summer depends on variables such as the amounts of sunshine and rain, the number of abnormally hot or cool days, the efficiency of the equipment, and the local power rate. It is also influenced by human factors such as operation of equipment only during the hottest weather, opening windows at night,[5] and difference in preferred indoor

Table 1 . . . Approximate kw Input per 12,000 Btuh Cooling Capacity

Item of Power Load	Type of Heat Rejection[a] Water Cooled Condenser			
	City Water	Atmospheric Cooling Tower	Mechanical Draft Cooling Tower	Air-Cooled Condenser
Refrigeration Compressor	1.00	1.00	1.00	1.35
Blower for Air Conditioner	0.10	0.10	0.10	0.10
Blower for Rejection Air	—	—	0.15	0.15
Pump, Cooling Water	—	0.15	0.15	—
Total kw per 12,000 Btuh	1.10	1.25	1.40	1.60

[a] Other heat rejection means include wells, spray ponds, evaporative condensers, water coils in the ground, finned water coils in air, etc.

temperatures.[16] Nevertheless, it is important that lending agencies and prospective buyers of equipment be given a reasonably accurate estimate of the operating cost during normal summer weather and under usual operating conditions. Adjustments can then be made for any special conditions anticipated. The approximate electrical power inputs for the various motorized components in mechanical cycle air conditioners are shown in Table 1.

Power cost per hour can be estimated by multiplying the estimated power per ton, the cooling capacity in tons and the cost per kilowatt-hour. Thus the estimated cost per hour for a 3-ton air conditioner cooled with city water will be 1.1 kw × 3 tons × the power rate. It is essential to use the correct step of the utility residential rate structure to get a good estimate. The basis of the method used[16] requires the use of a table of the estimated annual hours of operation for properly sized equipment in typical cities. See Table 2.

The values in Table 2 have been substantiated by utility records of actual performance in several major cities when the average indoor temperature is maintained at 80 F. Low indoor temperatures increase operating cost as do weather conditions above normal.

Water usage is another important factor with water-cooled equipment. Various manufacturers have published water usage data for their equipment at varying summer water temperatures. Representative water consumption values are given in Table 3.

For a given application the power rate and water rate may be obtained from the local utilities. Since the average power requirement depends on the particular equipment used and

Table 2 . . . . Estimated Annual Hours of Operation for Properly Sized Equipment in Typical Cities during Normal Cooling Season

Summer Water Temperature, Normal Extremes F	Gallons Per (Hour) (Ton)	Summer Water Temperature, Normal Extremes F	Gallons Per (Hour) (Ton)
55	34	75	58
60	39	80	70
65	44	85	88
70	50		

the condensing method, values obtained from the manufacturer should be used in preference to those in Table 1.

If the evaporator fan cycles with the compressor, the power requirement as found from Table 1 also represents the total power requirement for air-cooled condenser applications. For continuous fan operation the number of hours of compressor operation should be subtracted from the number of hours in the cooling season to obtain the extra hours of fan operation. This value may then be used with the appropriate value of power consumption and power cost for the fan motor only, to find the added power cost for continuous fan operation and the result should then be added to the power cost during compressor operation.

For water-cooled condenser applications the water cost, as determined from the operating hours, water rate, and manufacturer's data on equipment water usage, is added to the power cost to obtain the estimated total operating cost.

Another method has been developed using cooling degree days above 70 F as a criterion but tabulated values of cooling degree days for various localities are not available.[13] Approximate values can be obtained from degree-day maps.[14, 15] The daily range of temperatures for various localities is also required with this method.[16] It is important that the method used in estimating operating cost be consistent with the method used in calculating the heat gain of the structure.

EFFECTS ON FUTURE HOUSE DESIGN

Air conditioning, like automatic heating, has brought about improved practice in residential construction, particularly in those regions where cooling is of primary importance. Although it is true that construction practices which reduce the heating load also reduce the cooling load, there are certain considerations that are unique in their effect upon the cooling load. Special attention should be paid to window orientation and shading. South windows may be shaded by awnings or roof overhangs, but it is not practicable to shade large window areas having an east or west orientation except by exterior solar screening of some type. The use of insulation in the walls and ceiling of the residence will reduce the cooling load appreciably. In addition, attention should be paid to adequate ventilation of the attic. Double-glazed and weather-stripped windows, heat-absorbing glass, planned shade tree locations, and light-colored exterior wall and roof surfaces, also help to reduce the cooling load.

CHAPTER 47

SCHOOL SYSTEMS

General Considerations, Criteria for Design, Design Considerations, Preliminary Design, Mechanical Plant Design, Types of Ventilating Systems, Types of Heating and Cooling Systems, Automatic Control, Operation, Maintenance

The purpose of this chapter is to outline the factors affecting the selection of heating, ventilating, and air-conditioning systems for schools. The components of these systems are the same as used for other types of buildings. Their combination in school systems, in some cases, will be the same as for other buildings, but may differ considerably in others in order to provide optimum conditions for effective school work and to comply with local regulations.

GENERAL CONSIDERATIONS

The proper criteria for heating, ventilating, and in many instances air conditioning, of school buildings, particularly classrooms, are often not recognized fully.

Many designers and school administrators approach the problem as one of heating, whereas analysis may show that cooling, rather than heating, is required during periods of occupancy throughout most of the year. Ventilation systems are frequently designed to supply air at 72 F for ventilation and, when feasible, at 55 F to 60 F to provide the cooling required during occupancy.

With regard to ventilation, code requirements vary from acceptance of natural ventilation, such as obtained by opening of windows, to a requirement of mechanical supply of a specified quantity of air, which sometimes is as high as 30 cfm of outdoor air per occupant. The variations in quantity of outdoor air specified are due to the basis adopted whether it is the quantity needed *to replace oxygen for breathing* or that required for the *dilution of odors*. A discussion of air requirements will be found in Chapter 6.

When planning for introduction of ventilation air into rooms, careful consideration should be given to air distribution and circulation within the occupied space, as well as the natural convection and temperature effects.

Elementary schools of recent design are generally single-story buildings, often placed at considerable distance from each other. They are often provided with windows 7 ft or more in height extending the full length of one or more classroom walls. These large glass areas constitute one of the *greatest problems in maintaining an optimum indoor* atmospheric environment.

Secondary or high schools are more often two- and three-story structures but present problems only slightly less severe than grade schools. Separation of school buildings results in increased cost of the mechanical systems.

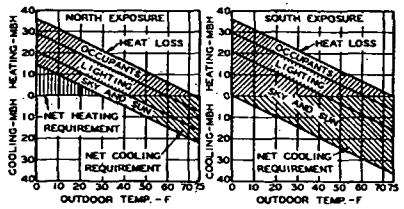
A further characteristic of school buildings is a wide variation in use and occupancy. Classrooms (the largest single group of occupancies), lecture rooms, assembly rooms, auditoriums, and other similar areas have uniformly dense occupancies. Gymnasiums, cafeterias, laboratories, shops, and similar functional spaces have lighter occupancies and also have different and varying ventilation temperature requirements. Many schools include multipurpose rooms serving as auditoriums, gymnasiums, and community centers.

The normal periods of operation are five days per week for nine months per year, with complete shutdown during week-ends and vacation periods. Few schools operate during the summer months and therefore do not require complete air conditioning, except in southern climates. Systems for administration areas, gymnasiums, auditoriums, and multi-purpose rooms, *suitable for community activities*, will often be operated at times when the systems for classrooms and other general educational areas may not be in operation.

Automatic control of temperature and system equipment is a necessity if comfortable conditions are to be obtained. Proper application of controls may return the cost of investment by savings in labor and fuel within a year or two.

Frequently, insufficient consideration is given to provisions for access and maintenance with the idea that the mechanical system is a fixed part of the structure and should last as long as the structure, without attention.

School boards are often criticized by their constituents for spending large sums of money for so-called luxury items, with the result that economy in construction and design becomes a paramount factor. This often tends to limit size of the mechanical equipment selected below that required to maintain a proper indoor atmospheric environment. However, many schools in areas having warm spring and fall climates are now being designed to include air conditioning, at least in spaces of densest occupancy and greatest use.



CRITERIA FOR DESIGN

Comfort, cleanliness, reduction of odors, maintenance of alertness, compliance with codes, installation cost, ease and cost of upkeep, cost of operation, and adaptability to control in relation to periods of use as related to outdoor conditions are the chief criteria by which a design for maintenance of indoor environment for learning may be judged.

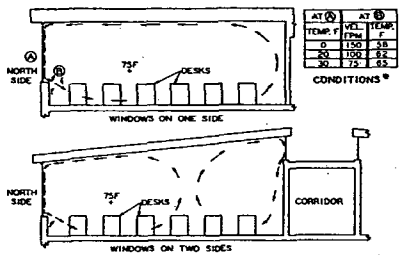
Comfort, which may be defined as freedom from strain in accommodating to the environment, is a necessity. Uniformity of air movement and temperature within the space is required to provide a comfortable environment. Fundamentals in this respect are discussed in Chapter 6, Physiological Principles, and Chapter 20, Air Distribution. Intermittent currents of air or air movement at varying velocities may result in discomfort. Similarly, variations in temperature may contribute more to discomfort than uniform maintenance of slightly higher or lower temperatures.

Odors, while they may not be deleterious to health, are disagreeable and distracting, even to the point of being nauseating. Odors should not be perceptible in schoolrooms.

Local codes may establish requirements for construction, glass areas, ventilation rates, etc., which exceed values used in normal design practice.

Basis: Floor area—1000 sq ft. Windows on one side only—240 sq ft. Heat transmission factors, U; roof—0.15, wall—0.25, glass—1.13. No infiltration. Heat gains based on artificial lighting at 2.3 watts per sq ft of floor area. Occupants, 35. Solar intensity and incidence at 45 deg N. latitude, December 1. Windows shaded by venetian blinds. Since the consideration is cooling, a room temperature of 75 F, instead of the 72 F shown in Table 1, was used in the above charts. Net cooling requirement for the south exposure approaches that of the north exposure on a day when the sky has a heavy cloud cover.

Fig. 1 . . . . Typical Net Heating and Cooling Requirements of Classrooms



Installation cost is a prime consideration in design. It should be considered in relation to the overall cost of school operation. The cost of maintenance is reflected in man hours required to provide proper operation and reasonable life of the equipment. Proper location, access, and working space for the equipment are reflected in reduced operator or custodian time. Some systems require more frequent attention, overhaul, or replacement than others. Operating costs may be held to a minimum by: (1) selection of the proper fuels for system requirements based on fuel economics in a particular area; (2) providing flexibility for operation of sections of systems according to use; (3) provision of adequate automatic temperature control and system control.

Periods of use contemplated for the entire school building, or sections of it, due to summer school, or community use of an auditorium throughout the summer or during spring and fall months (in a region where these are mild) may influence a decision to include air-conditioning systems.

DESIGN CONSIDERATIONS

Design for the required indoor environment for learning must be made in consideration of the heat losses, heat gains, and air movements; ventilation means and ventilation rates; space temperature requirements; variability of occupant density; independent operation of various spaces; practicability of cooling; means of cooling (if it is to be included in the design); and automatic control of the environment.

A typical illustration of heat losses and heat gains in classrooms is presented in Fig. 1, applicable for sun effect to about 45 deg north latitude and design temperature for heating of 0 F. For the classrooms shown and based on the construction and conditions described in the footnote, heat gains in the classroom with north exposure equal the heat losses at 32 F. In the south classroom, practically no heating is required after the room is occupied and lighted. Accordingly, heat is required in the south classroom only for warm-up. Cooling is required in north classrooms at outdoor temperatures above 32 F and, in south classrooms, at all temperatures above 0 F. Conditions shown for the north classroom would apply to a south classroom when the sky is fully overcast.

** Conditions shown at windows are conservative; vary with number and shape of cross-members. Temperatures are often lower; velocities often higher.*

Fig. 2 . . . . Natural Air Currents in Classrooms

Natural air movements or air currents prevailing in the space must be taken into account in design. Fig. 2 illustrates two conditions: the first having windows located along one side, the second having windows for cross-lighting. Measured conditions are shown for classrooms of the first type. It is significant, as will be noted in these illustrations, that, even though the room temperature at the control point may be at the desired level, uncomfortable conditions could be expected for the students in the first or second rows paralleling the windows. Direct radiation installed at the glass exposures cannot be fully effective in warming the descending currents of cold air unless it extends the full length of the windows, is located close to the window sill, and is in operation whenever the outdoor temperature is low enough to cause these downdrafts.

Ventilation means and rates are largely fixed by state and municipal codes and vary considerably with type and intended use of any building. Applicable ventilating systems are shown in Table 1. Natural ventilating systems are those relying on opening of windows to admit and exhaust air. Mechanical supply or exhaust systems are those using fans to supply or exhaust air. Natural ventilating systems are not suitable for spaces such as gymnasiums, auditoriums, cafeterias, and meeting rooms, because of size or density of occupancy; nor for laboratories, large toilet rooms, locker rooms, or kitchens in which intense odors are common; nor in shower rooms where high vapor concentrations are likely to occur. It is not possible to obtain consistently good room conditions in classrooms by means of any ventilating system that depends on openable windows for introduction of air. This is the case with each of the natural ventilation systems shown in Table 1. The problems are due to the following factors:

1. At low outdoor temperatures, the windows are kept closed, resulting in high odor intensities.
2. As outdoor temperatures rise, up to temperatures of 60 F, uncontrolled, uncontrollable, and variable drafts will occur in the occupied zone. Typical conditions are shown in Fig. 3.
3. Frequent adjustment of window openings by the instructor, with consequent distraction from teaching duties, will be necessary to provide adequate ventilation without excessive drafts and to maintain proper room temperature.
4. Manual readjustment of window openings is an erratic method of controlling ventilation.
5. The advantages of saving time and obtaining greater accuracy of temperature control are lost.

12. Showers	No	No	No	Yes	No	75–80

[a] Subject to conditions. See text. [b] If permitted by code. [c] Unless rooms are interior. [d] If rooms are small and have openable windows.

Temperature requirements of various spaces depend on occupancy, function, degree of activity, and type of clothing. Values generally accepted are listed in Table 1.

In meeting spaces such as auditoriums, cafeterias, gymnasiums, and the like, the variability of occupant density may warrant the use of separate units or systems for the several spaces in order to permit their individual operation without operating the entire school system.

It may be practicable to counteract the net heat gains shown in Fig. 1 or some of them by cooling with ventilation air or other means besides refrigeration. This would require the use of mechanical air supply with sufficient cooling capacity at a 55 F outdoor air temperature to offset the net heat gains. If the amount of air required results in an excessive cost of the mechanical system, a study should be made of means of reducing the various cooling load sources, particularly the solar load. When outdoor temperatures are in excess of 65 F, windows with ample opening to produce rapid changes of air in the space are necessary to maintain comfortable conditions, unless cooling by refrigeration is installed. When the outdoor temperature is above 65 F, relatively high velocity air movement in the space is not objectionable from the standpoint of comfort. Even under the most favorable conditions, ventilation systems cannot maintain comfort when the outdoor temperature exceeds 72 F.

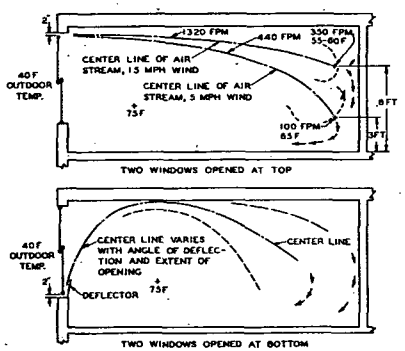
DESIGN OF THE MECHANICAL PLANT

Heating, ventilating, and cooling loads are computed according to the procedures given in Chapters 9, 11, 12, and 13. The performance requirements of the various parts of the system, whether combined or operating separately, according to use, are then established, with due consideration being given to the method of control and operation of the entire school project. Heating requirements should be determined for design conditions and for warm-up periods, the heaviest warm-up load being that which occurs after a weekend shutdown when the outdoor temperature is at design value.

The load applicable during occupancy, considering net heating and cooling loads, is determined and evaluated as shown in Fig. 1. If planned use of the building extends through the summer, cooling design dry-bulb temperatures used are those established by the ASHAE Technical Advisory Committee on Weather Design Conditions which are shown in Column 6 of Table 2, Chapter 13, and referred to as "TAC 2½% Basis." Design temperatures in common use, both dry- and wet-bulb, may also be found in the same table in Columns 7 and 8. For detailed analysis of frequency of occurrence of extreme conditions by months, reference may be made to *Region Climate Analyses and Design Data*, published in 1951 by the American Institute of Architects. These analyses are available for all United States areas.

The requirements of each of the mechanical systems incorporated in a school plant are as follows:

1. An adequate warm-up rate for heating, the ability to raise room temperatures to required conditions shown in Table 1 within an acceptable interval of time when the outdoor temperature is at design value. Usually, warm-up requirements after a weekend shutdown are used as a basis.
2. Maintenance of indoor design temperature when cooling is required. Considering the heat gains shown in Fig. 1, a typical analysis of ability to provide cooling with outdoor air is shown in Fig. 4.
3. Uniformity of air motion, discussed under Criteria for Design. Generally this requirement is satisfied by a system providing constant air flow, with proper distribution of the air supplied.
4. Uniformity of temperature of supply air, discussed under Criteria for Design.
5. Introduction of ventilation air, according to applicable codes; otherwise on a rational basis, as discussed in Chapter 6 for quantity and Chapter 20 for distribution.
6. Interception of deflection of window drafts in rooms having extensive fenestration, such as classrooms. (See Fig. 2.)
7. Acceptable noise levels which will depend on location of the school and on the equipment provided.



TYPES OF VENTILATING SYSTEMS

Any ventilating system provides air circulation and thus includes means of supply and exhaust. Ventilation systems may be classified by the type of supply (window or mechanical) or exhaust (window, gravity, or mechanical).

Air Supply Methods

Windows are generally of double hung type or consist of metal architectural sections, the bottom section being arranged to swing inward to deflect air upward and the top section to swing outward from a hinge at its top or center. If double hung windows are used, a deflecting device, generally of glass, to prevent interference with light transmission, is provided at the bottom to deflect incoming currents upward, as illustrated in Fig. 3, and thereby prevent them from blowing directly on room occupants at desk level. Since windows require manual opening, proper control of air currents cannot be provided.

Mechanical air supply is generally provided by a central

Wind[a] Mph	Air Volume Cfm	Cooling in MBh			
		40 F Outdoor Temp.		55 F Outdoor Temp.	
		Required[b]	Obtained	Required[b]	Obtained
0	0	19.0	0	27	0
5	730	19.0	25.3	27	14.5
15	2190	19.0	69.0	27	39.5

duct system, the air being delivered through wall grilles or ceiling diffusers, or by self-contained units within the rooms, such as unit ventilators and unit conditioners located at the outside walls. Grilles are generally located most conveniently at the inside or corridor wall. They must be of the deflecting type, deflecting upward in consideration of the drop in the air stream when air is introduced at lower than room temperature. Diffusers are generally located in ceilings of rooms in a pattern to provide proper air distribution. In location of both wall grilles and diffusers, it is important that the air-delivery path be free of obstructions, which might be light fixtures and crossbeams, since presence of obstacles will result in uncontrollable and turbulent currents of air extending into the occupied zone and causing drafts. Grilles and diffusers are generally selected to provide a terminal velocity of 50 fpm at approximately one-fourth the distance from an opposite wall or other obstacle to air flow.

Exhaust Methods

Windows, when used for exhaust, are opened at the top to take advantage of natural rise in the warm air to be exhausted. Windows are not fully effective for exhaust purposes, except in completely still weather. Typical conditions are shown in Fig. 3, indicating that, if the windows are on the windward side, air is introduced rather than exhausted.

Gravity exhaust ventilation is obtained through exhaust grilles in the ceiling (or in a wall away from the windows)

Basis: Cooling requirements shown in Fig. 1.
A = Net heat gain with ventilation air controlled at room temperature of 75 F.
B, C, and D = Net heat gains using 525, 1000, and 1500 cfm, respectively, controlled to 55 F, minimum. Cooling air temperature will be higher as outdoor air temperature rises above 55 F.

Fig. 4 . . . Typical Cooling Capacities, Using Outdoor Air

connected to roof ventilators. Air is exhausted by wind effect and chimney effect due to differential pressure resulting from thermal head. This type of exhaust is used in conjunction with air supply obtained by admitting air at the windows. Satisfactory air changes can be obtained by this method within limits shown in Fig. 3, if the room ventilators are adequately large. However, room conditions cannot be fully acceptable, since objectionable cold drafts are certain to occur in cold weather. Control of conditions depends on manual adjustment of window openings, a method that is reasonably satisfactory only in mild climates, but is not recommended where the design temperature is lower than 30 F. Gravity exhaust ventilation may be used with satisfactory results in combination with mechanical air supply systems.

In *mechanical exhaust systems* the roof ventilators described in preceding paragraph on *gravity exhaust ventilation* are replaced with motor-driven exhaust fans. If this system is used in conjunction with *window supply of air*, it should be remembered that when windows are closed, replacement air is drawn from the corridor or the ventilation rate is greatly reduced. At such times, negative pressures will prevail in the building, with adverse effects on incinerators, hooded equipment, and other local exhaust and fuel-firing equipment.

TYPES OF HEATING AND COOLING SYSTEMS

Systems may be classified according to methods of heating and cooling. Each may be combined with means for ventilation in various ways. Only a few states have specific requirements with respect to types of systems. Accordingly, except in these states, engineers and administrators of school construction are free to analyze and choose kinds of systems. The possible combination of such systems are extremely numerous. A discussion of those encountered most often will follow.

Direct Radiation

This type of heating includes cast-iron radiators, cast-iron or nonferrous convectors, and continuous finned-pipe heating elements in connection with steam or water heating systems (see Chapters 14, 26, and 28). The radiation must extend the full length of the outside or window walls and the full width of high windows used in cross-lighted designs illustrated in Fig. 2. Control is obtained by manual valves, by individual automatic control valves for each room, or by an automatic valve or valves controlling zones of the system according to exposure.

Direct radiation may be used with natural ventilation, natural ventilation with gravity exhaust, and natural ventilation with mechanical exhaust. It is designed for the warm-up load and to provide a warm curtain of rising air to mix with the incoming cold air to temper it. However, it is inadequate for this purpose, because heating requirements are satisfied at relatively low outdoor temperatures as soon as classrooms are occupied and lighted, as illustrated in Fig. 1. The system requires the teacher to adjust openings for ventilation. Installation costs can be relatively low.

Electric Heating

This consists of electrical heating elements in baseboard type of radiation extending the full length of the window walls, electric ceiling panels, or panels formed of heating cable buried in the ceiling plaster. Control of heating is automatic by means of individual room thermostats. Any of the ventilating systems discussed previously can be combined with electrical heating, much as discussed under Direct Radiation. Electrical heating has the same shortcomings as direct radiation; namely, that when classrooms are occupied and lighted, heat is not available for counteracting downdrafts at windows. The system requires the teacher to adjust openings for ventilation. The cost of energy will depend on the local electrical rates.

Panel Heating

Floor panel heating is adaptable to the slab-on-ground type and to the open-corridor type of school, particularly in the warmer climates. Design data are given in Chapter 30, Panel Heating, which also describes features of panel heating control systems. (See also Chapter 43, Automatic Control.) The floor system lends itself well to individual room control, although zone control, including several rooms of the same exposure in the same zone, is practicable. *Floor panel heating systems* are adaptable in areas having design temperatures down to 0 F. Since the requirement for heating is materially reduced when the spaces are occupied and lighted, as illustrated in Fig. 1, the panels should be constructed to have minimum mass and thus minimum storage effect. This is accomplished by using a slab, only sufficiently thick to enclose the tubing or piping, underlaid by a slab of insulating concrete. Even with light concrete panels, there is enough storage effect to cause overheating after warm-up and to make it difficult to follow rapidly changing loads. Any of the types of ventilating systems already discussed may be combined with panel heating systems. However, the panel heating system cannot be effective in combating the natural condition of downdrafts at the windows. The system requires the teacher to adjust openings for ventilation. The panel system is well adapted for use in primary classrooms with slab-on-ground floor construction, where students spend much time on the floor.

Central Indirect Air Systems

In these systems, air is supplied for ventilation and heating. At a central point or points, outdoor ventilation air and recirculation air is mixed and heated by automatically controlled steam or hot water coils. Gravity or mechanical exhaust is coordinated with the air supply system. The central system can be arranged to recirculate air from window sills to intercept the flow of uncontrolled cold window drafts into the classroom. Such returns are fully effective only if the openings are located in the window sills; if located below the sills, the natural air currents will not be intercepted. There are many variations of the system, which may include features of central systems described in Chapter 19. Air supply may be controlled by zones of similar occupancy and identical orientation. Individually controlled booster or reheat coils may be located within ducts leading to each of the spaces. Individual room control may also be provided by a double duct system, equipped with mixing dampers for each room located within a short distance ahead of the supply grilles or diffusers serving the room. Central air conditioning can be included.

Split Systems

The central indirect air systems may be combined with direct radiation or convection units described in the previous section, Direct Radiation. In this combination, air may be supplied by the ventilating system at constant temperature, usually 55 F, when the outdoor temperature is less than 55 F. In this case direct radiation may be designed to take care of the building heat loss. In order to prevent window drafts, the temperature of the ventilation air should be controlled to require operation of the direct radiation when the outdoor temperature is below 55 F. The direct radiation is controlled by automatic valves operated by a room thermostat for the individual room. This system has wide flexibility.

Central Direct-fired Air Systems

These systems are forced circulation warm air furnace systems. They may be arranged for single or double duct air distribution, as discussed under Central Indirect Air Systems. This type of system is further discussed in Chapter 18, Warm Air Heating. They are usually installed with zone controls and arranged to permit use of any desired proportion of outdoor air during periods of space occupancy. Mechanical cooling may be obtained by installation of cooling coils in the main supply ducts.

Unit Ventilators

Unit ventilators are used in classrooms to provide heating, controlled ventilation, and cooling, using outdoor air as the cooling medium. Auditorium unit ventilators are used in large rooms such as auditoriums, gymnasiums, and large lecture rooms. Classroom unit ventilators are often combined with matching storage cabinets or may be combined with ducts extending the full length of the windows and arranged either to discharge air upward along the window sills or withdraw air at the window sills and thereby prevent downdrafts from the windows. In order to effectively intercept natural downdrafts, the return grille must be located with the top of the unit at the level of the window sill. Classroom unit ventilators may also be combined with extended finned-pipe radiation at the window sills to combat cold window downdrafts. Electrical unit ventilators are also available. Unit ventilators using hot water for heating and chilled water for cooling are used for school buildings where year-round use is contemplated or where warm fall or spring seasons warrant the installation of air-conditioning equipment. These units and their controls are described in Chapter 15, Unit Ventilators and Unit Heaters. The noise level of the unit ventilators under the operating conditions of the installation should be considered. These systems have a high degree of flexibility.

Unit Conditioners

Unit conditioners are essentially the same as unit ventilators, discussed above, except that the cabinets contain refrigeration equipment, a direct-expansion coil, and a steam or hot water coil piped from the central boiler source. Noise

levels of unit conditioners are generally somewhat greater than those of unit ventilators. Unit conditioners are described in Chapter 16, Unitary Air-Conditioning Equipment.

AUTOMATIC CONTROL

Discussion of automatic control in this chapter will be limited to general factors peculiar to school systems, and their effect on control or the need for it. Chapter 43, Automatic Control, provides a detailed discussion of the proper application of automatic control to the various system elements normally encountered.

Automatic temperature control equipment is justified in school systems because manual control will not maintain the temperature or environment within desirable limits.

Automatic control, made an integral part of the system design, can reduce the *initial cost* of the mechanical installation. Examples of this type of control include *warm-up clocks* or low-limit thermostats, which prevent the use of outdoor air until the building has been heated for a set period of time, or until a minimum space temperature is reached. Such controls permit selection of the minimum size of equipment such as boilers, furnaces, burners, coils, piping, etc., having the least excess capacity for warm-up purpose. Controls to prevent the heating of service water in large storage tanks during the warm-up period accomplish a similar result.

Controls which reduce the man-hours of attendance at the heating plant or reduce fuel costs, can reduce *operating costs*. Time clocks, relays, temperature and pressure control, which allow the starting of the heating plant without the presence of supervising personnel, are included in this category, together with controls to reduce the use of outdoor air during warm-up periods.

Where fans and extended surface coils are used to maintain the temperature in an occupied space having outside exposure, it is not possible to control the capacity of the equipment manually without producing alternately high and low space temperatures because of the rapid changes in load due to shifting occupancy, variation in solar intensity, and wind variation in speed or direction, and the relatively high capacity of this type of equipment. Where occupancy is particularly dense, the changes in load due to changes in occupancy alone are enough to make proper automatic control necessary in order to maintain space temperatures within acceptable limits. This applies to a large percentage of the spaces in a school building.

There are many other factors or conditions that make proper automatic control necessary in order to achieve acceptable environmental conditions. Those already discussed illustrate some basic considerations in applying temperature control to mechanical systems for schools.

OPERATION

The proper method of operation of a system depends upon its design and the automatic control applied to it and will vary with each individual system. To insure good operation throughout the life of a system, it is essential that adequate written instructions be prepared and made readily available to the operating personnel. There should be at least two copies of the instructions, one of which should be placed in a secure depository to insure its preservation in good condition during the life of the building.

The operating personnel should be thoroughly instructed regarding proper operation of the equipment upon completion of the installation. Someone having authority in the school administration, in addition to the operating personnel, should be instructed in the operating characteristics of the system, not only to insure that a change in the operating personnel does not result in the loss of knowledge required for the proper operation of the system, but also to insure that the operating personnel adheres to the instructions.

It is seldom that the personnel in charge of the operation of a school system has training particularly applicable to the characteristics of mechanical equipment or the automatic control applied to it. Therefore, it is essential that this type of operating personnel be made to understand the exact limits that must be observed in adjustment and operation of the system. Where temperature control is applied to a system, it must be realized that any instrument used for control purpose is of necessity very sensitive to any change or adjustment made in the setting of the instrument. Therefore, it is necessary that only personnel fully trained in the proper handling of the instruments should make adjustments other than those expressly designated as proper for the operating personnel.

It is common practice for officials in large school districts where there are many buildings to employ specialists acquainted with the adjustment of critical items of equipment such as temperature and automatic control. Where individual schools do not have such personnel available, it is necessary that the operating personnel be instructed to communicate with qualified service agencies to make changes in automatic control settings and instrument characteristics when they are found to be necessary by experience in the operation of the system. Continuing service contracts for proper maintenance of equipment can be had from companies in this field.

When systems are installed and designed on the basis of natural or gravity ventilation, the teacher or person in charge of the individual room or space must perform the functions of adjusting window openings or ventilator settings to provide the conditions of comfort and proper environment in the space. To accomplish efficient operation of the system and maintain a suitable environment, it is necessary that these people be instructed in detail regarding the techniques necessary to achieve the proper environment. It is necessary that the administrative authorities supervise the maintenance of such conditions by periodic checks on the efficiency of the people responsible for the spaces.

MAINTENANCE OF MECHANICAL SYSTEMS

The proper maintenance of a mechanical system will result in a minimum of repair and the extended life of the system equipment. As is the case with operating instructions, it is essential that written instructions for the maintenance of the system be prepared and given to the owner when the system is completed and placed in his charge. These instructions should include detailed information on the lubrication and care of each item of equipment. A schedule showing items of maintenance to be performed for each month of the year should be prepared.

Name plates and identification for each valve and item of equipment should be prepared. Manufacturers' catalogs and parts lists for the equipment should be obtained. One copy of each of these items should be placed in a secure depository, together with the operating instructions.

A list of the proper service agencies should be prepared and placed in the hands of the operating personnel. Any changes in service agencies should be recorded for the benefit of the administration as well as the operating personnel.

CHAPTER 48

TRANSPORTATION AIR CONDITIONING

Railway Passenger Car Air Conditioning; Passenger Bus Air Conditioning; Automobile Air Conditioning; Aircraft Air Conditioning; Ship Air Conditioning, Heating and Ventilating, Air-Conditioned Space Treatment, Systems and Controls

THE principles of air conditioning applying to stores, restaurants, hospitals, theaters, and homes are applicable to railway passenger cars, passenger buses, automobiles, streetcars, trolley coaches, airplanes, and ships. However, equipment used for mobile applications differs from that used for stationary purposes in that it must meet additional requirements. Equipment must be compact, accessible for quick inspection and servicing, light-weight and unaffected by vibration and impact. Freedom from vibration which could be transmitted to supporting vehicle and thus to passengers, is essential.

RAILWAY PASSENGER CAR AIR CONDITIONING

The railway passenger car represents a very difficult air-conditioning problem. Space is strictly limited so that all equipment and ducts must be reduced to minimum size. Electric power supply and water supply also are limited. All equipment must withstand severe vibration and shock, and must be very reliable since servicing points are frequently far apart.

During the heating season it is necessary to heat conventional cars with steam from the locomotive at pressures that may vary from 250 psig to only 5 or 10 psig on the last car in long trains. Passengers in window seats sit only a few inches from cold outside walls and windows, and are close to heating surfaces installed along sides of cars. Sudden changes in load may be caused by changes in sun, wind, or train movement. Even in coldest weather, outside doors must be opened frequently.

During the cooling season, the problem is further complicated by a highly concentrated internal load due to the passengers. Air distribution problems are increased by low ceilings and short air throws.

Heating

The heating of passenger cars is accomplished by using a split system consisting of an overhead air-circulating system with heating and cooling coils, and heating surfaces (floor heat) along car sides. The floor heaters, which usually consist of finned tubing, may be made more effective by addition of covers designed to increase gravity air circulation, and to direct the warm air from finned heating surface along cold outside walls and car windows. In some new cars, wall convector panels are used and extend the full length of the car, with air intakes along the floor and outlets at window sill height and at window head height in dead-light panels. The heated panel protects passengers from cold outside walls, and the chimney effect of the panel duct increases air flow and improves heating surface effectiveness.

Floor heat is supplied by introducing steam into an inner tube within a finned tube or by means of a separate steam-to-liquid heat exchanger. The liquid (usually an antifreeze) is mechanically circulated through plain finned tubing. When steam is used directly, the tube-within-a-tube construction makes it possible to obtain uniform distribution throughout the length of the car. It is achieved by means of heat transfer between the steam within the inner tube and the condensate returning in the annular space between the tubes.

The finned tubing at the floor must have sufficient capacity to offset effects of cold walls and windows during normal operation, and to heat the entire car to a minimum temperature of 60 during standby when the overhead system is not operating. The maximum capacity required (determined by standby requirements) varies with car construction and design temperatures, but is approximately 90,000 Btu per hour. This requires a heating capacity in finned tube of approximately 650 Btu per linear foot.

The overhead air heating coil must have sufficient capacity to heat the outdoor air brought into the car for ventilation, and to supply approximately 20 percent of the internal heat loss of the car so as to permit supply of floor heat at all times at an output that will not be objectionable to passengers sitting near it. The usual capacity of the overhead heating coil is approximately 100,000 Btu based on 2400 cfm of circulated air, with 600 cfm of this being outdoor air for ventilation. All Btu values are approximations of actual heating requirements, and do not include heat losses in the trainline (or leakage) or losses in the undercar piping. Present car designs have enabled the car builder to run the steam supply lines in recesses within the car body, thus greatly diminishing under-car losses.

Refrigeration

For cooling and dehumidification during summer, refrigeration may be obtained from ice bunkers, steam-jet systems, or mechanical compressors (driven directly from car axle by electric motors or by gas engines). Refrigeration required varies with load conditions, but 7½ tons per car is one capacity frequently used. Evaporative-type condensers are sometimes used in combination with the usual air condenser on either steam-jet or mechanical refrigeration.

When an electric motor (approx. 10 hp) is used to

drive the air-conditioning compressor, the electric power source is a problem. If the power source is an axle-driven generator, there is an appreciable increase in the drag on the locomotive. The power available for refrigeration, when train is stopped at a station, it limited to storage batteries. One solution to this problem is to use a direct-current generator driven by a gas engine. Another is to use a Diesel-driven alternator in a special head-end car to furnish power to the entire train. Recently there have been installations in which a Diesel-driven alternator is mounted on an individual passenger car to supply the power requirements of the car. The attractiveness of this type of installation can be increased by utilizing spare alternator capacity in winter for electric heating. If this capacity is supplemented by exhaust heat from the Diesel engine, there is sufficient capacity to heat the entire car and to provide hot water for washrooms when outdoor temperatures are above approximately 30 F. This feature is important on trains using Diesel locomotives, since it eliminates the need for operating the steam heating boiler in the locomotive during a portion of the year.

Air Distribution and Cleaning

Railway cars present critical problems in air distribution because air space per passenger is small (60 to 190 cu ft), and the sun load is great. An average passenger car contains approximately 5000 cu ft of air, and may seat as many as 80 passengers. The occupants are continually liberating heat, carbon dioxide, moisture, odors, and some organic matter from their breath, skin and clothing. The heat and moisture can be removed by cooling and dehumidification, but the other constituents can be successfully handled only by proper ventilation and air cleansing. In an average car, from 2000 to 2500 cfm are circulated by the air-conditioning unit. Some of this air may be recirculated, but a portion of it should always be brought in from outdoors. The amount of outdoor air desirable depends upon the type of car, number of passengers, air temperature, humidity, odors, and whether or not the occupants are smoking. It will vary from 15 to 90 percent of the total air circulated.

Careful attention must be exercised in specifying the rate of outdoor air taken in so as to fit the type of service adequately, and yet not supply more ventilation than is necessary. Conditioning of this outdoor air is a major factor in determining size of both summer and winter equipment.

For normal conditions, 10 cfm of outdoor air per passenger are provided. When smoking is permitted, at least 15 cfm should be admitted. In some dining cars, and deluxe sleeping cars, outdoor air rates as high as 20 to 30 cfm per occupant are used. A ceiling duct lengthwise along the center of the car is usually used to distribute the air to the interior by fans or blowers. A perforated ceiling supplied from an overhead duct, or delivery grilles and plaques designed to give considerable entrainment and mixing, are used to deliver air to the car space.

Smoking rooms present a special problem. The cloud of smoke that usually hangs near the ceiling can be broken up by directing incoming air along the ceiling at a velocity somewhat higher than that used for the rest of car. The air is exhausted through the washroom or lavatory. For compartments, provision is made in the door or partition for removal of used air. Lower berths are provided with a low-velocity air outlet.

Recirculating air grilles are usually of straight-flow types. Outdoor air intakes are usually located in the vestibule, on the side of the car, or on the roof, depending upon location of the cooling coils. On many air-conditioned cars, there are no dampers or shutters at the outdoor air intakes; the percentage of the outdoor air is controlled by adjusting flow through the recirculating grille.

Many coach cars are now being equipped with return-air ducts fitted in the structure of baggage racks. Part of the air circulated is returned to the blower unit through these ducts, and part through the car body. This arrangement reduces quantity and velocity of air returning through the car body, and removes smoke fumes at the source. This, and any other design features aimed at taking recirculated air at the floor and adjacent to both end doors (rather than drawing all recirculated air to one end of the car) also reduces infiltration of cold air in ankle-height strata, when doors are opened during the heating season.

All air circulated by the blower is filtered before passing over the cooling and heating coils. In some cars outdoor air and recirculated air are filtered separately before mixing, while in others air from the two sources is mixed before passing through a common filter. Filters in use are combinations of metal, wool, cloth, spun glass, hemp, paper, hair, and wire screen. Most filters have a viscous coating of oil for greater cleaning efficiency. Some types may be cleaned, re-treated, and re-used, while other types are discarded when dirty. Applications are also being made of electric precipitation for air cleaning. In this system the coarser particles are removed from the air by mechanical separation; finer materials, by electrostatic action.

Activated carbon units sometimes are used in addition to the regular filters for adsorbing odors and other impurities, thus reducing the amount of outdoor air necessary for ventilation.

Temperature and Humidity Control

Controls in a passenger car should be as automatic as possible. The regular train crew cannot be relied on to make adjustments for the comfort of passengers. For this reason the latest systems of temperature control have only an off-on switch to be operated by the train crew. When the system is in operation, heating or cooling is provided automatically as required.

When heating, it is important that floor-heat finned tubing be controlled at stable temperatures. Wide fluctuation in its temperature is highly objectionable because of location close to the passengers. Stable operation may be secured by cycling the floor heat on the basis of indoor conditions in conjunction with an overhead air-circulating system to maintain final car temperatures.

Because of window condensation and other problems, no attempt is usually made to raise relative humidity in a railroad car in winter time.

When cooling, the steam-jet refrigeration system is controlled in an on-off manner. Some means are ordinarily provided for operating mechanical compressor systems at partial capacity. In this case split evaporators are used, so that evaporator surface and compressor capacity can be reduced together under light load conditions.

Attempts have been made in the past, largely on an experimental basis, to control the relative humidity in railway cars. This was done by operating the air-conditioning equipment according to outdoor temperatures

and then re-heating the air to an acceptable temperature. This was found to be an expensive method of operating and the results did not justify the cost. A common method of controlling heating and cooling is to provide a thermostat to control heating only and a separate thermostat set at a slightly higher temperature to control the cooling equipment. This obtains heating control, ventilation, and cooling control and the reverse, as the case may be. A car in service can go from heating into cooling in a very short time. An example of this is found on the full-dome cars in service on several railroads in the country. In the early morning hours before sunrise, the car may be requiring a considerable amount of heat. Shortly after sunrise, the car may go into the ventilating cycle and as the sun load increases, cooling may be required. On the majority of car heating systems, frequent cycling of the compressor is prevented by the one degree difference between the heating and cooling control points and by lag imposed on the system by applying artificial heat to the heating thermostat when cooling is required. On some car heating systems, a degree of modulation is obtained by the use of split evaporation. This requires two cooling thermostats with one of them set at a somewhat higher temperature than the other. The lower temperature cooling thermostat controls a portion of the cooling capacity and, if unable to maintain the car temperature, the higher thermostat adds the remaining capacity.

PASSENGER BUS AIR CONDITIONING

The passenger bus designed for urban transportation operation presents a greater problem to the designer of heating systems than does the inter-urban bus. More frequent stops, and rapidly changing passenger load create this problem on urban vehicles. Provision of heat for the driver independent of the passenger heating system, is a further problem. The inter-urban bus, however, is usually a deluxe vehicle and may require a comfort cooling system. Space and weight limitations and vibration must be considered.

Heating

Recent designs of bus heating systems obtain improved air distribution. Heat in the engine coolant liquid is used to warm air by means of suitable finned coils and this heated air is distributed throughout the passenger space by ducts and outlets directed toward the floor. Some designs include finned surface near the floor in an application similar to that in railway passenger cars. Forced air circulation over this finned floor-heating surface has been provided to increase its effectiveness. Oil-burning booster heaters have been applied to many Diesel-powered buses to raise the temperature of the engine coolant for maximum engine operating efficiency, and to provide sufficient heat for the passenger space.

Ventilation

Air for ventilation is usually brought into a bus at the front, and distributed throughout the length of the passenger space by a duct or ducts near the ceiling. Except for a few designs employing 100 percent outdoor air for heating, no heating of the ventilating air has been provided. One type of distribution system for an inter-urban bus provides for a fixed minimum of outdoor air, and is arranged to increase the percentage of outdoor air to 100 percent when the heating or cooling load diminishes. The distribution ducts and diversion-damper arrangement of this system make available two supply ducts and one return duct for heating and for cooling, with a change-over to all three ducts to supply air during the intermediate ventilating cycle. This system permits utilization of atmospheric cooling and ventilation to the greatest degree when it can be most economically employed in the interval between the heating and cooling demand.

Conventional throw-away type filters or renewable filters are used in intake air ducts for many vehicles. Electrostatic filters have been successfully used in some installations. The need for elimination of dirt is great, but the problem is complicated by space limitations and limited power.

Refrigeration

Summer conditioning systems for inter-urban vehicles range in cooling capacity from 36,000 to 48,000 Btu per hour. Mechanical compression systems using refrigerants are used, and are powered by water-cooled gasoline engines of approximately 14 hp.

Complete systems add from 800 to 1300 lb to the weight of the coach. Sometimes an auxiliary generator driven by the refrigeration system engine is used and serves to help charge the bus battery, thereby offsetting power drain imposed by the ventilating blower. Belted reciprocating compressors and direct-driven V-type and rotary compressors are used, with engine speeds up to about 1800 rpm. Air-cooled condensers for this service require about 5000 cfm of outdoor air, and this is provided by either centrifugal or propeller type fans belted or direct-driven by the air-conditioning engine. Preventing noise and vibration from affecting passengers is of vital importance. Installations must be made for quick daily engine servicing. In all cases fuel is obtained from the main bus tanks, and in some, the main engine cooling system cools the air-conditioning engine.

Control

The simplest control system for heating of buses consists of a single thermostat, located in the passenger section to start and stop the blower of the heating unit. This method of control is not generally satisfactory because, without continuous air circulation, temperature gradients from floor to ceiling and from front to rear are quite pronounced. A more satisfactory method of control provides for continuous fan operation whenever heating is required. In this method a thermostat, usually in the return air to the heater, operates a modulating valve in the supply line to the heater to throttle the flow of engine coolant to the heater coil in accordance with bus interior temperature. On some systems a means of remotely adjusting the control point of the thermostat is provided at the operator's location. Automatic means are available for starting and stopping booster heaters in the engine coolant system, under control of the thermostat. Also, some systems provide for automatically stopping the blower of the heater unit and the booster coolant pumps when no heat is required in the bus. Outdoor air for ventilation, drawn into the bus by the heating unit blower, is usually not automatically controlled but is preset, either by means of a manual damper or by sizing the outdoor-air intake to provide the desired amount of outdoor air.

On buses equipped with mechanical refrigeration for air

conditioning one method of control includes a thermostat located in the passenger section to start and stop the refrigeration compressor. If the compressor is driven by the bus engine a clutch is provided which can be energized or de-energized by operation of the thermostat. On systems employing a compressor, driven by a separate engine, automatic means of starting and stopping the engine are controlled by the thermostat. Modulating control of engine driven compressors may be accomplished by automatic control of the engine throttle by a thermostat in the passenger section. Some systems provide for continuous operation of the compressor when cooling is required, the compressor being manually started by the operator. Temperature in the interior of the bus is maintained by reheating the air from the cooling coil. Automatic control of temperature is provided by a thermostat in the passenger space or the return air to the blower which operates a modulating valve on the engine coolant supply to the reheat coil.

AUTOMOBILE SUMMER AIR CONDITIONING

The basic components used for automobile air conditioning are fundamentally the same as in any stationary air conditioning system using the vapor compression cycle. For automobile application the source of power is always a major obstacle to overcome. The best solution to date for automobile applications is to operate the condensing unit by belt drive from the car motor and then control the variable refrigerating capacity caused by the variable car motor speed by suitable means.

One to seven or more horsepower are required. Compressors must be capable of operating at speeds of 4000 to 5000 rpm to last in this service. Refrigeration capacity required is about 1¼ to 1½ tons. Radiant heat, as well as high conduction heat gain due to single-glazed large glass areas, and lack of adequate insulation in car bodies require this much capacity. Proper air distribution to avoid undesirable drafts on passengers also requires careful design. Air distribution fans and electrical controls secure power from the car's electrical system which in some cases may require heavier generators and batteries to handle the load. Most systems weigh about 200 lb or less.

Early designs, and many current ones, have the cooling units installed in the rear of the car with the cooled air introduced through the package shelf at the rear of the passenger compartment. Cooled air is then distributed with or without ducts. Warm air is returned through a grille in the package shelf, or below the rear seat, thence through a filter into the cooling units. Refrigerant lines from condensing unit to cooling unit are carried from the engine compartment to the luggage compartment along the car frame under the body.

Performance at open-road speeds has been very satisfactory (even with early systems—when they were operating properly). Twenty percent or more outdoor air should be supplied, especially if passengers smoke. This air may be picked up by scoops on the side of the car or cowl, carried into the cooling unit, and mixed with returned warm air from the car.

Car temperature control, compressor capacity control to compensate for the variable compressor speed, and prevention of ice formation on the evaporators (a common fault of early systems) are accomplished by bypassing compressor discharge gas into the low-pressure side of the system, or cycling the compressor with a magnetic clutch. The solenoid bypass valve or a magnetic clutch is electrically operated by a thermostat, usually controlled by the return air to the cooling unit. The bypass is opened or the compressor stopped when the air gets too cold.

A recent development is a complete factory-assembled system, charged with refrigerant and ready to run, which is dropped into position ahead of the *fire wall* of the car and bolted into place. Flexible suction, liquid, and discharge lines are used to connect the refrigeration components together. This facilitates initial installation. It also simplifies removal for service and maintenance and eliminates the necessity to open the refrigeration components to the atmosphere with resultant loss of refrigerant or infiltration of moisture into the system.

This system combines winter heating with summer cooling. It also permits use of all or limited quantities of outdoor air, with or without heating or cooling. Outdoor air is taken in through cowl openings. This air is then pulled through a combined heating and cooling coil assembly by a fan inside the car on the fire wall. Cooled air is discharged from adjustable nozzles on the dash inside the car. Hot air for heating is discharged onto the floor as with conventional car heaters. Dampers change the air distribution from heating to cooling, and dash controls activate or shut off either heating or cooling.

Temperature control, prevention of evaporator icing and compensation for variable compressor speed are controlled by a thermostat with bulb in the air leaving the evaporator. This cycles the compressor on a magnetic clutch.

Public acceptance of current offerings has been excellent. Performance has been very satisfactory. What service difficulties have been encountered have been readily cared for by car dealers who have trained personnel to render this type of service, or by competent refrigeration service organizations. Future demand is estimated as high as 10 percent of total car production by one major manufacturer, while another estimates a million or more of its cars will be equipped in the not too distant future.

AIRCRAFT AIR CONDITIONING

In recent years, heating, cooling and ventilating of airplanes has progressed from comparatively simple systems to highly complex multi-purpose designs. The attendant control problem has become correspondingly complex. On older, non-pressurized planes, the heating system consisted either of a steam boiler and radiator or a single stage or double stage heat exchanger. On both types, the cabin temperature was adjusted by positioning the face and bypass dampers. While these were sometimes moved by an automatic modulating control, in the majority of cases they were positioned by one of the ship's crew. As these planes cruised at less than 200 mph and normally operated at low altitudes, changes in outdoor air temperatures were generally gradual enough so that manual readjustment of controls could maintain reasonably comfortable cabin conditions. Nearly all of these heating systems were marginal in respect to heat available, and the main problem was lack of heat, rather than inadequate control.

Non-Pressurized Cabins

With the advent of the combustion type heater, and use of larger and faster planes, use of manual controls became impracticable. The combustion type heaters reach full rating in less than a minute after being turned on, and as they are rated at 100,000 Btu per hr and up, and since several heaters are generally used, it would take full time of one crew member to keep cabin temperature regulated. As ships of this type are not pressurized, the heating system is still comparatively simple.

In one type, two 100,000 Btu heaters are placed in parallel positions and the ram air from an external scoop is passed through the heaters and discharged through a series of distributing outlets located in the cabin ceiling. The cabin air is discharged through grilles located in the bottom walls of the cabin. An auxiliary nose heater is used by the crew to obtain additional heat for the cockpit or for windshield defrosting.

The cabin is maintained at the desired temperature by means of an automatic control which operates both heaters simultaneously. This control consists of two duct thermostats, one being mounted in the air inlet duct between the air scoop and the heaters so that it is affected by outdoor ambient temperatures, and the other being mounted in the heater outlet duct so that it is affected by the discharge air temperatures. A thermostat in the cabin is so located that a continuous stream of cabin air passes through it. This type of control has been found to respond to a 1 deg temperature change in less than a second.

As the outdoor temperature starts to drop, the outdoor air duct thermostat decreases in resistance, unbalancing an electronic bridge. This unbalance is amplified by vacuum tubes and causes a power tube to close a relay, turning on the combustion heaters. The resulting increase in temperature is sensed by the warm air duct thermostat which increases in resistance, thus rebalancing the bridge and causing the relay to open. If there were no loss by radiation or convection from the aircraft cabin, these two duct thermostats would be sufficient for adequate control. However, the cabin thermostat is given approximately 30 times more influence than the duct thermostats and so acts as the master controller, and the duct thermostats prevent overheating or underheating and keep the discharge air from alternating between extreme cold and extreme heat.

In a slightly more elaborate system, two combustion heaters supply a plenum chamber which is maintained at a constant temperature. Air from the plenum chamber is then mixed with outdoor air to maintain desired cabin temperature. All of the warm air is discharged into the cabin through the walls. The discharge grilles are located on the floor under seats, and a modulating-type controller varies proportions of heated and outdoor air necessary to maintain desired cabin temperature. The same type of control system as previously described is used, except that an amplifier operates a two-phase motor capable of positioning control dampers instead of operating a relay which would merely open and close the fuel valve. An auxiliary duct, running from the plenum chamber, is used by the pilot as a source of windshield defrosting air.

Pressurized Cabins

With the advent of the new high-speed pressurized transport planes, and the addition of cabin cooling in addition to heating, the control problem becomes more complex. On all of these airplanes, the heat of compression from cabin supercharger must be controlled, the air cycle or expansion turbines must be turned on and also, the heat exchanger or combustion heaters, which are used in the system when cooling is required for additional heat, must be automatically controlled.

Assuming that one of these airplanes is operating in an extremely cold climate, the sequence of operation would be as follows:

The automatic controller for the supercharged-air intercooler would be in full closed position, so that none of the heat of compression would be removed, and the air would bypass the expansion turbine and its compressor and the secondary after-cooler. An additional automatic controller would be operating the combustion heater and supplying the additional heat necessary to maintain the desired cabin temperature. If a heat exchanger were used as a supplemental source of heat, a modulating control operating a damper on this exchanger would run towards full heat position.

As the airplane enters a warm climate and heat requirements drop, the combustion heater would cease operation or the heat exchanger would go to full cold position, and the modulating control on the supercharger compressor would move towards the cold position. When the outdoor ambient temperature rises so high that cooling is desired, the cabin supercharger intercooler would be opened wide. If further cooling were required, the air would go into an air cycle turbine, which is modulated to deliver the required amount of cold air to maintain a comfortable cabin temperature.

Pressure in the cabin is maintained by providing a controlled, constant rate of air flow into the cabin sufficient to maintain ventilation, and adjusting the cabin-pressure relief valve setting, by means of a cabin pressure selector, to maintain the desired cabin pressure. Limits on maximum inside to outside pressure may be of the order of 4 or 5 psi, and safety controls should be provided to prevent exceeding this limit. There is a maximum rate at which the cabin can change to a newly selected value, this rate being in some cases also adjustable.

The requirements for controls of this nature are extremely rigid. It is commonplace for ships of this type to experience changes in outdoor ambient temperatures of as much as 100 deg in a space of 5 min. For this reason, speed of sensing a change and rapidity of response in the control system is essential if satisfactory control is to be accomplished. The older type thermostats cannot be used in airplanes, due to mass of the thermostat and to vibration experienced on all airplanes. All modern controls use some type of bridge system with temperature-sensitive resistors as sensing elements. In some types of controls, the bridge system feeds a sensitive balanced relay, which in turn runs a modulating motor or controls an on-off power relay. A recent sensitive and quickly responding type uses an electronic amplifier, which in turn controls a two-phase motor, or, through relays, controls a d-c motor, or merely closes and opens a power relay for on-off applications.

In addition to extreme speed and accuracy which are required of all aircraft temperature controls, they must be able to operate under great extremes of temperature, pressure and humidity, and also withstand continuous extreme vibration. Heaters should have, in addition to control from thermostats, suitable limit controls to prevent overheating due to failure of air supply, or any other cause. Also, there should be safety devices to shut off fuel in case of flame failure.

On the latest *high speed jet airplanes*, the temperature control problem is still more severe than on the latest transports; as in addition to the accuracy required, control response must be phenomenally fast. For example,

on some, the air going to the cabin from the jet engine compressor can change the temperature at the rate of 150 deg per second. This, coupled with the fact that on smaller size pursuit ships air is changed in the cabin as much as four times per minute, makes the instantaneous sensing of change and an extremely rapid control movement essential. Also, in airplanes operating at Mach numbers in excess of 0.7, the control must react to the large adiabatic temperature rises encountered.

SHIP AIR CONDITIONING

In air conditioning a ship, the designer is faced with all problems that would normally arise on shore installation plus additional factors. Mechanical ventilation is an absolute necessity for the comfort of passengers and ships' personnel, and for utility and preservation of cargo and stores. Ships are constructed with water-tight bulkheads dividing the vessel into several compartments. This complicates the running of ductwork and results in a multiplicity of both supply and exhaust fans. Temperature and humidity requirements of various spaces aboard ship vary widely. Passenger staterooms and public spaces must have year-round air conditioning which is also being applied more and more to the quarters of the officers and crew. Boiler rooms, galleys, laundries, etc., must have ventilation, and some must have tempered air. Cargo spaces are quite likely to need dehumidification in addition to ventilation.

Inasmuch as ventilation is such a necessary factor aboard ship, the majority of recently built vessels have been utilizing the air distribution system for heating purposes.

A ship is a self-contained structure quite likely to be away from repair ports for long periods. Adequate spare parts, therefore, form an integral part of equipment furnished. The same type of equipment should be used in as many places as possible throughout the ship, in order to reduce the number of spare parts to be carried.

Preliminary system design is simplified by uniformity of conditions which apply to most ships. Among such conditions are: (1) the necessity for the vessel to supply its own power, (2) the availability of an unlimited supply of low cost steam at suitable pressure, (3) limitations of available space and permissible weight.

The problem of heat transfer and insulation must be given careful consideration. The thermal conductivity of ship building material, such as steel, copper and brass, is many times the value of building material used ashore. The length of ducts between heat sources and fans necessitates extra duct insulation. Hull insulation must be of high quality, with attention given to fireproofness, low density, low thermal conductivity, ruggedness, vermin resistance, and ease of application. Board types are most common.

Duct insulation must have the same characteristics as hull insulation. Semi-rigid and rigid board are most common. Corrugated asbestos is not used because in the presence of moisture, it tends to disintegrate. There is a growing use of natural cork on chilled air ducts because of great difficulty in applying an adequate vapor seal due to space limitations.

SHIP HEATING AND VENTILATING

It is usually most economical in weight and space to use steam duct heaters for heating spaces served by mechanical supply systems. Spaces which do not have mechanical supply, or do not require ventilation in cold weather, are heated by steam convectors or, where the load is large, by unit heaters. Ventilation air, except that supplied to auxiliary and main machinery spaces, is usually preheated to temperatures of 50 to 70 F. No recirculation is used in ventilation and heating systems, but a manual reduction (25 to 50 percent) of air quantity is made during the heating cycle. All heaters are automatically controlled, and preheaters are designed and installed to minimize possibility of freezing of condensate. Preheaters are frequently located close to the outdoor air intake in order to conserve insulation and, for the same reason, zone reheaters are located as close as possible to each zone. Where a reheater serves only one space, it is commonly located in the space.

Table 1 .... Design Conditions for Ships

Area	Outdoor Design Temperatures			Indoor Conditions		
	Heating	Ventilating	Cooling	DB & R.H.		Effective Temp.
	F	F	F	F	%	F
Living Quarters	0	95	95 (DB) 80(WB)	80	50	73–74
Public Spaces	0	95	95(DB) 80(WB)	80	55	73½–74½
Naval Vessels	+10	88(DB) 80(WB)	88(DB) 80(WB)	85	50	75–78

Combinations or variations of duct type and convection or radiant heaters are used, depending upon basic design requirements, such as weight and space limitations, and the economic justification of the cost of the type selected.

Some design temperatures and humidities for various spaces aboard ship, are given in Table 1. The resulting quantities of air should be checked against typical heating and ventilation practices for ships.*

Living Spaces

The minimum quantity of ventilation air provided for any sleeping or office space, including hospital space, should be based on a temperature rise over the outdoor air of not more than 10 deg (a rise of 7 deg is more satisfactory), with not less than 30 cfm per person.

In spaces fitted for eating, recreation, or manual work, the rise may be taken at 10 deg with not less than 20 cfm per person. The same requirement applies to mechanical exhaust, although natural exhaust may be used where only a short run of duct exists.

Heat should be furnished to maintain the following temperatures:

Staterooms, Berthing, Messing and Office Spaces 70 F
Working Spaces and Shops 60 F
Hospital Spaces 75 to 78 F

Machinery Spaces

The prime purpose of machinery space ventilation is to maintain a habitable temperature for the operating

* See Ventilation and Heating of Maritime Commission Ships, by J. W. Markert (*Heating and Ventilating*, Feb. 1943, p. 333).

personnel. It is more practicable to use *spot cooling* of personnel at working areas than to attempt to obtain uniform ambient temperature. The permissible temperature rise (above outdoors) at working stations is usually 15 deg, while the overall temperature rise is usually between 30 and 50 deg.

These spaces must be exhausted adequately, preferably by mechanical means. Every attempt should be made to *remove air at or close to the heat sources. The capacity* of the mechanical exhaust systems should be greater than the supply, taking into consideration the expansion of the supply air, to insure an indraft through access openings to the space.

Heat is not required for machinery spaces, except for those fitted with electrically operated equipment, which may remain inactive during periods while in port when heating to about 50 F will be required.

Storerooms and Cargo Spaces

The ventilation provided for these spaces depends on the type of vessel, location of space, and nature of cargo.

Ventilation is required for all closed spaces. Even if ventilation is not necessary to preserve the stores or cargo, it is required to prevent the accumulation of toxic or combustible gases and odors. One air change in 15 to 30 min is common practice, except where inflammable liquids or proximity to hot spaces requires additional ventilation. Mechanical supply and natural exhaust are usually used. However, where inflammable gases may exist, natural supply and mechanical exhaust are provided.

Many ships are fitted with dehumidification facilities for eliminating damage to the dry cargo by preventing condensation and dampness. The dehumidification load consists of moisture removed from the ventilation air passed through the dehumidifier, plus the moisture on, or given off by, the cargo, packaging, dunnage, battens, and other materials in the ship's holds. The most severe outdoor condition requires a moisture removal of 90 grains (140–50) per pound of dry air, with 88 F cooling water. The largest cargo ships are provided with equipment for removing about 250 lb of water per hour.

The dehumidifying systems generally utilize silica gel or lithium chloride with inhibitor. (See Chapter 42.) In most cases central drying equipment is provided. On large passenger ships consideration is given to the use of two dehumidifying units, because the cargo-carrying spaces are usually concentrated at the extreme ends of the vessel. A simple duct system distributes the dry air to the hold supply ventilation system. These ventilation systems use outdoor air when weather conditions are favorable. Recirculation and dehumidification are used only when necessary, i.e., when the weather dew point approaches or exceeds the temperature in the hold. Two control stations are generally provided, one in machinery space and one in chart or wheelhouse. These stations are arranged so that either may change the cargo conditioning system controls from use of outside air to use of conditioned air.

AIR-CONDITIONED SPACE TREATMENT FOR SHIPS

The application of air conditioning to new American passenger ships is well established. All passenger staterooms, except steerage and third class, are usually air conditioned. This includes staterooms for ship's personnel and offices within conditioned passenger areas. Third class staterooms are air conditioned on some ships, depending on the particular trade. Theaters, lounges, smoking rooms, beauty shops, barber shops and similar closed public spaces are usually air conditioned.

All messrooms, recreation rooms, officers' offices, crew's inboard rooms, and those having fixed portlights are usually air conditioned on passenger vessels. The treatment *depends on the requirements of the operator and the* proposed itinerary of the vessel.

SHIP SYSTEMS AND CONTROLS

The types of comfort conditioning systems used to date generally have followed conventional lines, except for those serving staterooms, offices, and similar small spaces. Large public spaces are fitted with individual systems which supply dehumidified and cooled air during *the cooling cycle, and warm air during the heating cycle.* In many cases these rooms are fitted with large glass windows and doors, and require direct radiation to offset the downdraft which would occur in cold weather. Finned-tube radiation running the full length of the glass area is commonly used for this purpose. Introduction of warm air at the sill, in lieu of direct radiation, is also used.

Systems serving most public spaces are designed to provide all outdoor air as long as the refrigeration load is less than the capacity of the cooling equipment. Many central systems are simplified by using 100 percent outdoor air all-year-round. The important problem in ship air conditioning concerns the treatment of the small spaces such as passenger staterooms, offices, and crew quarters. Low headroom, congested quarters, double berths, and unsymmetric arrangements make each space a problem in air distribution and treatment.

The simplest system used for small spaces consists of a central filter bank, supply fan, preheater, and cooling and dehumidifying coil. The preheater steam valve and cooling coil water valve are controlled in sequence by a duct thermostat, in the fan discharge, set to maintain a constant outlet air temperature. Zone reheaters are provided to take care of variations in heating loads. The reheater steam valve is controlled by a submaster thermostat at the reheater outlet. Control of room temperature is obtained by operating manual dampers in the air supply to the space. A recirculation exhaust fan is frequently provided, and operates in conjunction with automatic dampers to utilize the maximum quantity of outdoor air consistent with capacity of the cooling coils.

One system utilizes the same central supply equipment and recirculation exhaust system as the one just described, except that zone reheaters are replaced by individual space hot water reheaters. Each reheater is provided with a control valve, controlled by room thermostat. Generally, a forced-circulation single-pipe hot water system is used. This system is generally used for staterooms and small spaces devoted to first and second class passengers. The average total air per person is about 60 cfm, and average outdoor air per person is about 18 cfm.

A third system, used to a limited extent, is similar to the system just described, except that each room is provided with an induction unit (floor type where possible) which reheats the primary air supply. Control of heating coil in the induction unit is the same as noted for the system described in the previous paragraph. The average primary air supply is about 40 cfm per person. Recircula-

tion is not always used. The amount of induced air varies with unit design.

A fourth less common arrangement is similar, but makes use of hot water in the induction unit in winter and cold water in the induction unit in summer. Control of the valve on the unit is obtained by use of a summer-winter type thermostat. The unit is provided with drip pan and drain piping to remove condensation. No recirculation is used.

On cargo ships, tankers and vessels not carrying passengers or not having air conditioning, heating of crews' spaces and officers' staterooms is usually obtained through a central system having filters, preheaters and reheaters. A minimum temperature of air leaving the preheater is controlled by a duct thermostat. The reheater is controlled by a sub-master discharge-duct thermostat, reset by outside master control. Relationship between sub-master and master control (wherein discharge temperature is raised as outdoor temperature drops), is set according to a schedule based on the ship's itinerary.

Ductwork for all systems described is designed for conventional velocity. However, if power is available, and suitable duct construction and adequate sound absorbing facilities are provided, high velocity systems may be used.

CHAPTER 49.

SNOW MELTING

Design: Heating Requirement, Hydraulic Requirement, Installation: Safety, Internal Corrosion, Slab Construction, Thermal Stresses, Control, Testing, Draining, Drifting Snow, Design Example

THE practicability of melting snow by means of heated coils has been demonstrated in a large number of installations in sidewalks, roadways, ramps, and runways. In addition to eliminating the need for snow removal, other advantages gained are greater safety to pedestrians and vehicles, and reduction of labor in removal of slush from floors.

The design of a snow-melting system must determine and satisfy two primary requirements: (1) the heating requirement, and (2) the hydraulic requirement. Each of these is treated in this chapter. Several points regarding installation practices are also discussed.

DESIGN

Heating Requirement

The heating requirement for snow melting is affected by four atmospheric factors: (1) rate of snowfall; (2) air temperature, (3) wind velocity, and (4) humidity. The effects of these factors can be evaluated by consideration of the action of snow falling on a warmed surface.

The first flakes fall on a dry, warm surface, and are then warmed to 32 F and melted. The water from the melted snow soon forms a film over the entire area and starts to evaporate. The evaporation of the film is a *mass* transfer from the surface to the atmosphere. In addition, there is a *heat* transfer from the film to the ambient air and surfaces.

Mass transfer due to evaporation. The rate of evaporation of the melted snow from the snow-melting slab is affected by the wind speed and the vapor-pressure difference between the air and the melted snow. The vapor pressure of air, however, is fixed by the relative humidity and the temperature of the air. If the slab surface temperature is fixed, then the evaporation loss varies with changes in air temperature, relative humidity, and wind speed.

Heat transfer by convection and radiation from the melted snow to the ambient air and surfaces. A combined film coefficient has been used with sufficient accuracy to determine the combined convection and radiation loss. This coefficient is based on a heat transfer from a *wetted* surface, such as the film of melted snow, to air. The coefficient is a function of wind speed alone. The heat transfer, of course, is dependent upon the film coefficient and the temperature difference between the surface and the air. Since the surface temperature is fixed, the convection and radiation losses vary with changes in air temperature and wind speed.

To determine evaporation and heat transfer from the melted snow to the air it is necessary to know three of the four climatic factors: (1) wind speed, (2) air temperature, and (3) relative humidity, and (4) rate of snowfall. The fourth factor, rate of snowfall, is necessary to determine the heat required to warm the snow to 32 F, and to melt it.

Before deriving equations to give quantitative values for the effects of these four factors, it is necessary to consider the insulating effect of the snow before it is melted. As stated previously, the first flakes fall on a dry, warm surface, and are then warmed to 32 F and melted. During the time that the flakes are being warmed, and before they are completely melted, they can be considered as tiny blankets or insulators. The effect of this insulation has been measured[1] and can be of considerable magnitude. Since the snowflakes cover a fraction of the surface area, it has been convenient to think of the insulating effect as an area ratio. The area covered by the snowflakes is the insulated area, and the uncovered area is the uninsulated area. The term free area ratio A_r has been adopted to represent the ratio of the uncovered, or free, area to the total area or,

$$A_r = \frac{A_f}{A_t} \tag{1}$$

where

A_r = Free area ratio.
A_f = Free area, sq ft.
A_t = Total area, sq ft.

hence

$$0 \leq A_r \leq 1$$

For $A_r = 1$, the system would have to melt the snow so rapidly that the snow accumulation would be absolutely zero. This is impossible from a theoretical standpoint, but for all practical purposes it is permissible to have $A_r = 1$ as a maximum. For $A_r = 0$, the surface would be completely covered with snow to a depth sufficient to completely prevent evaporation and heat transfer losses. Research on the insulating effects of snow indicate that there are just three practical values for the free area ratio, 0, 0.5, and 1. This will be covered in greater detail in a later section.

The equations for the heating requirements of a snow-melting system have been derived and thoroughly explained in Reference 2. The general equation for slab output, q_s, as derived and discussed thoroughly in Reference 1, is

$$q_s = q_s + q_m + A_r(q_e + q_h) \tag{2}$$

where

q_s = sensible heat transferred to snow, Btu per (hour) (square foot).
q_m = heat of fusion, Btu per (hour) (square foot).
A_r = ratio of snow-free area to total area, dimensionless.
q_e = heat of evaporation, Btu per (hour) (square foot).
q_h = heat transfer by convection and radiation, Btu per (hour) (square foot).

[a] From *Air Conditioning, Heating and Ventilating*, August, 1957, p. 87.

[1] The period covered by this table is from No. 1 to March 31, incl. with February taken as a 28¼ day month. Total hours in period = 2520. [2] The percentage in Columns 2 and 3 plus the percent under hours of snowfall total 100 percent. Note that *Hours of Snowfall* does not include idling time, and is not actual operating time. See text. [3] Snowfalls of trace amounts are not included; hence, *Hours of Snowfall* includes only those hours of 0.01 inches water equivalent per hour snowfall. [4] Output does not include allowance for back or edge losses since these depend on slab construction. [5] Percentages total 100 percent of the number of hours of snowfall. [6] *Freezing Period* is that during No Snowfall when the air temperature is 32 F or below. [7] When heat output for $A_r = 0$ equals or exceeds the heat output for $A_r = 1$, the heat transfer q_s is *from* the air *to* the slab. This occurs when snowfall is at temperatures above 32 F.

The sensible heat, q_s, to raise the temperature of the snow to 32 F is

$$q_s = 2.6s\,(32 - t_a) \qquad (3)$$

where

s = rate of snowfall, inches of water equivalent per hour.
t_a = air temperature, Fahrenheit.

The heat of fusion, q_m, to melt the snow is

$$q_m = 746s \qquad (4)$$

The heat of evaporation, q_e, (mass transfer) is

$$q_e = h_{fg}(0.0201v + 0.055)(0.185 - p_{aw})A_r \qquad (5)$$

where

h_{fg} = heat of evaporation at the film temperature, Btu per pound.
v = wind speed, miles per hour.
p_{aw} = vapor pressure of moist air, inches of mercury.

The heat transfer, q_h, (convection and radiation) is

$$q_h = 11.4(0.0201v + 0.055)(t_f - t_a)A_r \qquad (6)$$

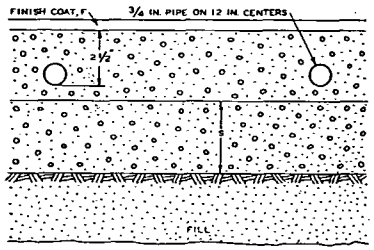
where

t_f = water film temperature, Fahrenheit.

In addition to determining the four heating requirements, it is necessary to make allowance for back and edge losses. These losses vary from 30 to 50 percent, depending upon the slab construction and fluid temperature.

The equation for the required fluid temperature to provide an output q_o has been derived in Reference 2. For construction similar to Fig. 1, the equation is

$$t_m = 0.5q_o + t_f \qquad (7)$$



where

t_m = mean fluid temperature (antifreeze solution), Fahrenheit.

Equation 7 will apply to 1 in. as well as ¾ in. IPS pipe—see Fig. 1.

Equations 2 to 7 permit the designer to determine the heating requirement of a snow-melting system. The solutions of these equations, however, require the *simultaneous consideration* of the four climatic factors: (1) wind speed, (2) air temperature, (3) relative humidity, and (4) rate of snowfall. It is not satisfactory to use annual averages or maximums for the climatic factors. If averages or maximums are used there is no assurance that they will *ever* occur simultaneously. It is necessary, therefore, to make a frequency analysis of the solutions to Equation 2 for all the occurrences of snowfall for a period of several years. Such an analysis for 33 cities appears in Table 1 which contains the operating information for a snow-melting system. For freezing temperatures (32 F and below) without snowfall the system may be *idling* which means that some heat is supplied to the slab so that there will be immediate melting when snow starts to fall. Column 4 of Table 1 gives the average temperature during freezing periods. This temperature is used in calculating the *idling load*. The other term needed to calculate *idling load* is the wind speed during the period of freezing temperatures.

The column, Hours of Snowfall, indicates the number of hours that snow is falling at rates equal to or greater than 0.01 in. of water equivalent per hour. There are snowfalls of

F = Depth of Finish Coat—Assumed as ¼ in. of concrete. Finish Coat may be asphalt but then cover slab should be reduced from 2 in. Depth of slab should always keep thermal resistance equal to 2 in. of concrete.
S = Depth required by structural design (should be a minimum of 2 in. of concrete).

Fig. 1 .... Detail of Snow Melting Panel

trace quantities about twice as often as there are for measurable quantities of 0.01 in. or more. It is assumed that these light falls can be handled by the *idling load*.

The remaining columns of Table 1 represent the frequency distribution of required heat output. This distribution is based on the solution to the basic equation for two values of the free area ratio, A_r. This distribution represents the basis of the analysis and is also the basis for Tables 3 and 4.

For specific conditions, or for cities other than those given in Table 1, the solutions to Equation 2 are given in Table 2.

Table 2....Heat Output and Fluid Temperature for Snow-Melting System

From *Air Conditioning, Heating and Ventilating*, August 1957, p. 92.

* Where idling rate is greater than Class I design rate, idling rate is given in parenthesis and should be used as Class I design output.

[1] For Class I (residential) Systems, the design output is set at that required heat output (see Table 1) when A_r = 0 at the 98th percentile of the frequency distribution; that is where 98% of the hours have this output or less.

[2] For Class II (commercial) Systems, the design output is the maximum output when A_r = 0 in Table 1 (last column).

[3] For Class III (industrial) Systems the design output is determined by the following four requirements: (1) Output is never exceeded for two consecutive hours; (2) Output for A_r = 1; Table 1, is at least 1 Btu per hour per sq ft greater than maximum output for A_r = 0; (3) A_r is greater than or equal to 0.5 maximum requirement shown in Table 1 for A_r = 1. That is, $q_s = q_r + q_m + 0.5(q_c + q_k)$ for the conditions where $q_r = q_c + q_m + q_k + q_r$ are a maximum; (4) The free area ratio A_r is unity for at least 98% of the hours listed in Table 1.

[1] From Table 1, Column 3 × 3630 (hr per year).
[2] Rate when idling, Btu per (Hr) (Sq Ft) = $(0.27v + 3.3)(32 - t)$, where v = wind speed from Column 5, Table 1, and t = air temperature from Column 4, Table 1.
[3] Product of the two preceding columns.
[4] Hours of Snowfall, from Column 7, Table 1.
[5] See footnote for Table 2.
[6] Based on the condition that surface temperature is maintained at 32 deg until required output exceeds designed output, at which time design output is used regardless of required output. Distribution of required output based on Table 1.
* Based on Idling Rate rather than Design Rate.

Air Conditioning, Heating and Ventilating, August 1957, p. 94.

Notice that these solutions are for a relative humidity of 80 percent. For other values of relative humidity, corrections can be obtained by using Equations 8 and 9 as follows:

$$\frac{dq_s}{dp_{ss}} = -A_r(0.0201v + 0.055)h_{fg} \qquad (8)$$

$$\frac{dt_m}{dp_{ss}} = \frac{-A_r}{2}(0.0201v + 0.055)h_{fg} \qquad (9)$$

Snow-melting installations are classified in Table 3 according to types as Class I, II, or III. These classes have been discussed thoroughly in Reference 3, and are defined in

the footnotes to Table 3. Briefly, snow-melting systems are classified as to the urgency for melting as follows:

Class I (minimum): Residential walks or driveways and *interplant areaways*.

Class II (moderate): Commercial (stores and offices) sidewalks and driveways, and steps of hospitals.

Class III (maximum): Toll plazas of highways and bridges, and aprons and loading areas of airports.

These classifications depend upon the allowable rate of snow melting. For example, a residential system does not have to melt snow as rapidly as a commercial system. In fact, a depth of snow of an inch for an hour or so during a heavy storm might not be objectionable with a residential system. On the other hand, a store manager would consider the system inadequate if half an inch of snow accumulated on the sidewalk in front of the store. The difference, then, between a Class I system and a Class II system is in the required ability of each system to melt snow. The one feature that is common to all classes is that the systems must be adequate for some combination of weather factors. The designer may select equipment having capacity to melt snow whenever conditions are milder than some critical values, but be willing to have an inadequate system for a given fraction of the time. In other words, the designer will take a calculated risk providing he knows the odds of that risk. For a residential system, where initial cost must be at a minimum, the designer must accept more frequent snow accumulations.

Table 3 contains the design heat requirements for the 3 classes of snow-melting systems. Under Class I systems, the values in parentheses are *idling rates* and, since they exceed the Class I design rates, should be taken as design output for this classification. Design rates may be altered by the designer if he feels that a particular job should have different design criteria from those given in the footnotes of Table 3. Any change in design conditions used should be based on the frequency distribution given in Table 1.

Use of Tables 1, 3, and 4 is illustrated by *Example 1*.

Example 1: An engineer has been retained to design snow-melting systems for the service areas of a turnpike running from the eastern edge of the Wisconsin-Illinois border northwest to the Wisconsin-Minnesota border just east of St. Paul. He decides that Chicago data will be adequate for the southern terminus and that Minneapolis-St. Paul data will be adequate for the northern terminus. His problem is to determine the heat and hydraulic requirements of the systems for service areas between Chicago and St. Paul.

Solution: Assume, for this example, that the city in question is Madison, Wis. Weather bureau records indicate that the annual average number of days with snow cover of an inch or more would be 100, and that the engineer can assume an average snowfall of 40 inches. In addition, he can estimate about 11 days per year with a snowfall of an inch or more (see Reference 3).

For the walkways to the restaurant from the parking area a Class I design rate could be used. This rate could be taken as 90 Btuh per sq ft. This is in good agreement with data in Tables 3 and 4 which give the rate at 89 (design rate) for Chicago and 95 (idling rate) for Minneapolis.

The lanes leading from the turnpike to the gasoline pumps and parking areas should be rated as Class II areas. A check of Tables 1 and 3 would indicate that 160 Btuh per sq ft would be adequate.

If an emergency area were included, for a wrecking truck, ambulance, or police garage, it would be wise to consider a Class III rate for such areas. An inspection of Table 1 for Chicago shows that a rate of 275 Btuh per sq ft would be adequate for $A_r = 1$ for 99.4 percent of the time. Similarly, 275 would be adequate 99.4 percent of the time in St. Paul. Therefore, 275 Btuh per sq ft seems sufficient for the emergency areas. Table 3 in Class III column lists 350 Btuh per sq ft for Chicago and 254 for St. Paul but for uses similar to the areas in this example, 275 should be adequate.

[a] Based on data given in Reference 6.
ν = Kinematic viscosity, (feet squared per second) (e.g. for oil at 40 F, ν = 0.000140 ft² per sec.). c = specific heat, Btu per (pound) (Fahrenheit degree). w = specific weight, pounds per cubic foot.

Hydraulic Requirement

After determining the heating requirements, it is necessary to determine the hydraulic requirements of the system. This can be done by means of the procedures explained in Chapter 4, Fluid Flow, but it is necessary to use the proper physical properties of the antifreeze solution. A complete discussion of the hydraulic problem is given in Reference 4.

The main consideration is the proper allowance for viscosity. Table 5 gives viscosities for typical fluids used as antifreezes for snow-melting systems. Viscosities are given in feet squared per second. Table 6 can be used in conversion of viscosity units. A large increase in viscosity will be noted for glycols and oils—about 20 times—as the fluid temperature changes from 160 F to 0 F. This viscosity change has two effects. First, an increase in viscosity will increase the fluid friction in the piping circuit. Second, an increase in viscosity will decrease the pump capacity—in both volume and head. The effect of viscosity on fluid friction in the piping circuit is illustrated in Fig. 2.

Table 6 .... Conversion of Kinematic Viscosity Units[a]

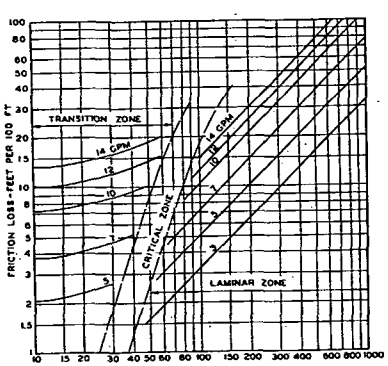
30	32.3	141.3			

Over 70.0 centistokes, SSU = 4.635 × centistokes.
[a] Kinematic viscosity in (ft²/sec = 1.076 × 10^{-5} × centistokes.
[b] Values listed for SSU (Saybolt Seconds—Universal) are for fluid temperatures of 100 F. To obtain the Saybolt Universal viscosity equivalent to a kinematic viscosity determined at a Fahrenheit temperature t, multiply the equivalent Saybolt Universal viscosity at 100 F by $1 + (t - 100)$ 0.000064; for example, 10 centistokes at 210 F are equivalent to 58.9 × 1.0070 or 59.3 sec Saybolt Universal at 210 F. (Taken from *ASTM* D 445 - 53.)

For large installations, the friction losses should be calculated by the Fanning equation



$$h_f = \frac{flV^2}{2gD} \qquad (10)$$

where

h_f = the loss in head of the fluid under conditions of flow, in feet.
l = the length of the pipe, in feet.
V = the velocity, in feet per second.
g = the acceleration due to gravity = 32.174 ft per (second) (second).
D = the internal diameter of the pipe in feet.
f = a dimensionless friction coefficient which can be determined from Fig. 4, Chapter 4. The Reynolds number can be computed from data in Table 5 of this chapter.

Solutions for the pipe friction should be plotted for temperatures at the starting condition (probably 0 F) and at the operating condition (use either 120 or 160 F). Then on the same graph, the operating curve of the pump should be plotted (see Reference 4 for such a graph). The intersection of the fluid friction curve and pump operating curve will give the operating point for the system. Table 7 can be used to allow for the viscosity effect on the pump.

The designer must decide on the tolerable viscosity limit. Generally it is between 300 and 500 SSU, although for

(For 1-in. Pipe)

Fig. 2 .... Effect of Viscosity on Friction Loss

4	4.026	0.335	1.26×10^{-2}	0.00462
5	5.047	0.421	3.14×10^{-2}	0.00186
6	6.065	0.505	6.50×10^{-2}	0.000898

commercial or private systems (where A_s is 0.5 or 0) it may go to 750 SSU.

Efficiency loss is not important, but head and capacity losses are. Reduced flow means a longer period of time for the system to become operative from a cold start.

The viscosity limit is controlled by means of a low-limit thermostat. For example, if it is desired to hold the viscosity of the solution to less than 200 SSU (43.1 ft sq per sec), then for the oil shown in Table 5, the low-limit control would be set at 0 F.

For small installations, a quick method of determining the fluid friction for a 1-in. IPS pipe circuit is given in Fig. 2.

The required pump capacity, in pounds of fluid per hour is given by the equation:

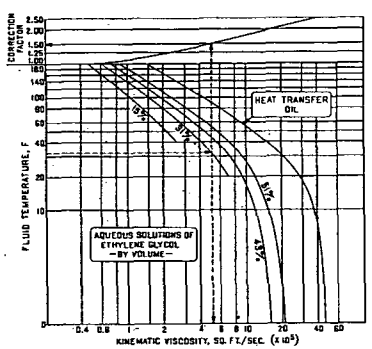
$$C = \frac{A_p q_t}{c_m \Delta t} \tag{11}$$

where

C = pump capacity, pounds per hour.
A_p = area of slab, square feet.
q_t = total heat requirement (slab output, q_s, plus back and edge losses) Btu per (hour) (square foot).
c_m = specific heat at temperature t_m, Btu per (pound) (Fahrenheit degree).
Δt = temperature drop through circuit, Fahrenheit degrees.

For a temperature drop of $\Delta t = 20$ F, Equation 11 becomes

$$G = \frac{A_p q_t}{160 w_m c_m} \tag{12}$$



where

G = gallons per minute.
w_m = mean specific weight at temperature t_m, pounds per cubic foot.

An approximate solution for systems using pipe sizes other than 1-in. IPS can be obtained by using Table 8 or Fig. 3. Table 8 is for use when the flow is in the laminar zone. Fig. 3 is for flow in the turbulent zone. For flows where Reynolds number falls between 2000 and 3000, no reliable prediction for pressure loss can be made. It is generally safe to assume the flow to be increased to a Reynolds number of 3000 with the pressure loss estimated at that flow rate.

Figure 2 is based on a pipe size of 1 in. IPS. If another pipe size is used and the flow is *laminar*, the correction factor K from Table 8 can be used. For example, assume a viscosity of 300 SSU, a flow of 5 gpm, and a ¾-in. IPS pipe. Fig. 2 shows that for 1-in. IPS, friction loss would be 15.50 ft/100 ft. Table 8 gives $K = 2.62$ for ¾-in. pipe; therefore, friction loss would be $15.5 \times 2.62 = 40.6$ ft/100 ft.

If the flow is in the *transition* zone or is *turbulent*, then Fig. 5 of Chapter 28 can be used in conjunction with Fig. 3. For example, assume a viscosity of 0.0001 sq ft/sec (56.5 SSU), a flow rate of 14 gpm and a 1¼-in. IPS pipe size.

(For $N_{Re} > 3000$)
(Based on data given in Reference 6)

Fig. 3 . . . . Friction Correction Factor for Viscosity

Fig. 5, Chapter 28, shows a head loss for water to be 190 milinches per foot or 1.58 ft/100 ft. Fig. 3 gives a correction factor K of 1.75 for a viscosity of 0.0001 sq ft/sec; hence, the pressure loss is $1.58 \times 1.75 = 2.77$ ft/100 ft.

INSTALLATION

There are certain precautions that must be taken during installation. They concern internal corrosion, flammability, toxicity, cleaning, joints, and hookup. A comprehensive discussion of these precautions may be found in Reference 5.

Safety

Since ethylene glycol and petroleum distillates are slightly toxic, the system should be installed and maintained independently. There should be no permanent connection between the snow-melting system and the drinking water supply.

Ethylene glycol is not considered flammable. In fact, aqueous solutions of less than 60 percent glycol are used for fire sprinkler systems. These solutions do not freeze, and they are effective fire extinguishing agents.

Petroleum distillates suitable for fluids in snow-melting systems are classified as non-flammable, but have fire points between 300 and 350 F. When using fluids of this type, care should be taken to collect any oil dripping from the seals on the pump. It is good practice also to provide some barrier between the oil lines and the boiler so that in the event of a leak, a flash back from the boiler will not ignite the oil.

There are other non-flammable fluids, such as those used in some transformers, that can be used as the antifreeze. These fluids are three or four times as expensive as the glycols or oils, but combine the fire protection of the glycols with the corrosion protection of the oils.

Internal Corrosion

Ethylene glycol solutions tend to become corrosive in service; therefore, rust inhibitors are generally included. Even with an inhibitor, the solution should be tested annually to determine any change in acidity. If the test indicates that the inhibitor has been exhausted, the entire system should be drained and a fresh solution installed.

To increase the life of the inhibitor, the heat exchanger surfaces should be kept below 285 F which corresponds to about 40 psig steam. Temperatures above 300 F accelerate the deterioration of the inhibitors.

Slab Construction

It has been found satisfactory to use ¾-in pipe or tube on 12-in. centers as a standard coil. If pumping loads require a reduction in friction the pipe size may be increased to 1-in., but the slab depth must be increased accordingly.

The piping should be supported in such a manner that there is a minimum of 2 in. of concrete above and below the pipe. This requires a 5-in. slab for ¾-in. pipe and 5½-in. for 1-in. pipe.

If an insulating material is used beneath the structural slab, it is generally good practice to provide a moisture barrier between the insulation and the fill. A roofing material (such as a 55 lb felt) is often used as a moisture barrier. The joints in the barrier should be mopped, and the fill made smooth enough so that there will be no holes or gaps for moisture transfer. Also, the edges of the barrier should be flashed to the surface of the slab so that the ends are sealed.

If the pipe must pass through an expansion joint, a protective coating should be applied to the pipe for a foot or two on both sides of the joint.

If the pipe is kept dry at all times in both summer and winter, no external corrosion problems will occur.

Thermal Stresses

This problem is discussed in Reference 7. In general, there will be no ill effects from the thermal stresses if these rules of installation and operation are followed:

1. Keep the temperature difference between the fluid and the slab surface to a minimum by:
   a. Close pipe spacing (see Fig. 1).
   b. Low temperature drop in fluid, $\Delta t \leq 20$ F deg.
   c. Continuous operation (if economically feasible).
2. Keep pipe near surface to obtain about 2 in. cover.
3. Use reinforcing steel designed for thermal stress if high structural loads are expected (such as on highways).

Control

Normally snow-melting systems are manually controlled. They are started by an operator when snow is anticipated or is falling, and they are shut off when the snow has stopped falling and the area is clear. This is strictly two-position control either 0 or 100 percent operation. One version, with some degree of control, provides a surface-temperature control. The system is started manually, as before, but a thermostat controls the heat input to maintain a surface temperature of approximately 33 F.

There are several fully automatic control systems, however. In general, these systems provide some means of detecting precipitation and simultaneously sensing air temperature. One method is to set a thermostat for a 35 F air temperature and arrange to have the signal from this thermostat activate a heating element on a receptacle. This warm receptacle collects the precipitation, and melts it if it is frozen. The water then runs through a tube and activates another circuit. This second circuit can be used to start the snow-melting system. Another thermostat can be used to control the surface temperature of the snow-melting slab.

For basic information on control equipment, such as thermostats, and for fundamentals of control circuits, see Chapter 43.

Testing

After installation and before pouring concrete, all piping should be tested to about 100 psig. This pressure should be maintained until all welds and connections have been checked for leaks. If an oil is used as an antifreeze, the test should be performed with air or some gas (only 50 psi required with an air test) but *not with water*. The danger of using water is that the pipe may not be thoroughly dried when the oil is introduced. The water will tend to collect, and when the temperature falls below 32 F the collected water may freeze and cause damage.

Draining

Proper drainage is necessary for both the slab surface and the coil.

The slab must be sloped so that the water from the melted snow can run off. Puddles are objectionable on sidewalks or drives. They cause splashing, and they retard heat flow from the embedded pipes.

The pipes must be placed so that they may be drained. If the antifreeze becomes corrosive it must be drained. It is not

good practice to rely entirely on blowing of air through the system.

Drifting Snow

It is quite likely that some drifting will occur on every system that is adjacent to a wall or vertical surface. The designer should try to anticipate this condition and add extra piping in these areas. If possible, coils should be added in the vertical surface. Another expedient is to carry the drainage to the area expected to be drifted. The drainage will tend to wash away some of the snow.

Design Example

Example 2: Assume that there are three independent hydraulic systems to be used in the snow-melting application described in *Example 1*. One system will be for the Class I area, another for the Class II, and the third for the emergency area, or Class III area.

Determine the hydraulic requirement for the Class II system, assuming an area of 100,000 sq ft.

Solution: The heating requirement has been determined as 160 Btuh per sq ft. Since an area of this type has a large perimeter, assume the edge and back losses add about 40 percent or 64 Btu per sq ft. The total heat requirement, then, will be taken as 224 Btuh per sq ft or 22.4×10^6 Btuh for the 100,000 sq ft area.

The fluid temperature is determined by using Equation 7:

$$t_m = 0.5\ q_o + t_f$$

Since

$$q_o = 160 \text{ Btuh per sq ft, and } t_f = 33 \text{ F}$$
$$t_m = 0.5 \times 160 + 33 = 113 \text{ F.}$$

If an oil antifreeze is used, the specific heat, c_m, the kinematic viscosity ν_m, and the specific weight w_m, at 113 F can be found by interpolation in Table 5 as

$$c_m = 0.440 \text{ Btu per (lb) (F deg)}$$
$$\nu_m = 3.88 \times 10^{-4} \text{ sq ft per sec.}$$

An accurate determination of viscosity cannot be made by interpolation in Table 5 and should therefore be made by use of *ASTM Standard Viscosity Chart B*.

$$w_m = 59.4 \text{ lb per cu ft}$$

Then from Equation 12

$$G = \frac{A_p q_t}{160 w_m c_m} = \frac{10^6 \times 225}{160 \times 59.4 \times 0.440} = 5380 \text{ gpm}$$

Equation 12 is based on a temperature drop of 20 F deg, therefore, the fluid must enter the slab at 123 F and leave at 103 F in order to have the desired mean temperature of 113 F.

Assume that the coil with the longest *equivalent* length is 300 ft and has a flow of 12 gpm. Such an arrangement would suggest the use of a coil of 1 in. IPS. From Table 1, Chapter 31, the ID = 1.049 in. = 0.0875 ft which gives an internal cross-sectional area of 0.00600 sq ft.

For 12 gpm the flow is 0.0268 cu ft per sec and the velocity is

$$V = \frac{0.0268}{0.00600} = 4.47 \text{ fps}$$

and Reynolds number, N_{Re}, is

$$N_{Re} = \frac{VD}{\nu_m} = \frac{4.47 \times 0.0875}{3.88 \times 10^{-4}} = 10{,}100$$

From Fig. 4, Chapter 4, using a roughness factor $e = 0.00015$, whence $e/D = 0.00172$, the friction factor f is found to be 0.0333. Substituting in Equation 10 yields

$$h_f = f \times \frac{L}{D} \times \frac{V^2}{2g} = 0.0333 \times \frac{300}{0.0875} \times \frac{4.47^2}{2 \times 32.16}$$

$$= 35.8 \text{ ft of fluid} = 14.8 \text{ psia}$$

The friction loss could have been approximated two ways: (1) by using Fig. 2, and (2) by using Fig. 3 of this chapter in conjunction with Fig. 5 of Chapter 28.

In order to use Fig. 2, the viscosity of the oil must be known in SSU. As given above the kinematic viscosity of the oil at 113 F is 3.88×10^{-4} sq ft per sec. From Table 6, 3.88×10^{-4} sq ft per sec is equal to 37.9 SSU. Entering Fig. 2 at 37.9 SSU and reading friction loss for 12 gpm gives 12.8 ft per 100 ft. For a 300-ft coil this is 38.4 ft of fluid. This compares fairly well with the more exact figure of 35.8 ft as found by using the Fanning equation.

If the friction loss were approximated by Fig. 3 and Fig. 5 of Chapter 28, the result would have been 40.5 ft which is determined as follows: From Fig. 5 of Chapter 28, the loss for *water* flowing at 12 gpm in a one-inch pipe is 1200 milinches per foot or 10 ft per 100 ft. In this case, then, the loss for *water* would be 30 ft.

The correction factor for oil as compared to water is given in Fig. 3 as 1.35. The friction loss then would be 1.35×30 or 40.5 ft. Both of the approximation methods are conservative, but for large systems, this conservative approach may be costly.

The pump must deliver 5380 gpm against a 14.8 psia head. The heat exchanger must deliver 22.5 million Btuh with an inlet temperature of 103 F and an outlet temperature of 123 F. Actually some allowance should be made for the temperature drop in the piping between the slab and the heat exchanger.

Both the pump and heat exchanger manufacturers should be advised that the fluid is an oil and will operate over a wide temperature and viscosity range. If a low-limit thermostat is placed in the fluid line so that the minimum fluid temperature is −10 F, it can be seen from Tables 5 and 6 that the viscosity can reach about 300 SSU. From Table 7, it can be found that such a viscosity can reduce the pump head 5 percent and the capacity 3 percent. This means that the pump should be rated at $\frac{14.8}{0.95} \approx 15.6$ psia and $\frac{5380}{0.97} = 5550$ gpm.

The expansion tank should be designed in accordance with the procedure outlined in Chapter 28, Hot Water Heating Systems. The amount of expansion should be based on the change in volume from the low temperature limit to the high temperature limit. Assuming the temperature range to be −10 F to +123 F, the expansion would be $\frac{62.7 - 59.1}{59.1} = 6.1$ percent of the total volume in the system.

CHAPTER 50

PROCESS AND PRODUCT AIR CONDITIONING

General Requirements for Manufacture, Processing, and Preservation; Design Conditions and Application Data; Classification of Problems; Moisture Content and Regain; Conditioning and Drying; Chemical and Biochemical Reactions; Crystallization; Control for Machining, Polishing, and for Static Electricity Elimination; Laboratory Conditions; Calculations

PROCESS and product air conditioning is concerned with the design and application of equipment for obtaining proper conditions for the manufacturing, processing, and preserving of material, equipment, and commodities. This chapter includes a general discussion of these conditions and also a comprehensive list of specific requirements for various types of products.

GENERAL REQUIREMENTS FOR MANUFACTURE, PROCESSING, AND PRESERVATION

In order to apply air conditioning to industrial processes, the air-conditioning engineer must have a thorough understanding of the processing problems involved. Since individual processes and machines are changing rapidly, air conditions must be revised constantly to meet new requirements.

Table 1 lists the temperatures and relative humidities required for storage of certain commodities, and for manufacturing and processing of others. In some cases the temperatures and relative humidities listed in Table 1 have no direct influence upon the product itself, but do affect the efficiency of employees and, in turn, the workmanship, uniformity, and cost of production. Sometimes, a compromise between the known optimum condition for processing and that required for worker comfort is unavoidable.

Air conditioning for industrial processes is so extensive and involved that a detailed treatment is beyond the scope of this chapter. In many industries the exact conditions to be maintained are determined and known only by the manufacturer who specifies them. In other industries there is a wide variance between manufacturers' requirements, depending on results desired, experience, and cost considerations.

CLASSIFICATION OF PROBLEMS

In general, any industrial air-conditioning problem in processing may be classified under one or more of the following:

1. Control of regain.
2. Control of rate of chemical reactions.
3. Control of rate of biochemical reactions.
4. Control of rate of crystallization.
5. Control of temperature for close tolerance machining, and grinding.
6. Control of dew point for protection of highly polished surfaces.
7. Control of humidity for static-electricity elimination.
8. Control of conditions for material-testing laboratories.

(*Text continued on p. 687*)

Table 1 .... Temperatures and Humidities Applicable to Industrial Air Conditioning*

Process	Temp. F	R.H.%
BAKERY		
Mixer (bread dough)	75–80	40–50
Fermenting	75–80	70–75
Proof box	92–96	80–85
Bread oven	375–450	
Cake oven	300–430	
Bread cooler (room or tunnel) Vacuum 28.6 in.	70–75	80–85
Cold room	40–45	
Make-up room	75–80	65–70
Cake mixing	70–75	65
Cake mixing (sponge)	95–110	
Crackers and biscuits	60–65	50
Wrapping	60–65	60–65
Dried ingredients, storage	70	55–65
Fresh ingredients, storage	30–45	80–85
Flour storage	65–80	50–65
Shortening (depending on type), storage	45–70	55–65
Sugar, storage	80	35
Water, storage	32–35	....
Wax paper, storage	70–80	40–50

Methods of Mixer Cooling

1. 35–40 F water circulated through mixer jacket.
2. 15–25 F brine.
3. Direct expansion, refrigerant circulated through mixer jacket.
4. Cracked ice added to dough in mixer.
5. Cold air introduced into mixer during mixing process.
6. Cooled agitators are used in mixers.

Mixer Load Calculations

Refrigeration is required to remove: excess ingredient, if any; heat generated by the beating and mixing of dough; excess heat in mixer body; heat of hydration of flour and water; and heat absorbed by mixer from atmosphere during mixing.

Additional factors are the design and speed of mixer, consistency, kind and mass of dough.

Data Used in Calculations:

1 bbl. flour = 200 lb.
Heat of hydration = 6.5 Btu per lb of flour.
Specific heat of flour = 0.42 Btu per lb.
Water is 65% of weight of flour.
Flour is 65% of batch.
Sponge is 60% of batch.

Total motor output is converted to heat in the mixer.

In fermenting rooms recent practice is to use direct radiation for heating, atomizing sprays for humidifying, and gravity con-

* Information in Table 1 is drawn from many sources. See bibliography at end of chapter.

Table 1 . . . . Temperatures and Humidities Applicable to Industrial Air Conditioning—(*Continued*)

BAKERY (*Continued*)

vection cooling surfaces for temperature reduction and dehumidifying—thereby eliminating objectionable air currents.

Proof box and bread cooler conditions vary slightly for dark bread.

Cakes are sterilized by ultra-violet rays before wrapping.

Process	Temp. F	R.H.%
BANANAS		
Ripening	68	90 to 95
Storage	60	85 to 90
Shipping	54 to 56	85 to 90

Forced ripening is accomplished in 4 to 5 days while slow ripening is extended to 7 to 9 days with lower temperatures.

The green fruit with a pulp temperature of 56 F is placed in a ripening room at 68 F and 90 to 95 percent relative humidity until it begins to change color. The temperature is then lowered sharply to 60 F (or slightly less) dependent upon how quickly the fruit is to be moved.

Typical refrigeration load for ripening room per carlot, with an 85 F ambient temperature:

Insulation and electric load	= 0.4 ton.
Live load	= 0.9 ton.
Pull down load (from 68 F to 60 F)	= 1.6 ton.

Minimum carlot—20,000 lb which represents about 300 stems.

Since bananas give off minute quantities of ethylene and possibly other gases necessary for ripening, ventilation during the early stages of ripening is undesirable.

Cooling unit to be sized to provide a complete air change every 1½ to 2 min.

Provide a heating system with a rated capacity to warm the fruit at a rate of not less than 2 deg per hr.

Specific heat—0.9 Btu per (lb) (F deg).

Approximate rate of evolution of heat by bananas when stored at temperatures indicated:

Bananas at 54 F	= 3,300 Btu (per ton) (24 hr).
green at 68 F	= 8,360 Btu (per ton) (24 hr).
turning at 68 F	= 9,240 Btu (per ton) (24 hr).
ripening at 68 F	= 8,360 Btu (per ton) (24 hr).

Room	Temp. F	R.H.%
BREWING		
Storage: Hops	30 to 32	55 to 62
Grain	80 max.	60 max.
Liquid yeast	32 to 34	
Lager	32 to 34	75 min.*
Ale	40 to 46	75 min.*
Fermenting Cellar: Lager	40 to 45	75 min.*
Ale	55	75 min.*
Racking Cellar	32 to 35	75
*. If wooden tankage is used, otherwise humidity controlled to prevent condensation on walls and ceiling.		

Wort cooled to 47 F for lager, 54 to 59 F for ale, by evaporative cooling or use of double pipe or plate type coolers with counterflow of cooling medium.

Fermentation produces 250 Btu per lb of sugar fermented. Lager fermented five days at 55 to 60 F, ale at 68 to 75 F, then cooled to storage temperature.

Bottled beer pasteurized by heating to 140 F in twenty minutes, maintaining temperature for eighteen minutes, then cooling to 80 F in twenty minutes. Canned beer requires one-third less time.

Cold water, brine, direct-expansion ammonia, or propylene-glycol and water solutions may be used as the cooling medium.

Process	Temp. F	R.H.%
CANDY (CHOCOLATE)		
Candy centers for coating	80 to 85	40 to 50
Hand dipping room	60 to 65	50 to 55
Enrober room	75 to 80	55 to 60
Enrobing		
Loading End	80	50
Enrober	90	13
Stringing	70	40 to 50
Tunnel	40 to 45	
Packing	65	55
Panned specialty room	70 to 75	45
General candy storage	65 to 70	40 to 50
Tempering room = Ventilation only		

Tunnel discharge room requires a dew point lower than the temperature of the product leaving the tunnel.

During the summer months the product is usually held in the tempering room for 24 hours prior to shipping.

Recovery of sugar fly in coating kettle rooms is accomplished by use of cyclone-type dust collecting devices. Supply air to coating kettles is maintained at 85 F dry-bulb and 61 F wet-bulb temperature.

Bacteriological control is employed.

Load calculations for hand dipping rooms are based on 100 lb of 90 F chocolate per (worker) (hr).

Specific heat of chocolate = 0.30 to 0.56 Btu per (lb) (F deg).
Latent heat of fusion = 34 to 40 Btu per (lb) (F deg).
Freezing point =
Sweet milk chocolate = 86 F.
Dark chocolate = 90 to 92 F.

Process	Temp. F	R.H.%
CANDY (HARD)		
Manufacturing	75 to 80	30 to 40
Mixing and cooling	75 to 80	40 to 45
Tunnel	55	
Packing	65 to 75	40 to 45
Storage	65 to 75	45 to 50
Tempering = (Ventilation only)		

Hot rooms used in the drying of jellies and gums are maintained at 120 to 150 F. A purge system using 100 percent outside air, bypassing the heating coil, is incorporated to produce rapid cooling of both the product and the room.

Cold rooms for cooling marshmallows and cast creams are maintained at 75 to 80 F with a relative humidity of 45 to 50 percent. Uniform air distribution is essential.

Standard starch drying equipment is employed.

Filtration of air is required.

Process	Temp. F	R.H.%
CERAMICS		
Refractory	110 to 150	50 to 90
Molding room	80	60 to 70
Clay storage	60 to 80	35 to 65
Decalcomania production	75 to 80	48
Decorating room	75 to 80	48

Relative humidity has no effect on the manufacture of the products.

Temperature and humidity must be controlled in the decorating shop in the whiteware plants, and the decalcomania production room.

Dust control is essential, and the dust count must be held down to four million particles per cubic foot due to the danger of silicosis.

Table 1 . . . . Temperatures and Humidities Applicable to Industrial Air Conditioning—(*Continued*)

Process	Temp. F	R.H.%
CEREAL		
Packaging	75–80	45–50
CITRUS FRUIT		
Lemons (storage)*	58	84 to 88
Grapefruit (storage)*	60	86 to 88
* Prior to transcontinental shipment		

Careful consideration must be given to air volumes, air temperatures, humidity, ventilation, and distribution.

In regions where end rot is prevalent, it may be necessary to store grapefruit at temperatures of 32 to 34 F for a period not exceeding six weeks.

Lemon and grapefruit storage requires an air-conditioning system to (1) maintain a constant temperature, (2) maintain a high relative humidity, (3) ventilate to maintain 0.1% CO_2 content, (4) obtain uniform air distribution, and (5) provide air washing or air filtration.

Load calculations include (1) transmission losses, (2) internal load-fruit cooling and respiration, cooling fruit boxes, electric load, and people, and (3) outside air load—72 cfm per carlot.

Specific heat—Btu per (lb) (F deg):

Lemons 0.94, Grapefruit 0.87, Boxes 0.40

HEAT OF EVOLUTION IN BTU PER (TON) (24 HR)

Temp.	Lemons	Grapefruit
32	580	460
40	810	1070
60	2070	2770
80	6200	4180

Approximately 10 percent of the cooling load is considered as latent heat load.

In a conventional system the air required is one cfm per storage box or 650 cfm per carload, resulting in a small temperature rise in the supply air making possible the required high humidities.

In a combination system the air required is one cfm per sq ft of floor area or 300 cfm per carlot with the addition of auxiliary humidifying nozzles to maintain the required high humidities.

Installation of metal ducts is required. Ductwork made of insulation board is sometimes preferred.

Process	Temp. F	R.H.%
DISTILLING		
Storage:		
Grain	60	35 to 40
Liquid Yeast	32 to 34	
General Manufacturing	60 to 75	45 to 60
Aging	65 to 72	50 to 60

Mashing done at 150 to 155 F, then cooled to 64 to 68 F.

Yeast culture fermented at 170 F, then cooled to 70 to 72 F.

Yeast propagated at 150 to 154 F.

Mash heated to 165 F and then cooled to 80 F, then pitched with yeast and fermented at maximum temperature of 85 F.

Cooling for various distilling processes normally accomplished by use of river or well water depending on temperatures and availability.

Low humidity and dust control important where grains are ground.

Viscous filters preferred as mold spores and bacteria are trapped in the viscous film, preventing propagation.

Process	Temp. F	R.H.%
ELECTRICAL PRODUCTS		
Electronics and X-Ray:		
Coil and transformer winding	72	15
Tube assembly	68	40
Electrical Instruments:		
Manufacture and laboratory	70	50 to 55
Thermostat assembly and calibration	76	50 to 55
Humidistat assembly and calibration	76	50 to 55
Small Mechanisms:		
Close tolerance assembly	72	40 to 45
Meter assembly and test	74 to 76	60 to 63
Switchgear:		
Fuse and cutout assembly	73	50
Capacitor winding	73	50
Paper storage	73	50
Conductor wrapping with yarn	75	65 to 70
Lightning arrestor assembly	68	20 to 40
Thermal circuit breakers assembly and test	76	30 to 60
Water wheel generators:		
Thrust runner lapping	70	30 to 50
Rectifiers:		
Processing selenium and copper oxide plates	74	30 to 40
Dust control is essential in these processes		
FLOOR COVERING		
Linoleum:		
Mechanical oxidizing of linseed oil	90 to 100	20 to 28
Printing	80	30 to 50
Stoving process	160 to 250	60 gr*
* grains per pound abs. hum.		

Some operations are stabilized to prevent mold growth.

Precise control of temperature and humidity is required for mechanical oxidizing of linseed oil. The rate of flow and the temperature of cooling water in the jacket surrounding the tank must be controlled.

Air filtration is recommended for the stoving process.

Process	Temp. F	R.H.%
FOUNDRIES		
Core making	60 to 70	
Mold making:		
Bench work	60 to 70	
Floor work	55 to 65	
Pouring	40	
Shakeout	40 to 50	
Cleaning Room	55 to 65	
* Winter design temp.		

The charging room is usually unheated.

In core making fume-exhaust hoods are required for oven and for cooling areas adjacent to ovens.

In mold making provide hoods at transfer points with wet collector dust removal system. Use 600 to 800 cfm per hood.

Pouring rooms require two-speed powered roof ventilators. Design for minimum of two cfm per sq ft floor area at low speed. Shielding is required to control radiation from hot surfaces. Proper introduction of air will minimize preheat requirements.

In shakeout room provide hoods with wet-collector dust-removal system. Exhaust 400 to 500 cfm per sq ft grate area. Roof ventilators are generally not effective.

In cleaning room provide hoods for grinders and cleaning equipment with dry cyclones or bag-type collectors.

Winter ventilation (preheated) is required to the extent of replacing exhausted air. Summer ventilation is usually supplemented by use of pedestal fans.

Spot coolers are sometimes used in larger installations.

Table 1 . . . . Temperatures and Humidities Applicable to Industrial Air Conditioning—(*Continued*)

Process	Temp. F	R.H.%
FUR		
Drying	110	....
Shock treatment	18 to 20	....
Storage	40 to 50	55 to 65

Shock treatment, for eradication of any insect infestations, requires the lowering of the temperature to 18–20 F for 3 to 4 days, then raising it to 60–70 F for 2 days, then lowering it once again to 18–20 F for 2 days and raising it to the storage temperature.

Furs remain pliable, oxidation is reduced, and color and luster are preserved when stored at 40 to 50 F.

Mold growth is prevalent with humidities above 80 percent, while hair splitting is common where humidity is lower than 55 percent.

Process	Temp. F	R.H.%
GUM		
Manufacturing	77	33
Rolling	68	63
Stripping	72	53
Breaking	74	47
Wrapping	74	58
LEATHER		
Drying:		
Vegetable tanned	70	75
Chrome tanned	120	45
Storage	50–60	40–60

After leather is moistened in preparation for rolling and stretching, it is placed in an atmosphere held at room temperature with a relative humidity of 95 percent.

Leather is usually stored in warehouses without temperature and humidity control. However, it is necessary to keep humidity below 85 percent to avoid mildew.

Air filtration is recommended for toggle machines.

Process	Temp. F	R.H.%
LENSES (OPTICAL)		
Fusing	75	45
Grinding	80	80

The air must be free of dust and temperature held constant.

To acquire desired cleanliness of air a combination of impingement and electrostatic filters are used. Dust collectors are required for grinding operations.

Rooms	Temp. F	R.H.%
LIBRARIES AND MUSEUMS		
Museum	70–80	40–60
Book storage	70–80	40–50

Spray type dehumidifiers used to eliminate SO_2. Water treatment is essential to maintain between 8.5 and 9.0 pH.

Reheat is usually needed for refrigeration cycle due to the low sensible heat load.

In extremely cold weather a lower relative humidity is required to prevent condensation on walls.

Positive high and low limit relative humidity controls are used. Do not locate water or steam piping where leakage can cause damage.

LIBRARIES AND MUSEUMS (*Concluded*)

CHECK FIGURES FOR COOLING ESTIMATES

	Low	Medium	High
Square feet floor area per person	40	60	80
Watts per sq ft of floor area	..	1	2
Room sensible heat, Btu per (hr) (sq ft)	20	35	45
Grand total heat, Btu per (hr) (sq ft)	30	51	75
Sensible heat factor	0.73	0.83	0.90
Cooling load per person, tons	0.12	0.23	0.40
cfm per sq ft of floor area	0.92	1.60	2.10

MALTING (BREWING)

Steeped 24 to 72 hr in 45 to 65 F water.

Germinated six days at 55 to 75 F.

Kilned at temperatures of 120 to 175 F.

MALTING (DISTILLING)

Germinated twenty days at 63 F.

Germination produces total heat of 16,000 Btu/bushel at varying rate depending upon grain and process.

Process	Temp. F	R.H.%
MATCHES		
Manufacture	72 to 74	50
Drying	70 to 75	40
Storage	60 to 62	50

Water evaporated is 18 to 20 lb per million matches simultaneously with the setting of the glue.

The match machine will turn out about 750,000 matches per hour.

MUSHROOMS

Sweating-out period	120 to 140	
Spawn added	60 to 75	nearly sat.
Growing period	48 to 60	moderate
Storage	32 to 35	80 to 85

As spawn starts to grow, it is necessary to abruptly cool the mushroom house by 15 deg in a 12 hr period (approx.). Usually, this is the controlling factor in selection of refrigeration equipment, unless there is portable equipment available for such a purpose.

Ductwork is usually of wood, due to the deterioration of ferrous metals during sweating-out period.

Air filtration is essential in spawn rooms. Viscous filters are preferred, as mold spores are trapped in the viscous film. Odorless oil should be used.

Heat of emission is 4 Btu per (hr) (sq ft of growing surface).

Process	Temp. F	R.H.%
PAINT APPLICATION		
Lacquers:		
Air drying	70–90	60
Baking	180–300	
Oil Paints:		
Air drying	60–90	60
Paint Spraying	75	

Spray booths to have 100 fpm face velocity. Make-up air must be preheated. Ovens must have air removed to keep fumes below explosive concentration. Equipment must be explosion-proof throughout.

Table 1 . . . . Temperatures and Humidities Applicable to Industrial Air Conditioning—(*Continued*)

Room or Process	Temp. F	R.H.%
PHARMACEUTICAL		
Powder storage (prior to mfg.)	70 to 80	30 to 35
Manufactured powder storage and packing areas	75 to 80	15 to 35
Milling room	80	35

Micro-analysis	80	50
Biological manufacturing	80	35
Liver extracts	70 to 80	20 to 30
Serums	74 to 78	50
Animal rooms	75 to 80	40
Small animal rooms	75 to 78	47 to 48

Gelatin capsules require varying relative humidities, depending upon size of capsule. Moisture content should not exceed 0.25 g per cu ft. Various kinds of gelatin require different temperatures.

Penicillin incubation process requires holding temperature within ½ deg F, with temperatures and humidity rigidly controlled during all manufacturing phases.

Ampule filling requires a 20 percent relative humidity when especially fine powders are used.

Uncoated tablet manufacturing requires accurate control of temperature and relative humidity, since low relative humidity causes formation of a hard outer layer, and high relative humidity retards drying at the proper rate.

Liver extracts require a low relative humidity after they are dried. Temperatures higher than 80 F will cause the extracts to deteriorate.

Tablet coating requires the control of the temperatures of all ingredients and the temperature of air introduced to coating pans.

Sterile conditions are essential in many pharmaceutical processes. Provide suitable air exhaust to remove surplus material from tablet compressing machine.

Air filtration is generally required, with positive air filtration in some areas.

ANIMAL ROOMS IN PHARMACEUTICAL LABORATORIES

In the following tabulation each of the items mentioned is equivalent in metabolism to one man:

Quantity	Animal	Weight Each
672	White Mice	21 g
110	Rats	200 g
73	Rats	400 g
70	Guinea Pigs	410 g
21	Rabbits	2.6 kg
16	Cats	3.0 kg
16	Monkeys	3.0 kg
5	Dogs	14.0 kg

Dogs are generally the worst offenders as far as odor generation is concerned.

Decontamination of exhaust air is recommended in populated areas.

For good air quality conditions the following space per animal and total air circulation (all outdoor or decontaminated in recirculation) should be provided:

Animal	cu ft	cfm	Animal	cu ft	cfm
Mice	3	0.5	Hamsters	8	1.5
Rats	4	0.75	Cats	35	10.0
Guinea Pigs	6	1.0	Dogs	150	28.0
Rabbits	10	1.9

Other paper storage	70–80	[b]
Binding, cutting, drying, folding, and gluing	70–80	45–50
Roll storage	73–80	50

[a] 5 to 8% above pressroom
[b] same as pressroom

Lithography requires constant humidity control of entire pressroom with paper conditioned 5 to 8 percent higher relative humidity at start. All printing requires conditioned paper otherwise it will not lie flat, with 40 to 45 percent R.H. low limit to eliminate static electricity; and 60 percent R.H. high limit to prevent swelling of the rolls and slow ink drying. Temperature is not critical, but extremes should be avoided due to softening of the rolls at high temperature and improper ink distribution at low temperatures.

Hoods must be provided for gas dryers, with solvent recovery recommended for all except job shops. Exhaust system with dust collectors incorporated is required for type and plate cleaning areas. Check use of gasoline and other solvents. Normal air cleaning is adequate. Air distribution must prevent drafts on paper in storage or process. Gas flame dryers impose unusual loads.

Air from press and storage rooms should not be recirculated through office areas.

Cotton: Relative humidity maintained in ring spinning depends on staple, twist, and whether leather aprons are used for conveying long draft stock. Aprons readily absorb moisture causing cotton to stick when relative humidity is above 55 percent.

With conventional 3 or 4 roll spinning, relative humidity may be as high as 70 percent dependent upon draft, twist, and staple.

Relative humidity carried in cotton weaving depends upon construction of the cloth. When automatic machines are to be tended and the warps are heavily sized, it may be as high as 90 percent.

Woolen: In woolen spinning, the relative humidity maintained for mules is generally 55 percent, with conditions over frame spinning at 55 to 60 percent. Both types of spinning depend on the class of stock spun, also the regain in the roving.

Worsteds: Top storage temperature depends on whether cellar long period conditioning at low temperature or quick conditioning at high temperature is used. Weaving relative humidity depends upon staple, quality, and construction.

Filtration of air is essential.

Rayon manufacture: The steeping room, where sheets of raw material are dipped in caustic soda then broken into a fine matted crumb, is held at 70 F and 55 percent relative humidity. Relative humidity is held down to prevent condensation on cold pipes and jackets.

In churn room, where sodium cellulose is converted into cellulose xanthate, temperatures of 75 to 80 F are maintained while humidity control is not important. Room temperatures are held below 85 F during the summer months.

The crumb is dumped into aging tanks located in a room held at 73 F with no humidity control.

For spinning operations it is desirable to limit the temperature to 90 F with a minimum relative humidity of 70 percent for the summer, while 70 percent and 75 F are desirable for the winter months.

In the storage room, where the material is held for later processing, design conditions are 85 F and 100 percent relative humidity.

The material is washed, desulfurized, bleached, and then washed again. It is then placed in a drier where controlled conditions of 100 deg and 65 percent relative humidity are required to bring the rayon back to the proper regain.

In the coning room, where winding machines place the rayon yarn on cones, temperature is held at a maximum of 80 F. Relative humidity is held at 55 percent.

In preparation for stripping, the tobacco undergoes a softening operation, whereby it is automatically heated, moistened, and then cooled.

Control of moisture regain, and of chemical and biological reactions is required in tobacco processing.

Exact temperature and humidity conditions maintained are usually trade secrets as they affect the finished product.

(*Text continued from p. 681.*)

Moisture Content and Regain

In the manufacture or processing of hygroscopic materials such as textiles, paper, wood, leather, tobacco, and foodstuffs, the temperature and relative humidity of the air have a marked influence upon the rate of production and upon the weight, strength, appearance, and general quality of the product. The moisture content of materials having a vegetable or animal origin, and to a lesser extent minerals in certain forms, comes to equilibrium with the moisture of the surrounding air. This moisture content is known as *regain*. Standards of *regain* are fixed in the trade, and are the fundamental basis for the control of certain physical qualities of the material during manufacture.

Manufacturing economy requires that the moisture content be maintained at a level favorable to rapid and satisfactory manipulation, and to a minimum loss of material through breakage. A uniform condition is desirable in order that high-speed machinery may be adjusted permanently for the desired production with a minimum loss from delays, wastage of raw material, and defective product. *Moisture content* refers to free moisture (as in a sponge) and to hygroscopic moisture (which varies with atmospheric conditions). It is usually expressed as a percentage of the total weight of material. *Regain* is more specific and refers only to hygroscopic moisture. It is expressed as a percentage of the *bone-dry* weight of material. For example, if a sample of cloth weighing 100.0 g is dried to a bone-dry weight of 93.0 g, the loss in weight, or 7.0 g, represents the weight of moisture originally contained. This expressed as a percentage of the total weight (100.0 g) gives the moisture content of 7 percent. The regain, which is expressed as a percentage of the bone-dry weight, is $(7.0/93.0) \times 100 = 7.5$ percent.

The use of the term *regain* does not imply that the material as a whole has been completely dried out and has re-absorbed moisture.

A basis for calculating the regain of textiles is obtained by drying, under standard conditions, a sample from the lot, and the dry weight thus obtained is used in the calculations to determine the regain.

Table 2 shows the regain or hygroscopic moisture content of several organic and inorganic materials when in equilibrium at a dry-bulb temperature of 75 F and various

relative humidities. The effect of temperature as compared to the relative humidity is comparatively unimportant, although sudden changes in temperature cause a slight change in regain even when the relative humidity remains stationary. Changes in temperature do, however, affect the rate of absorption or drying, although this property generally varies with the nature of the material, its thickness and density.

When hygroscopic materials absorb moisture from the surrounding air, they deliver to the air sensible heat equivalent to the latent heat released by the moisture to the material. This amount of heat should be included in the load estimate.

Conditioning and Drying

In general, the materials may be exposed to desirable humidities for treatment coincidentally with the manufacture or processing of the materials, or they may be treated separately in special enclosures. This latter treatment may be classified as conditioning or drying. The usual purpose of conditioning or drying is to establish a desired condition of moisture content and to regulate the physical properties of the material. When the final moisture content is lower than the initial one, the term *drying* is applied (See Chapter 53). If the final moisture content is to be higher, the process is termed *conditioning*. In the case of some textile products and tobacco, for example, drying and conditioning may be combined in one process for the dual purpose of removing undesirable moisture, and accurately regulating the final moisture content. Frequently, conditioning or drying is made a continuous process in which the material is conveyed through an elongated compartment by suitable means, and subjected to various controlled atmospheric conditions.

Control of Rate of Chemical Reactions

A typical example of control of the rate of chemical reactions occurs in the manufacture of rayon. The pulp sheets are conditioned, cut to size, and passed through a mercerizing process. It is essential that, during this process, close control of both temperature and relative humidity should be maintained. The temperature controls the rate of reaction directly, while the relative humidity maintains a constant rate of evaporation from the surface of the solution, and maintains a solution of known strength during the mercerizing period.

Another well-known example in this class is the *drying* of varnish which is an oxidizing process dependent upon temperature. High relative humidities have a retarding effect on the rate of oxidization at the surface, and allow the internal gases to escape freely as the chemical oxidizers *cure* the varnish from within. This produces a surface free from bubbles and a homogeneous film throughout. Desirable temperatures for *drying* varnish vary with the type. A relative humidity of 65 percent is beneficial.

Control of Rate of Biochemical Reactions

In the field of biochemical control, industrial air conditioning has been applied to many different and well-known products. All problems involving fermentation are classed under this heading. As biochemistry is a subdivision of chemistry, subject to the same laws, the rate of reaction may be controlled by temperature. An example of this is the dough room of the modern bakery. Yeast develops best at a temperature of 80 F. A relative humidity of 70 percent is maintained to hold the surface of the dough open to allow the carbon dioxide gasses formed by the fermentation to pass through and produce a loaf of bread, when baked, of even, fine texture without large voids.

Control of Rate of Crystallization

The rate of cooling of a saturated solution determines the size of the crystals formed. Both dry- and wet-bulb temperatures are of importance, as the one controls the rate of cooling, while the other, through evaporation, changes the density of the solution.

In the coating pans for pills, gum, and nuts, a heavy sugar solution is added to the tumbling mass. As the water evaporates, each separate piece is covered with crystals of sugar. A smooth, opaque coating is only accomplished by blowing into the kettle the proper amount of air at the right dry- and wet-bulb temperatures. If the cooling and drying are too slow, the coating will be rough and semi-translucent, and the appearance unsightly; if too fast, the coating will chip through to the interior. Only by balancing temperature, relative humidity, and volume of air to the sugar solution, can the proper rate be obtained and a perfect coating assured.

Control of Temperature for Close Machining Tolerances

Where tolerances must be held within 2 or 3 ten-thousandths of an inch, as in the manufacture of precision instruments, tools, and high quality lenses, temperature variations may cause expansion and contraction of material to an extent that will seriously affect the quality of the work. This type of work usually requires close temperature control to assure accuracy and uniformity of the product.

Usually the temperature level with respect to the product is not as important as controlling the temperature within close limits. For this reason, conditions are usually selected within the comfort range.

Control of Dew Point for Protection of Polished Surfaces

In the manufacture of certain metal articles, the presence of fingerprints, tarnish, or *etching* cannot be tolerated in the finished article. If these articles are manufactured under conditions of effective temperatures that will cause the hands to perspire, an unsatisfactory product will result. The salt and acid contained in body perspiration, when deposited on the highly polished article, can show corrosion and rust within a few hours if examined under a microscope.

It is therefore important to maintain temperatures and relative humidities (dew point) low enough to prevent sweating of the hands. In addition, the manufacture of polished surfaces usually requires a better-than-average job of air filtering to avoid abrasion of the surfaces.

Control of Humidity for Reduction of Static Electricity

The presence of static electricity is often detrimental to the satisfactory and economical processing of many light materials, such as textile fibers and paper. It is also extremely dangerous where explosive atmospheres or materials are present. Fortunately, this hazard is minimized by in-

creasing the relative humidity to at least 55 percent, if the material being processed is not damaged thereby.

It must be borne in mind that for successful elimination, the air that actually comes in contact with the material in the machine must be at a relative humidity of 55 percent or more. As some machines consume a great deal of power, which is converted directly into heat, the temperature in the machine may be considerably higher than the temperature adjacent to the machine where the relative humidity is normally measured. In such cases, the relative humidity in the machine will be appreciably lower than that elsewhere in the room, and it may therefore be necessary to maintain a room relative humidity of 65 percent, or even more, to maintain the desired humidity.

Control of Conditions for Material Test Laboratories

Laboratories having controlled conditions of temperature and humidity, are common, not only for the purposes of scientific research, but also for routine testing and for quality production control. A control of temperature and humidity within fairly-close plus or minus limits is usually required. Laboratories designed for scientific research may require control of conditions over a wide range, whereas the routine testing laboratory or quality control laboratory will usually be designed to maintain the ASTM Standard Conditions of 50 percent relative humidity and 23 C (73.4 F) temperature.

CALCULATIONS

The methods for determining the heating and cooling loads for the various industrial processes are similar to those outlined in Chapters 12 and 13. Some factors affecting heating or cooling requirements are given in Table 1. Because of the large number of motors and heat producing units usually found in an industrial application, it is particularly important that operating allowances, for the latent and sensible heat loads, be definitely ascertained and used in the calculations to determine the total design load.

CHAPTER 51

CONTROL OF THE INDUSTRIAL ENVIRONMENT

Heat Control of Industrial Work Areas, Thermal Standards, Control of Heat Exposures, Radiation Shielding, Roof Ventilators, Local Relief Methods, Physiological Aspects of System Design, Types and Requirements of Systems, Outlet Types and Design, Control of Contaminants

CONTROL of the industrial environment is concerned with the design and application of equipment for providing the necessary conditions within industrial areas for maintaining the efficiency, health, and safety of workers. This chapter includes a comprehensive list of the requirements for heat control and for control of gases and vapors, and dust and fumes.

General ventilation may be relied upon in some cases to control the industrial environment, as outlined in this chapter. Additional information on natural ventilation may be found in Chapter 11. If mechanical ventilation is to be used, Chapter 20, Air Distribution; Chapter 21, Air Duct Design; Chapter 22, Fans; Chapter 24, Air Cleaning; Chapter 40, Evaporative Apparatus for Heat Rejection; Chapter 41, Evaporative Air Cooling and Humidification; and Chapter 43, Automatic Control; will furnish information covering a broad range of industrial design conditions. Chapters 13, 23, and 38 provide data for mechanically cooled systems. Chapter 52, Industrial Exhaust Systems, should be consulted for the design of hoods and their exhaust duct systems. For further information on estimating radiant heat conditions see Chapters 5 and 30.

Information on globe thermometers and other instruments used to measure the industrial environment may be found in Chapter 44, Instruments and Measurements. More complete information will be found in References[1] and[2] at the end of this chapter.

Specialists in the field of industrial hygiene should be consulted in case of doubt concerning the presence of airborne industrial hazards to health. Chapter 7, Air Contaminants; Chapter 6, Physiological Principles; and Chapter 8, Air Conditioning in the Prevention and Treatment of Disease, will be of help in establishing the atmospheric conditions that should be maintained around the worker. Local codes, ordinances, or state labor laws must likewise be observed, particularly with regard to ventilation requirements for hazardous trades. Comfortable conditions, if possible, or tolerable conditions at least, are desirable because they are likely to increase the efficiency and, hence, the output of workers. The majority of air-conditioning and ventilation installations in a typical industrial plant are concerned with the control of sensible, latent, or radiant heat.

HEAT CONTROL IN INDUSTRIAL WORK AREAS

In certain industrial work situations there is considerable release of heat from the process equipment to the environment. It is not economically feasible to stop the escape of all of this process heat or to offset it completely by the usual methods of *comfort* ventilation and air conditioning. In the design and operation of control measures it is frequently necessary to accept some heat exposure in excess of simple comfort requirements.

The engineer must distinguish between the control needs for *hot-dry* industrial areas and *warm-moist* conditions. In the first case, the process gives off only sensible and radiant heat without adding moisture to the air. The heat load on exposed workers is thereby increased but the rate of cooling by evaporation of sweat is not reduced. Heat balance may be maintained although this will be at the expense, perhaps, of excessive sweating. In the warm-moisture situation, the wet process gives off principally latent heat. There may be no significant rise in the heat load on the worker but the increase in moisture content of the air will seriously reduce the heat loss by evaporation of sweat. The warm-moist situation is potentially more hazardous than the hot-dry.

Examples of hot-dry work situations are seen around hot furnaces, forges, metal-extruding and rolling mills, glass-forming machines, and the like. Typical of warm-moist operations are laundries, dye houses, and deep mines where water is extensively used for dust control.

The industrial heat problem varies in magnitude with local climatic conditions. Solar heat gain and an elevated outdoor temperature will increase the heat load at the work place but these contributions may not be very important compared with the locally generated heat of the process itself. The moisture content of the outdoor air, on the other hand, is a most important climatic factor affecting hot-dry work situations and on a moist summer day will seriously restrict evaporative cooling. For the warm-moist job, in contrast, solar heat gain and elevated outdoor temperature are the more important, since, compared with the moisture release on the job, that contributed by the outdoor air will be of little significance.

Thermal Standards for Industrial Work Areas

The work situations considered here are those in which the attainment of simple thermal comfort is not always practicable. The heat stress must be kept below the level of outright hazard, but how much below? On what criteria should the specifications for control be based? How should the standards be varied in recognition of the differing demands and work rates from one kind of job to another? What differences exist between older and younger workers or between workers with differing degrees of physical fitness? To what

extent can periods of heat exposure be offset by alternating periods of recovery? How is this expressed in terms of design of the control measures? These and other questions arise in the analysis of an industrial heat problem and must be considered by the design engineer and others before specifications are fixed. As there is no single set of thermal standards applicable to all work situations, failure to give proper recognition to the many facets of the problem can result in inadequate control measures.

Biophysical Basis for Fixing Thermal Standards

Under conditions of thermal comfort, the rate of internal heat production (metabolism) is just balanced by the rate of heat loss to the environment. This comfortable balance is maintained without active sweating, with optimum skin and deep-body temperatures and without unusual load upon the heart. At the upper limits of physiological tolerance to sustained heat exposure, thermal balance may also be established, but this is accomplished only with active sweating, elevated skin and body temperatures, and accelerated heart rate. The limit is fixed by the maximum permissible degree to which these indexes of physiological strain—sweating, body temperature, and heart rate—can be safely elevated. For practical work situations in industry, the permissible limits of these indexes must be set below the absolute physiological maxima.

The thermal relationship between man and his environment is dependent upon four independently variable thermal characteristics of the environment: air temperature, radiant temperature, moisture content of the air, and air velocity. These may combine in various ways, together with the rate of internal heat production, to create widely different degrees of heat stress. The need is to provide a rational basis for combining them into a single index that will predict the magnitude of the heat stress and will serve also as a basis for fixing permissible limits of exposure.

A start is made with the heat balance equation:

$$M \pm R \pm C = B + E \pm \Delta S \qquad (1)$$

where

M = metabolic rate.
R = rate of heat exchange with environment by radiation.
C = rate of heat exchange with environment by convection.
B = rate of heat loss from body in exhaled air.
E = rate of heat loss from body by evaporation of sweat.
ΔS = rate of change in heat content of body.

Terms on the left side of Equation 1 represent the heat load; those on the right represent the heat loss together with the heat storage or withdrawal from the body. R and C are positive when the environmental temperature is above skin temperature and negative when below.

In practice, B and ΔS are of small magnitude compared with the others and can be neglected. For a condition of heat balance, therefore, Equation 1 may be written:

$$M \pm R \pm C = E_{req} \qquad (2)$$

E_{req} = required rate of evaporation of sweat to maintain heat balance.

M can be measured by standard physiological techniques or estimated for a given work situation by reference to Table 1. On both theoretical and experimental grounds, R and C can be calculated with reasonable accuracy by means of standard equations of heat exchange:

$$R = K_r A_r (t_w - t_s) = 22(t_w - t_s) \qquad (3)$$

$$C = K_c \sqrt{V} A (t_a - t_s) = 2\sqrt{V}(t_a - t_s) \qquad (4)$$

where

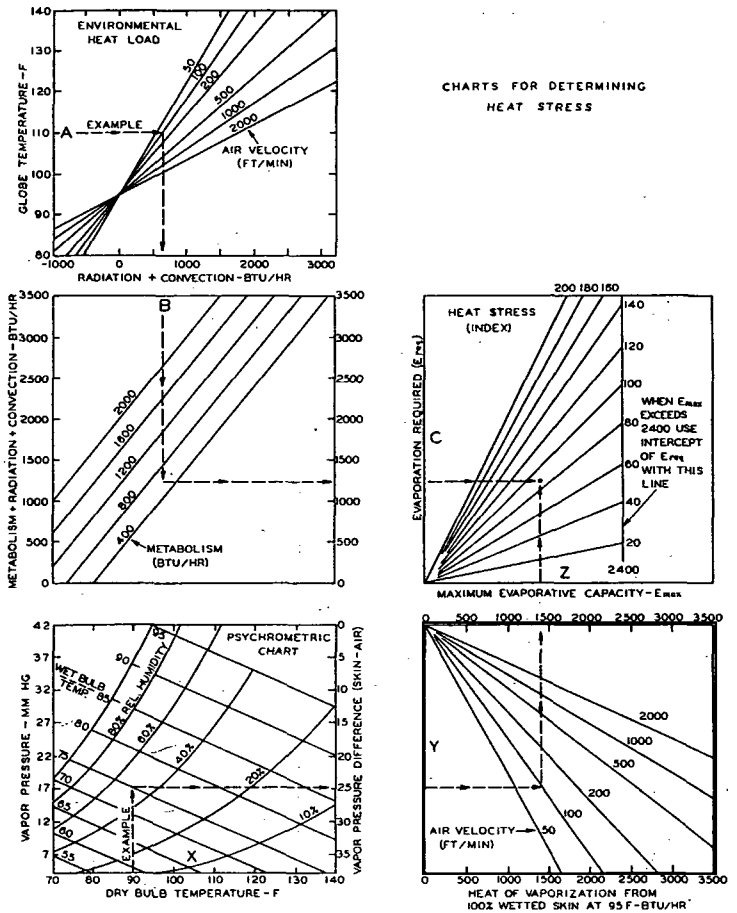
K_r = coefficient of radiant heat exchange, Btu per (hour) (square foot) (Fahrenheit degree temperature difference).

K_r varies in value; depending on the mean radiant temperature of the surroundings, t_w.

A_r = radiation area of body, square feet.
A_r differs with body position and is around 0.8 of total body surface for a standing man.

22 = $K_r \times A_r$ for average size man with moderately high mean radiant temperature, t_w.

K_c = coefficient of convective heat exchange, Btu per (hour) (square foot) (unit velocity) (Fahrenheit degree temperature difference).



A = surface area of body, square feet.
2 = $K_c \times A$, for average size man.
V = effective velocity of air movement, feet per minute.
t_w = (black-body equivalent) mean radiant temperature of environment, Fahrenheit.
t_a = ambient air temperature, Fahrenheit.
t_s = skin temperature, Fahrenheit.

So long as there is no limitation on evaporation rate, the

Table 1 .... Estimates of Energy Metabolism (M) of Various Types of Activity

(Values apply for a 154 lb man, and do not include rest pauses)

Kind of Work	Activity	M Btu/hr
	Sleeping	250
	Sitting quietly	400
Light Work	Sitting, moderate arm and trunk movements (e.g., desk work, typing)	450–650
	Sitting, moderate arm and leg movements (e.g., playing organ, driving car in traffic)	550–650
	Standing, light work at machine or bench, mostly arms	550–650
Moderate Work	Sitting, heavy arm and leg movements	650–800
	Standing, light work at machine or bench, some walking about	650–750
	Standing, moderate work at machine or bench, some walking about	750–1000
	Walking about, with moderate lifting or pushing	1000–1400
Heavy Work	Intermittent heavy lifting, pushing or pulling (e.g., pick and shovel work)	1500–2000
	Hardest sustained work	2000–2400

CHARTS FOR DETERMINING HEAT STRESS

Example: Determine Heat Stress Index for worker doing light arm work while standing at a bench.

Metabolism 600 Btuh

Environmental conditions:

Globe thermometer temperature	110 deg
Dry-bulb temperature	90 F
Wet-bulb temperature	75 F
Air velocity	100 fpm

Solution: Follow the broken lines from the globe thermometer temperature and from dry-bulb temperature to their intersection on above diagram C to read a heat stress index of 90.

Fig. 1 .... Flow Charts for Determining Heat Stress Index Values

sweat output is automatically limited by the body to that amount which satisfies the required value of E. With restricted evaporation, however, there is excessive sweating; the body becomes fully wetted and a maximum evaporative cooling rate is established which does not increase with further sweating. This maximum evaporative cooling rate E_{max} has been established experimentally and can be calculated by the equation:

$$E_{max} = K_e A V^{0.4}(P_s - P_a) = 10V^{0.4}(P_s - P_a) \quad (5)$$

where

K_e = coefficient of heat exchange by evaporation, Btu per (hour)(square foot)(unit velocity)(millimeter of mercury vapor-pressure difference).

10 = $K_e \times A$ for average size man, fully wetted.

P_s = vapor pressure of water at skin temperature, millimeters of mercury.

P_a = partial pressure of water vapor in ambient air, millimeters of mercury.

A combination of Equations 4 and 5 yields Equation 6 which is a statement of the maximum thermal conditions under which man can maintain heat balance, giving proper recognition to internal heat production M, skin temperature t_s and to all four of the thermal characteristics of the environment:

$$M + 22(t_a - t_s) + 2\sqrt{V}(t_a - t_s) = 10V^{0.4}(P_s - P_a) \quad (6)$$

Equation 6 provides a rational basis on which to construct a heat stress index and to establish thermal standards for different industrial work situations.

Two physiological criteria are important in fixing the limit of sustained heat exposure:

1. The increase in body heat content must not exceed a certain level. Practically, this is reflected in the rise in skin temperature. This temperature may be limited to 95 F.

2. Thermal balance must be accomplished with a rate of sweating not greater than one liter per hour (equivalent to evaporative cooling of 2400 Btu per hr). Studies on young acclimatized subjects have shown that this maximum rate of sweating can be maintained over a workday without undue strain or physiological cost.

The Heat Stress Index (HSI) proposed by Belding and Hatch[1] makes use of these criteria together with the previous biophysical equations. A so-called *standard* young man, in good physical condition and acclimatized to heat, can safely engage in simple physical work over a normal eight-hour day in a particular thermal environment so long as his skin temperature does not exceed 95 F and he maintains thermal balance with a sweat rate not exceeding 1 liter per hr. By definition, this degree of stress has an (HSI) value of 100 and is given by any combination of $M + R + C$ which is balanced by E_{max} within their defined limits. For other situations where E_{req} is greater or less than E_{max} ($\leq$2400 Btu per hr), the value of (HSI) is proportionately different from 100:

$$(HSI) = 100 \times \frac{E_{req}}{E_{max} \leq 2400} \quad (7)$$

By using the globe thermometer temperature (see Chapter 52) of the environment to represent the combined effects of mean radiant temperature and air temperature, the Heat Stress Index chart Fig. 1 has been constructed, to permit quick determination of (HSI) when M, t_s, t_a, t_{wb}, and air velocity are given. The procedure for finding (HSI) will be obvious by following the dash line in Fig. 1.

The Heat Stress Index was developed from research experience with young men in good physical condition and well acclimatized to heat. Table 2 assigns suggested physiological meaning to (HSI) values above and below 100, for older men as well as the standard young man and, also, for various kinds of jobs which differ in their demands upon mental and physical effort. From these it becomes possible to select (HSI) levels appropriate to each work situation.

The Heat Stress Index (HSI) differs from the Effective Temperature (ET) scale in the rational rather than subjective basis of its construction. Practically, the commonly recommended ET = 80 F for heavy work at moderately high air velocity agrees very well with the (HSI) limit of 100 for acclimatized young men. In Fig. 2 are shown the combinations of dry- and wet-bulb temperature (air and wall temperature alike) for three different air velocities and three

Table 2 .... Evaluation of Index of Heat Stress

Index of Heat Stress	Physiological and Hygienic Implications of 8-Hr Exposures to Various Heat Stresses
−20	Mild cold strain. This condition frequently exists in
−10	areas where men recover from exposure to heat.
0	No thermal strain.
+10	Mild to moderate heat strain. Where a job involves
20	higher intellectual functions, dexterity, or alert-
30	ness, subtle to substantial decrements in performance may be expected. In performance of heavy physical work, little decrement expected unless ability of individuals to perform such work under no thermal stress is marginal.
40	Severe heat strain, involving a threat to health unless
50	men are physically fit. Break-in period required
60	for men not previously acclimatized. Some decrement in performance of physical work is to be expected. Medical selection of personnel desirable because these conditions are unsuitable for those with cardiovascular or respiratory impairment or with chronic dermatitis. These working conditions are also unsuitable for activities requiring sustained mental effort.
70	Very severe heat strain. Only a small percentage of the
80	population may be expected to qualify for this work.
90	Personnel should be selected (*a*) by medical examination and (*b*) by trial on the job (after acclimatization). Special measures are needed to assure adequate water and salt intake. Amelioration of working conditions by any feasible means is highly desirable, and may be expected to decrease the health hazard while increasing efficiency on the job. Slight "indisposition" which in most jobs would be insufficient to affect performance may render workers unfit for this exposure.
100	The maximum strain tolerated daily by fit, acclimatized young men.

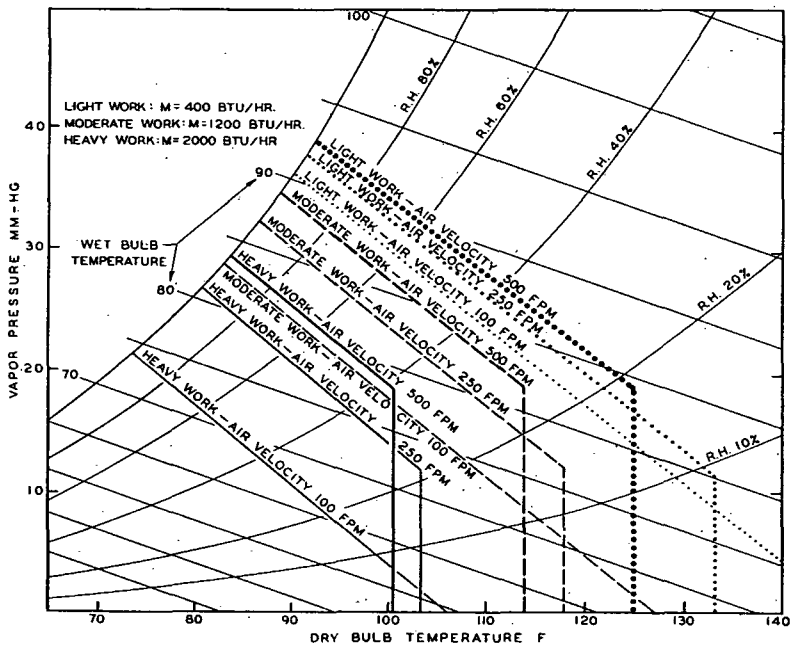


Fig. 2 .... Conditions for Stress 100 at Three Grades of Work and Three Air Velocities

different grades of work, all of which give (HSI) = 100. Points representing ET = 80 F with an air velocity of 300 fpm are also shown for comparison.

CONTROL OF HEAT EXPOSURES

Measures for control of heat exposures will be treated under the following headings: Control at Source, Local Exhaust Ventilation, Radiation Shielding, General Ventilation, Dilution Ventilation, Local Relief Ventilation.

Control at Source

The magnitude of heat exposure can be reduced by insulating hot equipment, locating such equipment most favorably (in zones of good general ventilation within buildings or even outdoors), covering steaming water tanks, providing covered drains for direct removal of hot water, and maintaining tight joints and valves where steam may escape. This method is an obvious one and requires no particular comment other than to emphasize the benefits to be derived from elimination of heat sources wherever possible.

Local Exhaust Ventilation

The natural convection column of heated air rising from a hot process may be captured by means of ventilated enclosures or exhaust hoods and removed with a minimum of dilution by air from the surrounding space when local exhaust ventilation can be used. Chapter 52 provides detailed information on the design of exhaust hoods and duct systems for local exhaust.

Radiation Shielding

In some industries, commonly referred to as the hot industries, there are many hot objects and surfaces such as furnaces, ovens, furnace flues and stacks, boilers, molten material, and hot ingots of metal, castings, or forgings and, in consequence, the major environmental heat load is in the form of radiant heat. Since air temperature has no significant influence on the flow of radiant heat, ventilation is of no help in controlling such exposures. The only effective control is the direct one of decreasing the amount of radiant heat im-

pinging on the exposed worker. This frequently can be accomplished by radiation shielding. Radiant heat exposures can be reduced by lowering the surface temperature of hot equipment by using insulation or water-cooled surfaces or radiation shields.

Hot surfaces emit infra-red waves which reach all objects within visible range. This is true not only if the hot surface is a primary one such as a furnace wall, a high temperature stack, or a hot ingot, but also if it is secondary in nature, that is, one which is reradiating heat after receiving it by direct radiation from a high temperature source. It may well be that all surfaces in a shop or building are hot because of radiant heat received from a few primary sources. Under these circumstances, the ventilation air is heated rapidly as it circulates through the building. The result is a very unsatisfactory thermal environment, all stemming from the few primary heat sources. Consequently if the radiant heat load *from these is reduced there will be a great improvement* in the entire building.

A shield is simply a sheet of material, opaque to the infra-red waves (or essentially so), placed between the hot object such as a furnace, and the cooler surroundings. The closer it can be placed to the hot object, the greater will be the effective coverage. Essential to most shielding is the absence of physical contact and the presence of an air space between the hot object and the shield to avoid heating of the shield by conduction. This is not a vital matter if the shielding material has a low coefficient of emission for infra-red rays as does aluminum, for example. Under such circumstances, very little heat is radiated even if the shield becomes very hot.

Radiation shields in the following 5 forms are very effective:

1. Sheets of reflective metal or insulating board, semi-permanently attached to the hot equipment (such as furnace buck stays) or arranged as semi-portable floorstands.
2. Aluminum foil-faced cloth curtains raised or lowered on spring rolls.
3. Transparent shields, including heat reflective tempered plate glass, reflective metal chain curtains, and close mesh wire screens. These have lower efficiency than opaque shields in items 1 and 2.
4. Water-cooled shields for absorbing the heat.
5. Reflective garments, such as aprons, or in the form of a sandwich in cases of continuous front and back exposures. For continuous wear the apron or sandwich width should be limited to from 14 to 18 in. in order to assure adequate continuous side openings for air circulation and body ventilation. In addition, gauntlets and face shields are particularly applicable to operations such as the pouring and casting of hot metal. Supply houses dealing in safety clothing for industry offer suitable light-weight flame proofed foil-faced cotton drill or denim of excellent reflectivity. For repairs inside hot coke ovens and industrial furnaces, a complete suit is available using forced ventilation from a small blower or a compressed air source. These suits may be made of asbestos cloth faced with a reflective metal in atomized form.

If the shield is a good reflector, it will remain relatively cool in the presence of severe radiant heat. This reflectivity is a surface characteristic and is not dependent on thickness. A thin foil is effective. Tinplate, stainless steel, and ordinary flat or corrugated aluminum sheets are efficient and long-lived. Foil-faced plaster board, though less durable, gives good reflectivity on one side. Since the best radiation shields are effective reflectors of infra-red rays, they must be used intelligently lest a radiant heat load merely be transferred from one place to another. The objective is to have the shield reflect the radiant heat back to the primary source where it may be removed by local exhaust. However, unless the shield completely surrounds the primary source, some of the infra-red energy will be reflected into the cooler surroundings and possibly into an occupied area. It is imperative, therefore, to study well where the reflected heat will go before shielding is installed, to avoid merely getting rid of the problem in one area by transferring it to another.

GENERAL VENTILATION

General ventilation, which involves sweeping of the space occupied by workmen and process heat sources with large quantities of outdoor air, may be used to limit the temperature rise within the space, if the outdoor air itself is not too hot. The method is particularly suitable for cases where the heat sources are spread over the entire area, and for the removal of solar heat from the space.

Dilution Ventilation

The principles of dilution ventilation furnish the basis for the design of the general ventilation system. The amount of air which must be circulated can be estimated as:

$$(\text{cfm}) = \frac{H}{1.08\Delta t} \tag{8}$$

where

H = Heat to be removed from the space, Btu per hour.
Δt = temperature rise of the air, Fahrenheit degrees.

All heat sources such as furnaces, electric motors, ovens, and kilowatts of lighting should be tabulated to give the total heat output in Btu per hour (See Cooling Load Calculations, Chapter 13). The amount of air to be exhausted is a function of the total amount of heat and the permissible air temperature rise which, in practice, may vary from 10 up to 40 deg, depending on many factors such as roof height, nature of work being done, and magnitude of heat release.

Advantage should be taken of the chimney effect of the heated air within the space by introducing the diluting air near the floor of the space and discharging the heated air as near the top of the structure as possible, regardless of whether natural or mechanical exhaust ventilation is used. Since the workmen ordinarily operate near floor level, the entering air temperature should be within acceptable limits as outlined earlier in this section. The leaving air temperature will have its effect on workmen through the radiant heat emitted by the upper parts of the structure which are heated by the air. A higher leaving air temperature can be used with a high than with a low ceiling, since the ceiling contribution to the mean radiant temperature will be less for the taller structure.

Roof Ventilators

Roof ventilators are basically heat escape ports located in the high section of a building and properly enclosed for weather-tightness. Stack-draft effect plus some wind induction are the motive forces for several common designs of continuous ventilators and round ventilators. The latter can be equipped with fan barrel and motor, thus permitting gravity operation, or motorized high capacity operation, at will.

Two other main designs are available: one is the low-type ventilator which consists essentially of a stack fan with a rainhood; the other contains a stack fan with a split butterfly closure that is floated to open position by the discharge air stream and is self-closing. Both employ mimimum enclosures and have little or no gravity capacity.

Various types of roof ventilators may be listed in diminishing order of temperature differential and heat-removal capacity. Next to chimneys and stacks, the continuous ventilation monitor is most effective for removal of substantial and concentrated heat loads. This may be in the form of an elevated length of roof ridge with extended overhang and no rain louvers. Such structures are commonly employed over open hearth furnaces and soaking pit buildings but, in practice they give uncertain performance. A more efficient type is a streamlined, watertight monitor constructed of noncorrosive metals or protected metals. Its capacity increases with wind velocity and it can be readily closed in winter to conserve building heat. Both types have tremendous capacity and are limited only by roof area and proper relation of low-level air inlets.

Next in capacity are the (1) round gravity or windband ventilator, (2) round gravity type with fan and motor added, (3) low-hood powered ventilator, and (4) vertical upblast powered ventilator. Popular modifications of these include the rotary type and the turbine ventilator.

Minimum-capacity ventilators of the gravity type are applicable to warehouses with light heat loads, and to manufacturing areas having high roofs and light loads. Non-mechanical ventilators are desired here because the wide spacing makes electrical wiring and maintenance of fans and motors a matter of concern.

Streamlined continuous ventilators must be able to operate effectively in the absence of mechanical power. While it is difficult to predict performance accurately, it can safely be said that efficient ventilator operation is generally obtained when difference in elevation between the average air inlet level and the roof ventilation is not less than 30 ft and the exit temperature is 25 F deg above the prevailing outdoor temperature. See Chapter 11, Infiltration and Ventilation. Under these conditions and with a wind velocity of 5 mph, the ventilator throat velocity will be about 375 fpm. It will thus remove 10,000 Btu (per hr) (sq ft of throat area):

$$25 \text{ deg} \times 1.08 \times 375 \text{ cfm} = 10{,}000 \text{ Btu}$$

To insure this level of performance it is essential that sufficient low-level openings be provided for the incoming air; otherwise the gravity ventilator becomes starved for air and capacity falls off. The manufacturers recommend 250 fpm to 450 fpm inlet velocity. Lack of adequate inlet area is the most common cause of failure of gravity-type roof ventilators. A positive supply of air to insure direct ventilation around the hot equipment may be necessary within buildings of considerable area where the external wall inlets are remote from the equipment.

A decision between gravity and mechanical ventilators may be difficult to reach. The electrical power required for fan operation may be a deterring factor but this is offset by the advantage of constant ventilation capacity given by fan operation. Mechanical ventilators will also function despite inadequate fresh air inlets. In many cases there is justification for a mechanical supply (make-up air) which will positively supply air to the work zone.

LOCAL RELIEF

General

The methods required for general ventilation of industrial areas have been described. Such ventilation may have to be supplemented, or in some cases replaced by local ventilation in large industrial areas having substantial heat loads, high ceilings, and scattered work stations. Provision must be made for local relief, to provide tolerable working conditions around the several operations where the heat loads are concentrated. The methods indicated to be described for local relief are based on the assumption that exhaust ventilation, radiation shielding, equipment insulation, and possible changes in process design have been fully utilized to minimize the heat loads.

Methods of Providing Relief

Relief in local industrial work areas may be provided by any of the following three methods (or a combination of the three):

1. Provide a complete enclosure around the worker with separate ventilation in order to maintain cooler working conditions. This may be in the form of a control room, small shelter booth, or ventilated crane cab. In effect, this is "localized" general ventilation, differing only in the conditions of air temperature, humidity, and motion required.
2. Surround the worker with a relatively cool atmosphere by a direct supply of air introduced at a low level over a small area of the plant. In such cases we are not concerned with the temperature at higher levels in the space so long as adjacent structures do not become hot and thus return radiant heat into the work space.
3. Direct a high-velocity air stream at the worker to increase the evaporative cooling effect. This method, commonly called *spot cooling* will incorporate varying degrees of Method 2, depending upon the number of employees and the distribution of the work stations.

Method Number 1, in the form of a work station enclosure, is the most desirable because it permits complete control of the environment. The second method is effective in large areas with many work stations, such as machine shops and assembly lines. The last method is used to provide *spot cooling* in large spaces where scattered work stations and localized sources of heat make it highly impracticable to maintain a tolerable environment throughout the building.

Physiological Aspects of System Design

Two different situations in respect to heat load are encountered: (1) where radiant heat sources are not important, and (2) where radiant heat sources are important. These two situations must be treated differently in design.

Where Radiant Heat is Not Important. Where no important sources of radiant heat are located within or close to the work area, *it is only necessary to introduce the relief air* into the work space in such a way as to displace the hot air and thus surround the worker with an acceptable atmosphere, consistent with his own needs.

Where Radiant Heat is Important. Where important sources of radiant heat are present and cannot be entirely controlled by radiation shielding, the air supplied for relief must do more than simply displace the hot air. It must also provide convective cooling to offset the radiant heat load. This requires that the air be supplied at a lower temperature and with sufficient velocity. Contrariwise, if the temperature of the relief air exceeds skin temperature, a convective load is added to the radiative load and these, together with the metabolic heat must be removed by evaporative cooling. As the temperature of the air impinging on the worker rises above the skin temperature, a critical point is approached where too high an air velocity will add to the body heat load and too low a velocity will fail to evaporate the sweat, and thus fail to provide the maximum evaporative cooling effect.[4, 5]

The level of air motion provided at the work station should be low, approaching normal room velocities, or about

50 fpm for light activity in a fixed position, and particularly when the individual is seated at a desk or bench. The maximum velocity around the worker should not exceed 200 fpm for continuous exposure. With a high work level and intermittent exposure (relief stations), velocities of 1000 to 2000 fpm have been used successfully. Great care must be exercised in using such high velocities, however, to avoid the undesirable effects of air at high temperature.

Ordinarily the temperature of the air supplied to the worker for convective cooling should be about 80 F. Evaporative cooling ventilation systems will usually provide this. Preferably, the air should be directed to the front and torso of the body. Impingement on the back of the head, neck, and shoulders should be minimized. The supplied air may require tempering in winter to raise it to an acceptable temperature. However, in areas of high heat load, the temperature of the air supplied during the winter may have to be lower than room temperature to provide adequate relief for the worker.

People vary considerably in their tolerance to air motion, temperature, and humidity, and this tolerance varies with the season. It is essential, therefore, that the air supply outlets for most local relief ventilation systems be adjustable in direction, and permit reduction in outlet velocity. A level of air motion which feels comfortable and refreshing in hot weather may feel disagreeable and drafty in the winter.

Types and Design Requirements of Systems

The supply air can be provided by local man-cooling fans; by outdoor air introduced directly or after dehumidification or cooling (evaporative or mechanical); and by combinations of outdoor and recirculated air either direct or after conditioning, as required.

Local man-cooling fans should be used with caution other than in light heat-load areas where the ambient temperature is below the skin temperature. In particular, where there is an elevated ambient temperature with or without high radiation load, the high velocity may add considerably to the convective heat load and thus seriously increase the demand for sweating and evaporative cooling.

A relief system employing outdoor air is to be preferred over man-coolers and will provide excellent relief in many industrial areas. However, when the outdoor air temperature exceeds the skin temperature, the direct supply of outdoor air is obviously reduced in effectiveness. Such a system is properly used only in geographical areas where the periods of hot weather are of short duration.

In geographic areas where outdoor humidities do not exceed 50 percent relative humidity at high daytime temperatures an evaporative cooling system offers greater relief for the worker in that the discharge air temperature can be lowered (within five degrees of the wet-bulb temperature) to obtain adequate convective body cooling. The sensible heat gain by the discharge air (through mixing) in a properly designed system will be sufficient to reduce the relative humidity (and vapor pressure) of the supply air and thus permit the necessary evaporative loss from the worker's skin. Generally the supply of evaporatively cooled air should not exceed 20 to 50 percent of the total ventilation through the building. So limited, the relative humidity will be kept low enough to avoid distress to the workers and rusting of equipment under most weather conditions in the United States. For information on the design of evaporative cooling systems, see References 5 and 6 and Chapter 41.

An air supply with mechanical refrigeration offers the greatest relief. Such systems are expensive in first cost and this has retarded their use. However, air supply with mechanical refrigeration is finding greatly increased use in precision work and testing areas, in areas requiring constant ambient conditions for product uniformity or control, and where the increased efficiency of the worker is reflected in a reasonable return on the investment.

It is essential that the outdoor air, (with or without cooling) be brought as directly as feasible to the proximity of the work station. Impingement upon hot equipment or mixing with hot ambient air should be minimized. Supply ducts passing through hot areas should be insulated. The use of aluminum ducts will minimize heat gain from radiant sources. For large work areas provided with a high rate of ventilation the local relief can best be obtained by locating the outlets as close to the floor as possible, consistent with the work and structural interferences.

Design of Outlets for Local Relief

In the design of outlets for local relief it is of great importance to consider the following: location; discharge velocity, discharge volume, and control of direction. The influence of these items will be discussed in the paragraphs which follow.

Location. The outlets should be kept as close to the worker as possible in order to minimize mixing with the warmer air in the space. In most areas the outlets can and should be brought down to the 7-ft level. Outlets at floor level can be used with success in many cases.

Discharge Velocity. The discharge velocity may be as high as necessary to obtain the desired velocity at the work station, as outlined above. Outlet velocities of 3000 to 4000 fpm may be necessary for remotely located outlets. Velocities of 1000 to 2000 fpm are the most frequently used for low outlets (at the 7-ft level). When the supply air is cooled, the velocity through an outlet directly at or over the worker must be kept low (around 50 fpm). It should be kept in mind that these recommended velocities are for conditions of maximum heat load. For more moderate weather and ambient conditions the workers will desire to reduce the velocities. Outlet dampers for velocity control (in the direction of the worker) should always be provided. The control must be designed so as not to reduce the ventilation for the space.

Discharge Volume. The outlet volume required will vary widely, depending upon whether the system is designed to provide highly localized *spot cooling* or is to provide general ventilation throughout a sizeable work area. Generally 1500 to 2000 cfm per station will be adequate for moderate loads, and 3000 cfm per station for higher loads such as at hot metal furnace stations. With remote outlets large air volumes are required to insure adequate relief because of the mixing of the supply air with the warmer surrounding air through which it is projected. The air stream from a large outlet will maintain an appreciable core of air at the original supply air temperature for a considerable distance from the outlet. Small outlets and slot outlets have small cores which are rapidly dissipated through induction. In small enclosures or semi-enclosures (shields against radiant heat, for instance) perforated panel supply outlets are very effective for mechanically cooled installations, because of their low induction characteristics. For further information on outlet design and the throw and induction characteristics, see Chapter 20.

Control of Direction. With very few exceptions, directional outlets are necessary in order to maintain ventilation or make-up air to the space even when the workers do not wish to have the air directed into their work zones. In this way, the air can be directed down in the summer when it is needed, and up in the winter for ventilation, heating, and make-up purposes. It will be possible, too, to direct the air toward one or another work station as needed. From the production standpoint, directional control may be necessary to direct the relief ventilation so as not to disturb the product or upset the performance of local exhaust hoods.

Types of Outlets for Local Relief

A few of the different types of outlets are shown in Fig. 3. In most cases, volume control is highly desirable. Directionalizing and damper control should be designed for easy adjustment from the floor by chain, sash cord, or pole. Where

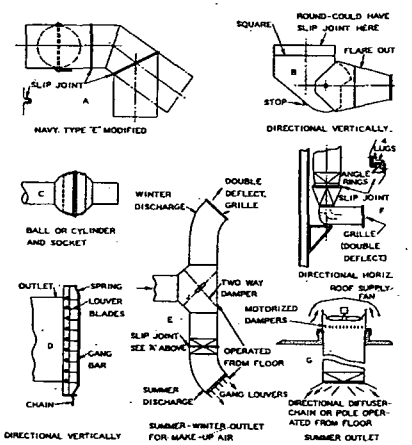

Fig. 3 .... Directional Outlets for Spot Cooling

a constant total volume of supply make-up air must be maintained, an outlet similar to *E* will permit volume adjustment to the *work zone* without reducing the total air supply to the building area. A double deflection grille is available with gang-operated, horizontal face bars (similar to *D*) to accomplish the desired objective by directing the air down to the work zone or toward the ceiling. Such a grille could be installed on outlet *F*. Outlets *A*, *B*, and *C* could be used without dampers for these applications. An inexpensive means of supplying summer relief air is shown in *G*. Easily-adjusted diffusers, which will provide a flat or down-blast air discharge pattern, are available.

Where overhead installations are not possible because of structural interferences or other difficulty, outlets near the floor may be used. These may be in the form of grilles located in pilasters, control panels, tables, equipment, or in the floor itself. Such outlets have been quite successful in welding and foundry areas and at the work locations in kitchens.

CONTROL OF ENVIRONMENTAL GASES AND VAPORS, DUSTS, AND FUMES

In general, the systems for the control of these atmospheric contaminants in industrial plants will be of three types:

1. *Local exhaust systems* will be indicated where the contamination originates at concentrated areas and is characterized by low or imperceptible air motion, or where the contaminant is a dust, mist, or fume requiring a capture velocity exceeding 25 fpm. Design of this type system is discussed in Chapter 52, and will not be further treated in this chapter.

2. A system employing the *dilution* method will usually be indicated where the contamination originates at scattered points dispersed generally throughout the area.

3. Combination of local *exhaust* and *dilution* methods is often economical, since well designed exhaust hoods or openings, removing from the space that portion of the contamination load which is susceptible to such treatment, will often reduce greatly the air volumes required for dilution purposes. The choice of the type of system should be made on the basis of economic comparisons.

Design of Dilution Systems

The first step in the design of a system employing the dilution method is to determine as exactly as possible the nature and extent of the contaminating load. This will often be difficult, and may require construction of pilot production models. Often, however, the required data will be available from production records, showing the weight or volume rate of loss of the contaminating agent to the atmosphere, or it may be estimated from parallel operations in other plants, or by applying experienced engineering judgment. However obtained, the determination of the nature and magnitude of the contaminating load is an indispensable step in the proper design of the corrective system. Designs based on number of air changes per hour, or other rule-of-thumb methods, are hopelessly inadequate, and lead either to unsuccessful operation or to excessive and unnecessarily high cost of installation.

1. *Gases and Vapors.* Once having established the nature and magnitude of the contamination load, it is rarely necessary to completely remove contaminating agents from the atmosphere. For cases involving diffusible vapor or gas contaminants, maximum allowable concentrations (MAC) of commonly encountered gases and vapors have been established, and these data are tabulated in Chapter 7. From these data, and the previously established rate of addition of the contaminant to the space, the volume of air required to dilute the addition to a tolerable level can be calculated by the equation:

$$Q_s = \frac{Q_c \times 10^6}{(\text{MAC}) - (\text{SAC})} \qquad (9)$$

where

Q_s = quantity of air circulated, cubic feet per minute.
Q_c = rate of generation of contaminant, cubic feet per minute.
(MAC) = maximum allowable concentration, ppm by volume.
(SAC) = concentration in supply air, ppm by volume.

The rate of generation of the contaminating vapor will often be available as a *weight or volume* of liquid evaporated into the space per unit time. These may be converted to the units of Equation 9 by applying the principle that a pound-mol of a

gas or vapor will occupy approximately 359 cu ft at standard pressure and temperature. Thus,

$$\text{cfm (vapor)} = \frac{W}{M_w} \times 359 \times \frac{t + 460}{492} \qquad (10)$$

where

W = rate of generation of contaminant, pounds of liquid solvent per minute.
M_w = molecular weight.
t = air temperature, Fahrenheit.

A special case occurs where local concentrations of solvent vapors *at the breathing zone*, resulting from concentrated sources of contamination, are intolerably higher than the average design concentration when using dilution methods. Data are available for calculations, but involve many assumptions regarding boundary conditions, such as convection area and random air movement in the vicinity.

2. *Dusts and Fumes.* Maximum allowable concentration of various dusts, fumes, and mists are also tabulated in Chapter 7. However, the dilution method as a means of treating particulate contaminating agents should be used with care, since the allowable air movement in spaces will ordinarily be lower than the capture velocity required for such particles. Exhausting at the source (see Chapter 52) will generally be the recommended treatment for these particulate contaminants.

CHAPTER 52

INDUSTRIAL EXHAUST SYSTEMS

Elements of Exhaust Systems; Hoods or Enclosures, Capture Velocities, Air Volume, Exterior Hoods, Special Exhaust Requirements, Exhaust of Hot Processes, Induced Air Flow, Duct System Design, Calculations, Construction Specifications, Materials, Details, Air Flow Producing Equipment, Air Cleaning Equipment, Make-up Air, Maintenance of Performance, Materials for Corrosion Resistance

IN industrial plants, some type of exhaust system designed to collect and remove dusts, fumes, mists, vapors, and gases is installed to protect health and safety of industrial personnel, promote worker efficiency, salvage usable material, or improve plant housekeeping. This chapter will not include consideration of systems similar in design, but used to convey heavy loadings (100 or more grains per cu ft) of materials. Definitions of various air contaminants, their particle sizes, maximum allowable concentrations, and upper and lower explosion limits are included in Chapter 7, Air Contaminants.

Exhaust systems are extensively used for control of contaminants from:

1. Mechanical cutting and abrading operations including abrasive blasting and rock cutting.
2. Fuel-burning and exhaust gas producing operations.
3. Molten materials handling operations.
4. Welding, burning, and soldering operations.
5. Fiber handling operations.
6. Volatile and gaseous material handling operations.
7. Chemical processes.

Local exhaust systems should be considered whenever possible rather than general ventilation methods which allow contaminants to be dispersed within the workroom. The former provide more positive control, as well as a great reduction in exhaust volume handled, thereby reducing the cost of air cleaning equipment required.

ELEMENTS OF EXHAUST SYSTEMS

An exhaust system consists of (1) hoods or enclosures at sources of air contamination, (2) branch and main ducts through which an air stream transports the contaminant to air cleaning devices or to the atmosphere, (3) air moving equipment to produce the required air flow into hoods or enclosures, and (4) air cleaning equipment when required. See Chapter 24, Part II, for discussion of types, applications, and principles of operation.

HOODS OR ENCLOSURES [1-10]

The most effective hood or enclosure is one that will require the minimum exhaust volume for effective contaminant control. The design must therefore be based upon a knowledge of the process or operation for which control must be obtained. The more complete the enclosure, the more economical and effective will be the installation.

Many designers give first consideration to a hood completely enclosing the operation and then provide necessary access and working openings. The familiar hoods, such as booths, sidedraft or downdraft hoods (with or without side shields) have been developed from this complete enclosure concept. Openings in hoods are kept to a minimum size and are placed away from the natural path of the contaminant travel when possible. Doors should be provided for inspection and maintenance when needed.

Capture Velocities and Air Volume Exhausted

Only after the hood design has been determined can the exhaust volume requirements be calculated. With enclosures, volumes are calculated from the known open area of the hood and the selected capture or indraft velocity sufficient to prevent outward escape.

Usual capture velocities for typical operations are listed in Table 1 and refer in the case of remote hoods to the air movement required at the zone of air contaminant generation. Required capture velocities for any operation will vary with the magnitude of the air volume handled, with uncontrolled air movement in the area, and often with the location of the process or operation and size of the workroom. Large remote hoods exhausting large air volumes will provide effective control at lower maintained capture velocities than will small remote hoods handling lower exhaust volumes. A hood at one end of a small narrow room with air supply at the opposite end will provide control with a lower capture velocity than that required from the same hood in a large room where no

Table 1 .... Minimum Air Velocities Required at Point of Origin to Capture Contaminant Effectively

Condition of Generation of Contaminant	Minimum Capture Velocity, Fpm	Process
Released without noticeable movement	50–100	Evaporation of vapors, exhaust from pickling, washing, degreasing, plating, welding, etc.
Released with low velocity	100–200	Paint spraying in booth; inspection, sorting, weighing, packaging, low speed (less than 200 fpm) conveyor transfer points, blending, mixing, barrel filling.
Active generation	200–500	Foundry shakeout, high speed (over 200 fpm) conveyor transfer points, crushers, screens.
Released with great force	500–2000	Grinding, tumbling mills, abrasive cleaning.

perceptible air flow will exist except in the immediate area of the hood.

Exterior Hoods

Where enclosure of the process is impracticable, the air flow pattern in front of the hood must be such that capture velocities required to convey the contaminant to the hood opening will be maintained in the area of contaminant generation.

The method for determining, approximately, the quantity of air that must be exhausted from an unobstructed hood, without flanges, to produce design capture velocities at the point or origin, is given in Equation 1:

$$Q = V_X(10X^2 + A) \qquad (1)$$

where

Q = quantity of air exhausted, cubic feet per minute.
V_X = air velocity at X-distance in feet from the hood and and on the center line of the hood, feet per minute.
X = distance along the hood center line, from the face of the hood to the point where the air velocity is V_X feet per minute, feet.
A = area of the hood opening, square feet.

Fig. 1 shows lines of equal velocities (velocity contours) for a rectangular hood opening with a side ratio of one-half. The velocities are expressed as percentages of the velocity at the opening. Studies have established the principle of *similarity of contours* which states that the positions of the velocity contours for any hood (when the contours are expressed in terms of the average velocity at the hood opening) are purely functions of the shape of the hood. Extensive studies[9, 11, 12] have revealed variations in values of such velocity contours for long narrow slots and for hoods with one or more planes shielded against air flow.

For smaller hoods, flanges which are usually 3 to 6 in. wide surrounding the hood opening usually will improve

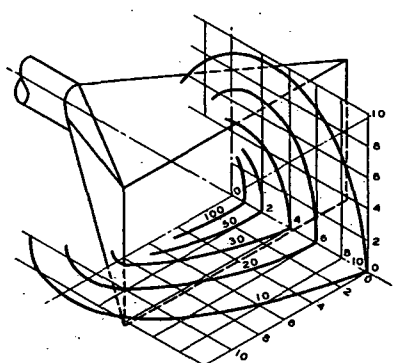

Fig. 1 . . . . Velocity Contours for Rectangular Opening with a Side Ratio of One-Half. Contours are Expressed as Percentages of the Velocity at the Opening

Table 2 . . . . Summary of Exhaust Rates Required with Common Types of Exterior Hoods Applied to Cold Processes Only[13]

X-Distance Inches	*Simple Opening, with or without Flange or Taper, but No Plane Flanking Openings*[a]	*Simple Rectangular Opening Flanked by Plane Parallel to Axis*[b]
	Exhaust Rate Cfm	Exhaust Rate Cfm
2	25–75	25–50
4	50–100	50–75
6	100–200	75–150
8	200–400	150–300
10	300–600	200–400
12	400–800	300–600
15	600–1200	400–800
18	900–1500	600–900
21	1200–1800	700–1000
24	1500–2200	800–1200
30	2500–3500	1200–1800
36	3000–4500	1500–2200
42	4000–6000	2000–3000
48	5000–7000	2500–3500

X-Distance	*Single slots flanked by parallel plane on which contamination process occurs* For *X*-distance (i.e., width of plane) always less than ½ length of slot[c]
Less than 2 ft	Exhaust rate 125 to 150 cfm per sq ft of plane area.
More than 2 ft	Exhaust rate 75 to 125 cfm per sq ft of plane area.

[a] Refers to simple hood opening that performs in accordance with Equation 1.
[b] Refers to hood having a complete flanking plane parallel to axis which prevents flow of air from half of normal air supply zone, and performs in accordance with the equation, $Q = V_X(5X^2 + A)$. Example: rectangular hood opening resting on bench top. Includes single slots, so flanked, for X-distance greater than ½ slot length.
[c] If X-distance is greater than ½ slot length, consider it as a single opening flanked by a plane (see upper right column). With exhaust rate divided between 2 slots, an additional safety factor is provided.

From *Plant and Process Ventilation*, by W. C. L. Hemeon (Industrial Press, New York).

the air flow in front of the hood and will reduce the air volume required to provide desired capture velocities by as much as 25 percent.

The exhaust volume calculated for an exterior hood by different designers may vary greatly due to their selection of different empirical design velocities. Usually capture velocity design values are in the 50 to 200 fpm range.

The exhaust rates calculated for large exterior hoods may become needlessly large if the capture velocity is selected blindly. Whether on not an individual particle or a small wisp of gas or smoke in motion away from the hood is captured before it escapes from the zone of influence created by the hood is determined not only by the specific air velocity (design capture velocity) at the immediate point of contaminant release but also by the depth of the moving air curtain it must traverse before it gets beyond the influence of the hood. The capturing force of the air flow in front of any exhaust hood is the summation of all the separate velocities beyond (away from the hood) the point of contaminant release multiplied by the distance through which each velocity acts; i.e., force

times distance, the force being a function of the velocity. For large hoods, or more accurately for large exhaust rates, the depth of the zone of influence is much greater than for small exhaust rates and, also for the former, the distance between successive velocity contours is greater. Further effectiveness for larger volumes can be obtained where the air supply source produces a *sweeping* flow toward the zone of contaminant release.

Table 2 presents design data by Hemeon[13] applicable to exterior hoods employed for exhausting contaminants originating in a *cold process* only. These values are based on Equation 1 wherein varying values of V_X have been employed according to a scale that takes account of velocity depth factors discussed in the preceding paragraph, and where X-distance is taken as the distance from the hood face to the point where any high velocity air currents engendered by the contaminating process itself have expended their energy. In addition, the ranges of exhaust volumes which have been found satisfactory in practice for many operations are reported in Table 3. These data provide a means of checking the calculated rates for specific applications.

SPECIAL EXHAUST REQUIREMENTS

It is important to note that certain operations may require exhaust volumes in excess of the quantities based on design data from Table 1 and Equation 1. Typical reasons for increased ventilation rates include:

1. Induced air flow caused by the thermal or stack effect from sources of extreme heat.

2. Induced air flow caused by falling granular material in large quantities through considerable height, or by internal rotating parts such as some types of crushers, knives, or macerators. (See discussion in later section Induced Air Flow and Table 4.)

3. Exhaust volumes insufficient to dilute mixtures of combustible vapor and air to less than 20 percent of the lower explosive limit of the combustible.

4. Room air currents caused by cross drafts, spot cooling, motion of machinery or operators. Cross drafts are of great significance in the exhaust of hot processes with high canopy hoods.

5. Design volumes, especially in the case of excess heat control and solvent vapors, may be based on dilution systems where exhaust volumes are selected to keep contaminant concentrations below design levels. See Reference 13, Chapter 7.

6. Local or State regulations may specify larger exhaust volumes for specific operations.

Exhaust volume requirements for many specific operations have been listed in Tables 3, 5, 6, and 7.

Exhaust of Hot Processes

In designing local exhaust hoods for hot processes, it is necessary to estimate the rate of delivery of hot air to the hood by the convection column. The exhaust capacity should exceed this by an amount sufficient to create a velocity in the excess air flowing into the envelope surrounding the convection column that will prevent escape of the heated air at the edges of the hood. Unless distances from the heat source to the receiving hood are small (possibly under 3 ft), the quantity of heated air entering the hood is increased substantially by the induction and turbulent mixing of large quantities of room air as the distance above the heat source increases. Unless the exhaust hood can handle this total volume, spillage of contaminated mixture will occur.

The exhaust rate for satisfactory control of hot processes can be kept at a minimum by enclosing the hot processes as completely as possible and exhausting from the top of the enclosure.

Low canopy hoods rank next to enclosures in economy of air flow. High canopy hoods must handle greatly increased amounts of air over that in the heated stream itself, in order to receive and dispose of the air entrained by the convection column from far below. Where lateral exhaust ventilation must be employed, the air flow toward the hood has to overcome the tendency of the heated air to rise and also must sweep it into the hood. Consequently, the required exhaust air flow is very much larger than for hoods that simply capture the upward flow of heated air. A combination of an exhaust hood with a positive jet of air blown across the top of the equipment and directed into the hood may be required above large pieces of equipment.

Hemeon has suggested[13] design Equations 2 to 6 which follow for various types of hoods.

Equation 2 is suggested for estimating the flow of heated air rising from the top of a hot body:

$$q_s = 29\sqrt[3]{H_s A_p^2 l_h} \qquad (2)$$

where

q_s = air flow rate at upper limits of hot body, cubic feet per minute.
A_p = cross-sectional area of air stream at upper limits of hot body, square feet.
l_h = height of hot body, feet.
H_s = convectional heat transfer rate, Btu per minute.

The area A_p may be approximated from the dimensions of the hot body. For horizontal rods, the width of the stream is practically the diameter of the rod. For vertical planes, the air stream appears to thicken at an angle of 4 to 5 deg with the plane. For horizontal planes, the area of the air stream may be taken as equal to the area of the plane itself.

In the case of horizontal plates, in the absence of better experimental information, l_h may be taken as equal to the horizontal diameter. Chapter 5 furnishes information which may be used in estimating the heat transfer rate H_s.

The flow rate, q_s, of heated air entering the hood after turbulent mixing and dilution have taken place may be approximated for low canopy hoods above horizontal surfaces and where no heat from steam is involved, as

$$q_s = 5.4\, A_s \sqrt[3]{l_h\, (\Delta t)^4} \qquad (3)$$

where

A_s = surface area of hot body, square feet.
Δt = the temperature difference, hot body to room air, Fahrenheit degrees.

Similarly, where the heat is furnished by steam from a tank of hot water,

$$q_s = 290\, A_s \sqrt[3]{l_h\, G} \qquad (4)$$

where

G = the rate of steam formation, pounds per (square foot water surface) (minute).

(*Continued on p. 707*)

Table 3 .... A Guide to Ventilation Rates for Typical Industrial Equipment

State or Local Regulations Should be Consulted and Followed Where Higher Ventilation Rates are Specified

Operation	Ventilation		Usual Transport Velocity Fpm	Remarks and References
	Type of Hood	Air Flow		
Abrasive blast rooms (sand, grit, or shot)	Tight enclosure with air inlets (usually in roof)	60–100 fpm downdraft (long rooms of tunnel proportions 100 fpm crossdraft)	3500	Ref. 8. Many codes specify minimum downdraft of 80 fpm
Abrasive blast cabinets	Tight enclosure with access openings	20 air changes per minute but not less than 500 fpm through all openings	3500	Ref. 14
Asbestos: Carding Spool winding	Enclosure Local Hoods	800 cfm per machine 50 cfm per spool	3000 3000	Ref. 2, 16, 17. See references for details and other operations
Bagging: Open Bag Top	Booth or enclosure (provide spillage hopper)	Paper bags—100 cfm per sq ft open area Cloth bags—200 cfm per sq ft open area	3500 3500	Ref. 18
Barrels—Drums (filling or removing material by scoop)	Local Hood Booth	100 cfm sq ft of container cross-section 100 fpm at face	3500 3500	Ref. 15, 19. Hood with 1-in. slot extending 120 to 180 deg container. Does not confine spillage. Confine spillage—also recommended for container upsetting.
Belt conveyors	Hood at transfer point	Belt speeds less than 200 fpm-350 cfm per foot of belt width, but not less than 150 fpm through open area. Belt speeds over 200 fpm—500 cfm per foot of belt width but not less than 200 *fpm through open area*	3500	Ref. 18, 20
Bins (closed top)	Connect to bin top away from feed point	150–200 fpm through open area at feed points	3500	Ref. 19, 20
Bucket elevators	Tight casing required	10 cfm per sq ft of elevator casing cross-section	3500	Ref. 19
Brick cutting and sizing (abrasive cut-off wheel used dry)	Local Hood Booth with saw at face of booth	500 cfm 150 fpm at face	3500 3500	Ref. 7, 19. For portable operations. Control not as effective as booth
Ceramics Dry pan Dry press Aerographing Fettling, brushing, sagger filling, and unload	 Enclosure Local at die Local at die At supply bin Booth Downdraft or side hood	 200 fpm through all openings 500 cfm 500 cfm 500 cfm 100 fpm (face) 100–150 cfm per sq ft of plan area of dust producing operation	 3500 3500 3500 3500 ... 3500	 Ref. 19, 21, 22 Automatic feed *Manual feed* Manual feed
Cooling Tunnels (foundry molds)	Enclosure	75–100 cfm per running foot of enclosure		Ref. 20
Crushers and grinders	Enclosure	200 fpm *through openings*	3500	*Ref. 18, 23*
Furnaces Stationary melting pots for nonferrous Tilting or rocking melting for non-ferrous Electric Arc for Steel	 Enclosure Canopy Hood attached to roof ring	 100–200 fpm at hood opening 3000–6000 cfm 2500 cfm per ton charged	 1500–2000 1500–2000 2500–3500	Ref. 11, 15, 22, 24, 25 Use higher ventilation rate for toxic fumes Ventilation rate can be materially reduced with more complete enclosures General ventilation of melting room may be substituted but involves greatly increased ventilation rate

Table 3 .... A Guide to Ventilation Rates for Typical Industrial Equipment (*Continued*)

State or Local Regulations Should be Consulted and Followed Where Higher Ventilation Rates are Specified

Operation	Ventilation		Usual Transport Velocity Fpm	Remarks and References
	Type of Hood	Air Flow		
Furnaces Forge (hand)	 Canopy	 200 fpm at face	 1500	 Ref. 24
Garage (tail pipe at servicing location)	Local hood slipped over tail pipe	100 cfm thru 3-in. flexible duct for autos up to 200 hp 200 cfm thru 4-in. flexible duct for trucks and autos above 200 hp 400 cfm thru 4½-in. flexible duct for Diesel engines	2000	Ref. 15
Granite cutting and finishing Pneumatic hand tools *Surfacing machine*	 Local hood Local hood	 500 cfm 500 cfm for tools up to 2⅜-in. diameter 1000 cfm for 2⅜- to 2⅞-in. diameter	 5500–6000 5500–6000	Ref. 26, 27 Typical hood 3 x 8 in. opening with 3-in. flange Hood surrounds tool
Grinders Polishers, buffers, etc. Portable Swing frame	 Standard wheel hood Downdraft bench Booth Booth	 See Table 5 Bench type, 2–400 cfm per sq ft of exhaust grille but not less than 150 cfm per sq ft of plan working area. 100 fpm at face 100–200 fpm indraft through opening in booth face	 3500 3500 3000	Ref. 22, 28 Ref. 15, 19, 22, 29 Recommended for larger parts (Usual cfm per grinder 2000–4000)
Kitchen range	Canopy	100 fpm at hood face	1500–1800	Provide drip gutter on all interior vertical walls to catch condensed grease. Ref. 30
Laboratory hood (provide with door)	Booth type	50–100 fpm		Ref. 24, 31. Air supply location very critical
Metalizing	Local hood Booth	200 fpm at hood face 125–200 fpm at booth face	3500 3000	Ref. 15. Not recommended for toxic materials Use higher ventilation rates for toxic materials
Mixers	Enclosure	100–200 fpm through feed and inspection openings	3000–3500	Ref. 19, 22
Motion picture projector (carbon arc)	Enclosure	12–100 cfm (for fume and gas removal) directly exhausted from projector housing		Ref. 31. 1000–1500 cfm or 20–30 air changes per hour for heat removal
Pharmaceuticals Blenders Coating pans Centrifuges Hammer mills Oscillators Shakers Mixers Process kettles and tanks	 Fully enclosed Hood Enclosure Local hood Hood Enclosure	 100 to 200 fpm through opening 120 cfm exh 24-in. dia pan 60 cfm supply direct to pan *Differential 60 cfm* 250–300 fpm through opening 200 fmp but not less than 50 cfm Not less than 75 cfm per sq ft of plan area 100–250 fpm through opening or manhole	 2500–3500 3000 1500–2000 2500–3500 1500–2000	 Exhaust required only when filling or emptying Flexible exhaust hood connection extended into pans. *Feed opening covered to* greatest possible extent Centrifuge to be provided with cover for 50–75 percent of opening Hood with slot at each end of mixer Ref. 33. Use higher ventilation rate when contents are being heated

Table 3 . . . . A Guide to Ventilation Rates for Typical Industrial Equipment (*Continued*)

State or Local Regulations Should be Consulted and Followed Where Higher Ventilation Rates are Specified

Operation	Ventilation: Type of Hood	Ventilation: Air Flow	Usual Transport Velocity Fpm	Remarks and References
Pouring hoods Foundry	Side hood	200 to 300 cfm per linear ft of hood with slot velocities of 1500 fpm. Exhaust take-off every 8 to 10 ft	3500	Ref. 20
Rock drilling Dry drilling (rock)	Special trap (see references)	60 cfm—vertical (downward) work 200 cfm—horizontal work	3500	Ref. 26, 27. May vary with size and speed of drill. Wet drilling offers alternate control methods
Rubber calender rolls	Canopy—side panels	75–100 fpm indraft	3500	Ref. 24, 31
Quartz fusing	Booth on bench	150–200 fpm at face		Ref. 34, 35
Screens Vibrating Flat deck	Enclosure	150–200 fpm indraft through hood openings but not less than 25–50 cfm per sq ft of screen area	3500	Ref. 15, 19
Shakeouts Foundry	Enclosure	200 fpm through all openings in enclosure, but not less than 200 cfm per sq ft of grate area	3500	Ref. 20, 22
Spray coating	Booth—operator inside Booth—operator outside Booth—downdraft	100–200 fpm at booth cross-section 150–200 fpm at booth cross-section 100–200 fpm downdraft	1500–2000 1500–2000 1500–2000	Ref. 15 Use higher ventilation rate for small booths 4 sq ft or less
Tanks, open surface	See Table 6			Ref. 36, 37, 38, 39
Tumbling mills Hollow trunnion type	Exhaust connection by manufacturer	Use branch diameter same size as exhaust outlet. For round mills branch dia should be ⅙ dia of mill; for square mills branch dia should be 1 in. plus ⅙ side dimension of mill	3500–5000	Ref. 14
Tumbling mills, drums, cages, barrels	Enclosure	400 fpm through openings but not less than 75 cfm per sq ft plan area	3500	Where equipment is enclosed and dust tight during rotation, enclosure may not be needed if feed and discharge operations can be otherwise controlled
Welding	Local hood with flange Downdraft bench Booth	6 in. from arc—150 cfm 6–9 in. from arc—275 cfm 8–10 in. from arc—425 cfm 10–12 in. from arc—600 cfm 150–250 cfm per sq ft grille area 100 fpm at booth face	2000–4000 2000 2000	Ref. 40
Woodworking	See Table 7			Ref. 22, 41
Miscellaneous Packaging, machines, granulators, enclosed dust producing units Packaging, weighing, container filling, inspection	Complete enclosure Booth Downdraft	100–400 fpm indraft through inspection or working openings, but not less than 25 cfm per sq ft of enclosed plan area 50–150 cfm per sq ft of open face area 75–150 cfm per sq ft of dust producing plan area	3000 3000 3500	Ref. 19

For high canopy hoods, Equation 5 may be used:

$$q_s = 7.4\, l_s^{5/3}\, H_c^{1/3} \qquad (5)$$

where

l_s = effective height, feet.

The effective height l_s may be taken as the actual vertical distance from hood to hot surface plus twice the width of the hot surface.

Where it is necessary to have openings at the top of a hood that is filled with heated air, leakage of the hood contents through these openings may be prevented by using sufficient ventilation to obtain a face velocity V as calculated from the following equation:

$$V = C \sqrt[3]{\frac{l_s H_s}{A_f}} \qquad (6)$$

where

l_s = height of the air column, feet.
A_f = area of the (sharp-edged) openings, square feet.
H_s = sensible heat released to air stream, Btu per minute.
C = a coefficient depending on the excess of temperature inside the hood above room temperature with values as follows:

Temperature excess (F deg)	0–200	200–400	400–600	600–800
Value of C	20	18	16	14

The American Society of Heating and Air-Conditioning Engineers has recognized the need for design criteria for determining exhaust ventilation requirements for hot processes in industry. Research studies on this subject have been in progress since 1952, and the results to date have been published.[42]

Induced Air Flow

Where quantities of individual particles are projected through an air space by gravity or by process forces, volumes of room air in proportion to the momentum of the particles are set in motion with resulting intermixing and flow in the same direction as the particles. Exhausted volumes from hoods or enclosures must be sufficient to include this induced air flow if control is to be effective. Induced air flow should be evaluated from high speed rotating machines including pulverizers, from material handling systems employing high speed belts or involving large tonnages of falling granular material, and from escaping compressed air jets from pneumatic tools. The energy represented by material of various particle sizes and falling heights has been computed by Hemeon.[13] The theoretical equivalent induced air flow resulting from unenclosed air streams is summarized in Table 4.

Where falling streams occur largely within an enclosure such as a storage bin, it should be recognized that much of the air set in motion is recirculated within the bin. Exhaust volumes from the enclosure need only include the extra air induced before the falling material enters the enclosure although the recirculating induced air can cause localized positive pressures and outward leakage if the enclosure is not of airtight construction.

The amount of air induced by falling material is much less if the space through which the material falls is enclosed effectively than if not enclosed, and can be reduced to a minimum by enclosing as well as possible the openings at the feed point of the material.

Table 4 . . . . Induced-Air-Flow Equivalent of the Energy in Falling, Unenclosed Streams of Particles

(For a solids flow rate R of 1 lb per sec and a specific gravity s = 1 referred to water)

Falling Distance, z	Stream Area, sq ft	Air Flow Equivalent, Cfm, to be multiplied by $(R/z)^{1/3}$: Particle Size, Millimeters: 1	2	5	10	20	50	100

From *Plant and Process Ventilation* by W. C. L. Hemeon, The Industrial Press New York (1955).

DUCT SYSTEM DESIGN

The duct system will consist of branch ducts connected to a main duct that will convey the air from the hoods to the exhaust fan and the air cleaning equipment, if used. Round ducts should be used wherever possible. Their gage size and construction differ from air supply practice due to the rougher usage encountered, and in the case of dusts, to the abrasive effect. (See later section on Construction Specifications for Local Exhaust Systems.) Usual conveying velocities are shown in Table 8. Where solid contaminants are handled, recommended velocities must be maintained throughout the system to prevent material from settling in the ducts and obstructing

Table 5 . . . . Exhaust Requirements[28] for Grinding, Polishing, Buffing, Scratch Brushing Abrasive Cut-Off Wheels, Grinding and Polishing Belts

(Air Volume: 4500 fpm in all branches.) (2-in. water suction at average hood.)

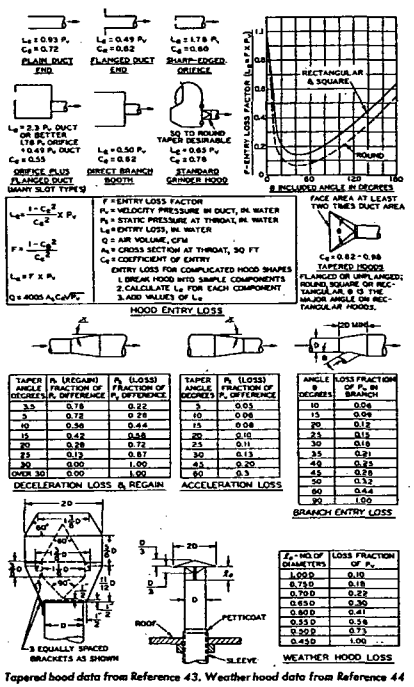
GRINDING OR POLISHING BELTS:
To 3 in. wide—3 in. branch, add ½ in. to branch diameter for each 2 in. or fraction increase in belt width over 3 in.

[a] Increase branch diameter 0.3 in., but not less than ½ in., for each 1 in. increase in width over dimension noted.

the air flow. For conveying of solid particles, velocities shown in Table 8 include a reasonable factor of safety and, consequently, design velocities may therefore be adjusted as required to permit use of commercial pipe sizes that are available generally in ½-in. diameter steps through 6-in. diameter, 1-in. steps through 16-in. diameter or larger, and 2-in. diameter steps for large diameters. For contaminants other than solids, conveying velocities are based on a consideration of the higher resistance and lower first cost of smaller diameter ducts against higher first cost and lower resistance of larger diameter ducts.

Main ducts connecting two or more branches are sized by the same procedure as for branches. The main should be designed for the total exhaust volume to be handled through all branch ducts.

Where exhaust systems handling solids are to provide for a substantial increase of future capacity, required conveying velocities can be maintained by:



1. Providing open end stub branches in the main through which air will be admitted into system until future connection is made. The volume admitted into the main can be adjusted to required *air flow rate (cfm) by use of a blast gate or orifice* plate in such stub branch.

2. Arranging the system layout so that exhaust from future points can be picked up by a separate main that will run directly to the fan or air cleaning equipment inlet.

CALCULATION OF SYSTEM PRESSURE LOSS

The pressure loss of the system includes entrance loss[44] as air is accelerated through the hood to a branch duct connection, resistance losses of ducts,[44] elbows, and junctions, and acceleration or deceleration losses from velocity changes within the system. Chapter 21 includes data on duct resistance and on resistance of elbows, and provides sample calculations. In exhaust systems, either the equal friction method (illustrated in Chapter 21) or the use of blast gates in the branches to equalize pressure loss of all runs is employed.[9, 22, 23, 29]

Data on losses for hood entrance, branch entry, transitions, and weather hoods are given in Fig. 2. The static pressure in branch ducts close to the hood connection is frequently referred to as *hood suction*. It is the sum of the branch velocity pressure and the hood entrance loss.

Tapered hood data from Reference 43. Weather hood data from Reference 44

Fig. 2 . . . . Exhaust System Design Data[15]

CONSTRUCTION SPECIFICATIONS FOR LOCAL EXHAUST SYSTEMS

Correct design and competent installation of sheet steel ducts and hoods, are necessary for the proper functioning of any exhaust system. The following specifications are those recommended in the *Industrial Ventilation Manual*.[18]

General

All exhaust systems shall be constructed with the materials recommended herewith and shall be installed in a permanent and workmanlike manner. The interior of all ducts shall be smooth and free from obstructions; with joints either welded, flanged, or soldered airtight.

Materials

1. Ducts shall be constructed of block iron welded or of galvanized sheet steel riveted and soldered unless the presence of corrosive gases, vapors, and mists or other conditions make use of such material impracticable. Galvanized construction is not recommended for temperatures exceeding 400 F. Welding of black iron of 18 gage and lighter is not recommended for field fabrication.

2. For average exhaust systems on non-corrosive applications the following metal thickness shall be supplied:

Diameter of Straight Ducts (Inches)	U. S. Standard Gage for Steel Duct		
	Class I	Class II	Class III
Up to 8	24	22	20
Over 8 to 18	22	20	18
Over 18 to 30	20	18	16
Over 30	18	16	14

Note 1—Column *A* refers to tank with hood along one side or two parallel sides when one hood is against a wall or a baffle running length of tank and as high as tank is wide; also to tanks with exhaust manifold along center line with $\frac{W}{2}$ becoming tank width in *W/L* Ratio.

Column *B* refers to free standing tank with hood along one side or two parallel sides.

Note 2—Complete control of the vapors and mist from degreasing operations requires the same ventilation rates as recommended for pickling. However, the solvents employed in degreasing operations are relatively volatile, and the solvent loss caused by evaporation increases rapidly as the exhaust rate at the tank increases. For this reason perfect control is usually sacrificed in favor of lower solvent evaporation rates. Where solvent loss does not present an important cost or operating problem, the exhaust rates given for pickling should be adhered to, but where solvent loss must be kept at a minimum, an exhaust rate of 50 cfm per sq ft of tank area is commonly employed. Where this rate is used, control will be adequate only if the tank is located in an area free of drafts and if the degreasing operations are carried out in accordance with a rigid schedule.[38]

Class I. Includes non-abrasive applications such as paint spray, woodworking, pharmaceutical and food product, and discharge ducts from dust collectors.

Class II. Includes applications for non-abrasive material in high concentration (low-pressure pneumatic conveying); moderately abrasive material; and highly abrasive materials in light concentrations. Typical applications are conveying of chemicals and wood dust; exhaust of foundry shakeouts and sand handling systems, grain dusts; coal crushing and screening; exhaust of grit blast cabinets; and grinding, buffing, and polishing.

Class III. Includes applications for all highly abrasive materials in moderate to heavy concentrations and moderately abrasive materials in heavy concentrations such as low-pressure conveying of tobacco; exhaust systems from sand and grit blasting and abrasive cleaning operations, from rock and ore screening and crushing, from dryers and kilns, and fly ash removal from boiler stacks.

Where aluminum duct is indicated, the following equivalent B & S gage thickness of sheets should be used:

Steel—U. S. Standard Gage	26	24	22	20	18	16	14
Aluminum—B & S Gage	24	22	20	18	16	14	12

3. For exhaust systems on corrosive applications, consideration should be given to non-corrosive materials or coatings.

(Continued on p. 711)

Table 7 .... Exhaust Requirements for Woodworking Operations[41]

(Air Velocity: 4000 fpm in all branches unless noted otherwise)

Self Feed Table Rip Saw
Use 1–5 in. branch at bottom pulley; 1–4 in. branch at saw head.

Large Self Feed Rip Saws Other Than Table Saws
Use 1–6 in. branch at bottom; 1–5 in. branch at top.

Swing Saws
Up to 20 in. use 1–4 in. branch; over 20 in. use 1–4½ in. branch.

Circular Saws

Up to 12 in. dia.	1–4 in. branch
Over 12 in. dia.	1–5 in. branch
Dado head saws	1–5 in. branch

Gang Circular Saws
Ventilation rate depends on effectiveness of hood and maximum number and diameter of saws.

Disc Sanders

Up to 12 in.	1–4 in. branch
12 in. to 18 in. dia.	1–4½ in. branch
18 in. to 26 in. dia.	1–5 in. branch
26 in. to 32 in. dia.	2–4 in. branch
32 in. to 38 in. dia.	1–4 in. branch and 1–5 in. branch
38 in. to 48 in. dia.	1–5 in. branch and 2–4 in. branch

Multiple Drum Sanders (over the table)

Up to 31 in. wide	5 in. branch (see note)
31 in. to 49 in. wide	6 in. branch (see note)
49 in. to 67 in. wide	7 in. branch (see note)
Over 67 in. wide	8 in. branch (see note)

Note: One branch of size indicated required for each drum. Fewer branch pipes may be used as long as total branch pipe cross-sectional area is not reduced. Some manufacturers use 1 extra branch of equal size on feed side. 1–4 in. branch may be required for exhausting bed rubber cushions or mechanically operated brush

Single Drum and Spindle Type Sanders

Up to 50 sq in. sanding surface	1–3 in. branch
50 to 200 sq in. sanding surface	1–4 in. branch
200 to 400 sq in. sanding surface	1–5 in. branch
400 to 700 sq in. sanding surface	1–6 in. branch
700 to 1400 sq in. sanding surface	1–7 in. branch
1400 to 2400 sq in. sanding surface	1–8 in. branch

Horizontal Belt Sander or Edge Sander (see note)

	Drive Pulley	Idler Pulley
Up to 6 in. wide	1–4½ in. branch	1–4 in. branch
6 in. to 9 in. wide	1–5 in. branch	1–4 in. branch
9 in. to 14 in. wide	1–6 in. branch	1–4 in. branch
Over 14 in. wide	1–7 in. branch	1–5 in. branch

Note: Where more than one belt is used, the pipe sizes specified shall be required for each belt. Where a common hood is used for more than one belt, a single pipe of an area not less than the sum of the areas of the pipes specified may be used.

Where belt is reversible, pipe at idler pulley shall be the size specified for the drive pulley.

Vertical Belt Sanders (rear belt and both pulleys enclosed)

Up to 6 in. wide	4½ in. branch on bottom
6 in. to 9 in. wide	5 in. branch on bottom
9 in. to 14 in. wide	6 in. branch on bottom
Over 14 in. wide	7 in. branch on bottom

Band Saws and Resaws

	Bottom	Top
Up to 2 in. wide	1–4 in. branch	1–4 in. branch
2 in. to 3 in. wide	1–5 in. branch	1–4 in. branch
3 in. to 4 in. wide	1–6 in. branch	1–5 in. branch
4 in. to 5 in. wide	1–7 in. branch	1–5 in. branch
Over 5 in. wide	1–8 in. branch	1–5 in. branch

Jointers

Up to 6 in. knives	1–4 in. branch
6 in. to 12 in. knives	1–5 in. branch
12 in. to 20 in. knives	1–6 in. branch
Over 20 in. knives	1–7 in. branch

Single Planners or Surfacers

Up to 20 in. max. working width	1–6 in. branch
20 in. to 26 in. max. working width	1–7 in. branch
26 in. to 32 in. max. working width	1–8 in. branch
32 in. to 38 in. max. working width	1–9 in. branch
Over 38 in. max. working width	1–10 in. branch

Double Planers or Surfacers

	Upper head	Lower
Up to 20 in. max. working width	1–6 in. branch	1–5 in. branch
20 in. to 26 in. max. working width	1–7 in. branch	1–6 in. branch
26 in. to 32 in. max. working width	1–8 in. branch	1–7 in. branch
32 in. to 38 in. max. working width	1–9 in. branch	1–8 in. branch
Over 38 in. max. working width	1–10 in. branch	1–8 in. branch

Molders, Matchers, Sizers (see note)

	Matcher head	Top	Bottom
Up to 4 in.	2–4 in. branch	1–5 in. branch	1–6 in. branch
4 to 6 in.	2–5½ in. branch	1–6 in. branch	1–6 in. branch
6 to 8 in.	2–6 in. branch	1–7 in. branch	1–6 in. branch
8 to 18 in.	2–6 in. branch	1–8 in. branch	1–8 in. branch

Note: Where profiler is used, provide additional pipe not less than that specified for top head.

Wood Shapers
1–4½ to 10 in. branch for each spindle according to size and character of work.

Tenoner
For cut-off saws: Up to 12 in. dia. 1–4 in. branch
Over 12 in. dia. 1–5 in. branch
Use 1–5 in. branch minimum for each top and bottom tenon, cope, and dado head.

Automatic Lathes
Use 1–3 in. to 1–10 in. branch according to work length.

Hogs
Air volume based on 50 cu ft per lb of refuse conveyed. Use 4500 fpm minimum conveying velocity.

Floor Sweeps
Use 6 in. branch for fine dust to 8 in. branch for coarse material.
Mouth at floor, 10 × 4 in. to 12 × 5 in.

Note: Area of floor sweep pipe need not be included in computing main pipe area.

Miscellaneous Equipment
Pulley pockets and chain mortises-3 in. branch; dovetail and lock corner machines, dowel machines, duplex molding sanders, forming lathes, panel raisers (each head), ploughs, rail shears, routers, sash stickers (each head) 4 in. branch; pulley stiles-5 in. branch; glue jointer-6 in. branch.

Table 8 .... Approximate Conveying Velocities

Material Conveyed	Design Velocity Fpm
Vapors, gases, fumes, very fine dust	2,000
Fine dry dusts	3,000
Average industrial dusts	3,500
Coarse particles	3,500–4,500
Large particles, heavy loads, moist materials	4,500 and over

(*Continued from p. 709*)

4. Elbows and angles shall be a minimum of two gages heavier than straight lengths of equal diameter.

5. Hoods shall be a minimum of two gages heavier than straight section of connecting branches.

6. Where flexible piping is necessary, a non-collapsible type of flexible piping shall be used and its length shall be kept at a minimum.

Construction

1. Longitudinal joints of ducts shall be lapped, and riveted or spot-welded on 3-in. centers, maximum. Double-lock seams may be used on Class I application only.

2. Girth joints of ducts shall be made with lap in direction of air flow with 1-in. lap for diameters up to 19 in. and 1¼-in. lap for diameters over 19 in.

3. Elbows and angles shall have an inside or throat radius of two pipe diameters whenever possible. Large radii are recommended for heavy concentrations of highly abrasive dusts. Construct elbows 6 in. or less in diameter of at least five sections, over 6 in. diameter of seven sections. Prefabricated elbows of smooth construction may be used. Angles shall be pieced proportionately.

4. Hoods must be free of sharp edges or burrs and shall be reinforced to provide necessary stiffness.

System Details

1. Connect duct to fan inlet with split sleeve drawband one pipe diameter long but not less than 12 in.

2. Transitions in mains and sub-mains are to be tapered; a taper 5-in. long for each 1-in. change in diameter is recommended when possible.

3. All branches shall enter the main at the large end of the transition at an angle not to exceed 45 deg (30 deg is preferred). Connect branches only to top or sides of main, with no two branches entering diametrically opposite.

4. Provide dead end caps within 6 in. from last branch of all mains and sub-mains.

5. Provide access openings or cleanouts every 10 ft and near each elbow, angle, or duct junction in horizontal sections except for non-corrosive gases and vapors containing no particulate matter.

6. Support ducts sufficiently to prevent placing of any load on connected equipment and to carry weight of system if plugged with material. Use maximum supporting interval 12 ft for 8 in. or smaller ducts and 20 ft for larger ducts.

7. Provide 6 in. minimum clearance between ducts and ceiling, wall, or floor.

8. Where blast gates are used for adjustment of system, place them near connection of branch to main. Provide means of locking after adjustments have been made. Butterfly-type dampers shall not be permitted.

9. Fire dampers, explosion vents, etc., should be installed in accordance with NFPA Codes or local fire ordinances.

10. Rectangular ducts can be used only when clearances prevent the use of round construction. Rectangular ducts must be as nearly square as possible. Weight of metal, lap, and other construction details are to be the equal of round duct construction whose diameter equals the longest side.

11. Where State or local laws conflict with the specifications given, the more stringent regulation shall be followed. Any other deviation must be approved before installation.

AIR FLOW PRODUCING EQUIPMENT

The principal types of air moving equipment are centrifugal fans, axial flow fans, and venturi ejectors. Chapter 22 includes information on fan types, arrangements, and application. Gravity stacks have application for some systems handling higher air temperatures or steam where no air cleaning equipment is installed.

Centrifugal fans are most frequently used for the bulk of exhaust system applications due to the system pressures involved. Where air cleaning equipment is included, fans are usually located on the clean air side. The paddle wheel or modified paddle wheel designs are heavily constructed and have few blades to make them more suitable if wear, corrosion, or accumulations are a factor. The higher efficiency backward-curved blade designs find application where relatively clean, non-corrosive air is handled. Forward-curved blade designs have limited application due to the number, shape, and metal thickness of the short curved blades.

Belt driven fans are recommended by many designers because a change in fan speed is often needed where future changes of the system may be involved, where added pressure losses from air cleaning equipment improvements are anticipated, or where the fan may be used at some later date for another application.

The axial-flow fan is used for systems having low-pressure losses. Propeller or disc designs develop pressures under 1 in., the vane-axial designs develop higher pressures but seldom are used where pressures exceed 3 in.

The venturi ejector[46] is an inefficient method of air movement, but has the advantage of causing air flow without having the exhaust air pass through the air flow producing equipment. It minimizes the explosion or corrosion potentialities in certain types of system.

Fans, motors, and drives should be located so that safe and easy access for periodic inspection, servicing, and maintenance is possible.

AIR CLEANING EQUIPMENT

As discussed in detail in Chapter 24, air cleaning equipment should be considered in all systems where it can prevent property damage, neighborhood pollution, or reentry of polluted air to the working space, or where it can salvage usable material, reduce fire and explosion hazards, or make possible some recirculation of air to the working spaces. The present growing emphasis on air pollution control makes it desirable to remove all contaminants to the greatest practical degree based on reasonable cost and maintenance.

MAKE-UP AIR REQUIREMENTS

A correctly designed exhaust system may be ineffective during periods when windows and doors are closed. This condition should be anticipated and prevented by making provision for an adequate air supply. Poor performance of exhaust hoods is caused by: absence of air supply systems; cold drafts due to high indraft velocities through cracks and openings in building construction especially at windows and doors; reverse air flow through low-pressure systems of roof ventilators or general ventilation systems; downflow through heater vent stacks preventing exhaust of flue gases to the outdoors. Systems for conditioning make-up air do not necessarily increase heating requirements for the space, as cold air due to infiltration

from the outdoors must be heated somehow to maintain comfortable temperatures in the area. The cost will depend on the ratio of exhaust air to that required for ventilation of the space occupied.

MAINTENANCE OF PERFORMANCE

Periodic inspection and checking of exhaust systems are necessary if control is to be maintained at the effective level of the original installation. Continued effectiveness depends on maintained design air volume flowing through the exhaust hoods. A checking procedure, therefore, must include some data to indicate at least relative air flow through the hoods. The static pressure or hood suction measurement will prove useful for such checking if data are available on air volumes and pressures at the time the system was installed. Testing and recording of such data for each new installation are of the utmost importance.

While hood suction readings have rightfully been discarded as a means of measuring air flow, they do offer a quick and accurate method of measuring relative air flow. If the hood suction is known while an exhaust system is functioning properly, its continued effectiveness can be assured so long as the hood suction is not reduced from its original value.

Difficulty from plugging may be encountered where heavy dust loads or moist air are encountered. Unless the hood design is altered or there are accumulations in the hood or branch pipe between hood and point of hood suction reading, the air volume exhausted from a hood cannot change without a change in hood suction reading.

The Pitot tube can be used for routine check purposes instead of the static pressure method but requires care in reading velocity pressures in an exact position with the tube paralleling the flow of air. The hood suction method of checking can, however, be more readily delegated to an assistant having no technical training. U-gages have been standard plant equipment long enough to eliminate any feeling of uncertainty in their use.

Since pressure readings vary as the square of the velocity or volume of flow, a slight change in flow is magnified by a comparison of gage readings. Normally, a reduction of volume or velocity of 10 to 15 percent will not be sufficient to reduce the effectiveness of the exhaust system. This range is equivalent to a reduction in static pressure readings of 19 to 30 percent.

A marked reduction in hood suction can often be traced to one or more of the following items:

1. Reduced performance by the exhaust fan caused by reduced speed due to belt slippage, wear on rotor or casing, or an accumulation of material in the rotor or casing obstructing the air flow.

2. Incorrect direction of exhauster rotation.

3. Reduced performance caused by defects in the exhaust piping, such as accumulations of material in branch or main ducts due to insufficient conveying velocities, condensation of oil or water vapors on duct walls, adhesive characteristics of material exhausted.

4. Leakage losses caused by loose cleanout doors, broken joints, holes worn in duct (most frequently in elbows), or poor connection to the exhauster inlet.

5. Losses in suction due to exhaust openings added to the system or due to a change of setting of blast gates in branch lines.

6. Increased pressure loss through the dust collector due to lack of maintenance, improper operation, wear, etc.

Table 10 .... Resistance to Corrosion of Materials Used for Exhaust Fans[46]

Classification	*Approximate Service Life*
E—Excellent	Over 5 years
S—Satisfactory	2 to 5 years
F—Fair	6 months to 2 years
P—Poor	6 months
Combinations	Variable performance

Note: Ratings are based upon collated field service reports. Forward curved fans are *not* recommended for open-tank ventilation service. Cleanout doors and bottom drains are recommended on all fans on open tank operations. The deposits which build up on fan wheels and casings should be removed by regular cleaning. Repaint where any coating has been broken and removed.

MATERIALS REQUIRED FOR CORROSION RESISTANCE

In many cases, exhaust systems including hoods, ducts, air flow producing equipment, and air cleaning equipment will require protective coatings if carbon steel is used, or other materials of construction will be required. Need for such materials will be determined by (*a*) the corrosion rates on interior or exterior duct surfaces, (*b*) protection against product contamination, and (*c*) explosion hazards.

Construction for *corrosion protection* is the most difficult due to the complex factors that influence rate of corrosion. It is seldom possible to predict the concentration, composition, and dry-bulb and dew-point temperatures that will exist in actual operations. A guide for selecting corrosive resistant materials based on a survey of actual experiences has been reproduced in Tables 9 and 10.[46]

CHAPTER 53

INDUSTRIAL DRYING SYSTEMS

Drying Terminology, Mechanism of Drying, Internal and External Conditions, Periods of Drying, Equilibrium Moisture Content, Application of Hygrometry to Drying, Determination of Drying Time, Commercial Drying Time, Dryer Calculations, Drying Methods and Equipment; Radiant, Conduction, and Convection Drying; Agricultural Drying, Solution of Drying Problem

THE term *drying*, in a broad sense, encompasses the removal of water, and occasionally other liquids, from gases, liquids, or solids. However, the common usage of the word confines the meaning principally to the removal of water or solvent from solids by thermal means. *Dehumidification* is the term that is commonly assigned to the drying of gases. This is usually accomplished by condensation or adsorption by various drying agents, and is treated in Chapter 42. *Distillation*, and more particularly *fractional distillation*, is associated with the drying of liquids.

It is usually more economical to employ, whenever possible, mechanical means of separating as much water as is practicable from the solid materials before undertaking drying or dehydration steps. These mechanical methods such as filtration, screening, pressing, centrifuging, or settling usually require much less power, and frequently less capital outlay, thereby making the operation cheaper in terms of cost per pound of water removed.

DRYING TERMINOLOGY[1]

The generally accepted definitions of terms used in drying technology follow:

Adiabatic drying occurs in a dryer when all of the sensible heat given up by the air in cooling is used to evaporate water from the wet stock.

Batch drying is that type of drying operation in which the material is fed to and discharged from the drying chamber in batches at definite intervals of time.

Bone-dry basis indicates the moisture content of a wet solid as pounds of water per pound of bone-dry solid. The advantage of using this basis is that the absolute amount of moisture loss is obtained simply by subtracting the moisture contents before and after drying. (See definition of *Wet Basis*.)

Bound moisture refers to liquid (held by a solid) which exerts a vapor pressure less than that of the pure liquid at the same temperature. Liquid may become *bound* by retention in small capillaries, by solution in cell or fiber walls, by homogeneous solution throughout the solid, and by chemical or physical adsorption on solid surfaces. Bound moisture can be removed from a solid only under specific conditions of humidity in the external surroundings.

Capillary flow refers to the flow of liquid through the interstices and over the surface of a solid. It is caused by liquid-solid molecular attraction.

Commercial dry basis expresses the moisture content of a product as pounds of water per pound of solid as it leaves the dryer, i.e., per pound of commercially dry solid.

Commercial drying time is the residence time of the material being dried in a commercial dryer.

Constant-rate period is that drying period during which the rate of water removal per unit of drying surface is constant.

Continuous drying is that type of drying operation in which the material to be dried is fed and discharged continuously to and from the dryer. The operating conditions are independent of time.

Critical moisture content is that obtaining when the constant-rate period ends and the falling-rate period begins.

Equilibrium moisture content is that to which a given material can be dried under specific conditions of air temperature and humidity.

Evaporative load is the total amount of water evaporated per hour in the dryer.

Falling-rate period is that drying period during which the instantaneous drying rate continually decreases.

Fiber-saturation point is the moisture content of cellular materials (wood, etc.) at which the cell walls are completely saturated while the cavities are liquid-free. It may be defined as the equilibrium moisture content as the humidity of the surrounding atmosphere approaches saturation.

Final moisture content is the percentage by weight of moisture remaining in the solid at the end of the drying operation.

Free moisture content is that liquid content which is removable at a given temperature and humidity. Free moisture may include both bound and unbound moisture.

Fuel economy is the number of units of fuel (cubic feet of gas, pounds of steam, gallons of oil, etc.) required to remove 1 lb of water from the solid being dried.

Humidity denotes the amount of water vapor actually present in a gas, and is generally expressed as weight of vapor per unit weight of any gas.

Hygroscopic material is material that may contain bound moisture.

Initial moisture content is the percentage by weight of moisture in the solid at the start of the drying operation.

Initial moisture distribution refers to the moisture distribution throughout a solid when drying begins.

Moisture gradient refers to the internal distribution of water in a solid at a given moment in the drying process, the nature of which depends on the characteristics of the solid involved.

Non-hygroscopic material is material that can contain no bound moisture.

Test drying time is the drying time of a relatively small and representative sample of the material which is dried in a laboratory dryer under conditions simulating commercial operation.

Through-circulation drying is that method of drying in which the air flow is directed through a permeable bed of solids.

Unbound moisture in a hygroscopic material is that moisture in excess of the equilibrium moisture content corresponding to saturation humidity. All water in a non-hygroscopic material is unbound water.

Wet basis expresses the moisture in a material as a percentage of the weight of the *wet* solid. This basis is less satisfactory than the dry-weight basis on which the percentage change of moisture is constant for all moisture contents.

MECHANISM OF DRYING[1]

When a solid dries, two fundamental processes are involved: (1) the transfer of heat to evaporate the liquid, and (2) the

transfer of mass as vapor and internal liquid. These two processes occur simultaneously, and the factors governing the rate of each process determine the rate of drying.

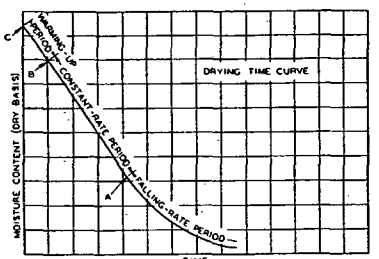
In any commercial drying problem, a principal objective is to supply the required heat in the most efficient manner. Consequently, heat transfer may occur by convection, conduction, or radiation, or by any combination of these mechanisms. The various types of industrial dryers may be shown to differ fundamentally with respect to the method used for transferring heat to the solid. In general, heat must flow first to the outer surface of the solid and then into the interior. An important exception is drying with high frequency electrical currents where heat is *generated within the solid*, producing a higher temperature at the interior than at the surface, and consequently, causing heat to flow from inside the solid to the outer surfaces.

Mass transfer in drying occurs as liquid or vapor flow, or both, within the solid, and as vapor flow from the external wet surfaces. The nature of liquid-concentration gradients in solids during drying depends on the mechanism of internal liquid flow, and this mechanism, in turn, depends to a large extent upon the physical and chemical characteristics of the solid being dried.

Internal and External Conditions

A study of how a solid dries may be based on the *internal* mechanism of liquid flow, or on the effect of the *external conditions* of temperature, humidity, air flow, state of subdivision, etc., on the drying rate of the solid. The former procedure involves a fundamental study of the liquid flow conditions within a solid during drying. The latter procedure, although less fundamental, is more generally used because the effects are easier to establish and the results have greater immediate application in dryer design and operation.

Internal Mechanism of Liquid Flow. Internal liquid flow may occur by several mechanisms, depending on the structure of the solid. Several mechanisms of flow are as follows:



1. *Diffusion* in continuous, homogeneous solids.
2. *Capillary flow* in granular and porous solids.
3. Flow caused by *shrinkage* and *pressure* gradients.
4. Flow caused by a *vaporization-condensation* sequence.
5. Flow caused by *gravity*.
6. Flow caused by an electrical *potential*, *electro-osmosis*.
7. Flow caused by temperature gradients, *thermal diffusion*.

Although more than one of these mechanisms of flow may be effective at one time, only one predominates as a rule at a given time in a solid during drying. However, a different mechanism may predominate at a different time in the cycle. The mechanism of moisture flow is usually established experimentally from a study of moisture gradients.

External Variables. The principal external variables involved in any drying problem are: *temperature, humidity, air flow, state of subdivision* of the solid, *agitation* of the solid, *method of supporting the solid*, and the *contact* between hot surfaces and wet solid. All these variables do not necessarily occur simultaneously in one problem.

Periods of Drying[1]

A typical drying time curve for a wet solid is shown in Fig. 1. This curve is a plot of the moisture content at any time in a solid undergoing drying. It is the usual method of presenting experimental drying data. Although Fig. 1 shows that the moisture content is subject to a continuous variation with time, a more precise illustration of the nature of this variation can be obtained by differentiating the curve and plotting the drying rate in pounds of water per (hour) (pound of dry material) against the moisture content in pounds of water per pound of dry material as shown in Fig. 2. The *rate curve* shows that the drying process is not a smooth, continuous one in which a single mechanism controls throughout.

From Reference 2

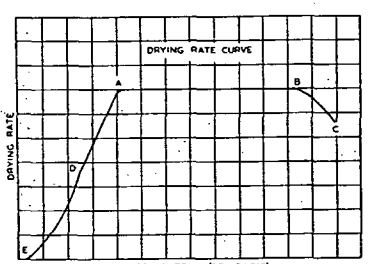


Fig. 1 . . . . Moisture Content w vs. Drying Time θ

Section BA on each curve represents a *constant-rate period*. In Fig. 1, it is shown by a straight line of constant slope $dw/d\theta$, which becomes a horizontal line on the rate curve in Fig. 2.

The curved portion of Fig. 1 is termed the falling-rate period, and, as shown in Fig. 2, it is typified by a continuously changing rate. Point A, where the constant rate ends and the drying rate begins to decrease, is termed the *critical moisture content*.

The portion of the curve designated by CB in Figs. 1 and 2 represents a warming-up period, and it may, or may not, be a significant item depending on the total time involved.

Constant-Rate Period. Drying during the constant-rate period is equivalent to evaporation from a free-water surface on the surface of the solid. The rate of drying in this period is determined by the rate of diffusion of water vapor through an air film at the wet surface of the solid. A constant rate of evaporation on the surface of the solid maintains the surface at a

From Reference 2

Fig. 2 . . . . Rate of Drying $\frac{dw}{d\theta}$ vs. Moisture Content w

constant temperature, which, in the absence of other heat effects, is very nearly the wet-bulb temperature of the air. If heat flows to the surface of evaporation by radiation and conduction, or both, in addition to convection, the surface temperature will be constant at some value between the air temperature and the wet-bulb temperature. This higher temperature in turn produces a higher constant rate of evaporation.

In those dryers in which heat is transferred to a wet solid by conduction through hot surfaces, and heat transfer by convection is not a factor, the wet surfaces approach the boiling point temperature rather than a wet-bulb temperature.

When all the heat for evaporation in the constant-rate period is supplied by a hot gas, a dynamic equilibrium is established between the rate of heat transfer to the material and the rate of vapor removal from the surface. This equilibrium between heat and mass transfer rates can be expressed as follows:

$$\frac{dw}{d\theta} = \frac{h_t A \Delta t}{H} = k_g A \Delta p \qquad (1)$$

where

$\frac{dw}{d\theta}$ = drying rate, pounds of water per (hour) (pound of bone-dry material).
h_t = total heat transfer coefficient, Btu per (hour) (square foot) (Fahrenheit degree).
A = area of heat transfer and evaporation, square feet per pound of bone-dry material.
H = enthalpy of evaporation at t_s, Btu per pound.
k_g = mass transfer coefficient, pounds per (hour) (square foot) (atmosphere).
$\Delta t = (t_a - t_s)$ = temperature difference between air and surface of evaporation, Fahrenheit degrees.
t_a = air temperature, Fahrenheit.
t_s = temperature of surface of evaporation, Fahrenheit.
$\Delta p = (p_s - p_a)$ = vapor-pressure difference, atmospheres.
p_s = vapor pressure of water at t_s, atmospheres.
p_a = partial pressure of water vapor in air, atmospheres.

When $h_t = h_c$, the coefficient of heat transfer by convection only, then t_s under equilibrium conditions becomes t_w, the wet-bulb temperature of the air, and p_s is the vapor pressure at this temperature. If heat is also supplied by radiation, then h_t is the sum $(h_c + h_r)$ where h_r is the radiation coefficient and h_c is the convection coefficient, and t_s becomes higher than the wet-bulb temperature. A similar result occurs when heat reaches the surface of evaporation by convection and conduction.

Effect of Air Velocity. The principal effect of air velocity is on h_c and k_g, since the rate of transfer of heat and mass in the constant-rate period depends mainly on the rate of diffusion of heat and vapor through the air film at the surface of the solid, and air velocity is the chief factor affecting the thickness of this film. The influence of direction of air flow on the heat transfer coefficient h_c and on the corresponding drying rate $\frac{dw}{d\theta}$ *is shown in Table 1.*

Effect of Temperature or Humidity. Temperature or humidity enters the drying rate equation as a driving force across the air film. The wet-bulb depression, which is the difference between the dry-bulb temperature and the wet-bulb temperature, is directly proportional to the drying rate in this period.

Table 1 . . . . Convection Heat Transfer (h_c) and Rates of Drying $\left(\frac{dw}{d\theta}\right)$ Coefficients for Constant-Rate Period

Direction of Air Flow	h_c	$\frac{dw}{d\theta}$
Parallel to plane surfaces[3]	$0.0128G^{0.8}$	$\frac{0.0128G^{0.8}A}{H}(t_a - t_w)$
Perpendicular to plane surfaces[3]	$0.37G^{0.37}$	$\frac{0.37G^{0.37}A}{H}(t_a - t_w)$
Through circulation[4] (for Reynolds number > 300)	$\frac{0.37G^{0.33}c_s}{D_p^{0.41}}$	$\frac{0.37c_sG^{0.33}\Delta t_m}{p_sHD_p^{0.41}}$

Letter Symbols for Table 1
(not previously defined)

h_c = convection heat transfer coefficient, Btu per (hour) (square foot) (Fahrenheit degree).
G = mass velocity of dry air, pounds per (hour) (square foot).
t_w = wet-bulb temperature of drying air, Fahrenheit.
a = drying area, square feet per cubic foot of bed volume.
ρ_s = bulk density of dry granular bed, pounds per cubic foot.
D_p = average diameter of particle, feet.
Δt_m = logarithmic mean difference between air temperature entering and leaving the bed and the wet-bulb temperature, Fahrenheit.
c_s = humid heat, Btu per (pound of dry air) (Fahrenheit degree).

When dealing with heat transfer coefficients the wet-bulb depression is the driving force, whereas with mass transfer coefficients the driving force is expressed in terms of humidity or vapor-pressure differential.

Fig. 3 permits a ready estimate of the constant drying rate for various air temperatures and humidities. The chart is based on the difference between the dry-bulb and wet-bulb temperatures of the entering stream of air, and on an air velocity of 300 fpm. It may be assumed satisfactory for tray drying of any material in the constant-rate drying period. It does not apply to rotary or through-circulation drying. A curve for correcting the air velocity is incorporated in Fig. 3. This curve is based on the variation of drying rate with the 0.8 power of the velocity.

Evaporation from Liquid Drops. For the important problem of spray drying, evaporation rates of liquid drops must be estimated. Below a value of Reynolds number (D_pG/μ) of 10 for spherical particles, the heat transfer coefficient across the gas film surrounding the drop is given by

$$h = \frac{2k_f}{D_p} \qquad (2)$$

where

h = film heat transfer coefficient, Btu per (hour) (square foot) (Fahrenheit degree).
k_f = thermal conductivity of gas film, Btu per (hour) (square foot) (Fahrenheit degree per foot).

Equation 2 is applicable when the Reynolds number for liquid drops is less than 10. Drop diameters are almost always less than 500 microns, and are usually in the range of 20 to 150 microns.

The rate of evaporation of drops may be expressed in terms of heat transfer or mass transfer. In terms of heat transfer, the evaporation rate is given by the equation:

$$\frac{dw}{d\theta} = \frac{2\pi k_f D_p}{H}(t_a - t_s) \qquad (3)$$

where

$\frac{dw}{d\theta}$ = evaporation rate, pounds per hour.

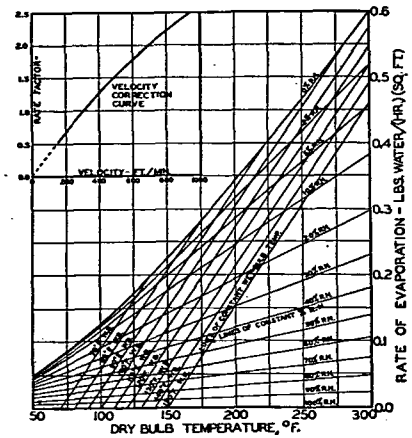

Fig. 3 .... Rate of Evaporation Chart[2]

Drying at Air Temperatures above the Boiling Point of the Liquid. When the temperature of the drying air is maintained above the boiling point of the liquid being evaporated, or when superheated vapors are used for drying, the usual equations for mass transfer, expressing rate of evaporation as a function of the vapor-pressure difference, lose significance, since large errors are introduced in the expression for vapor-pressure driving force due to its apparently small value. Such cases can be treated conveniently on a basis of heat transfer, since a temperature difference must always exist in order that drying may proceed.

Constant-Rate Period When Heat Transfer Depends on Conduction and Radiation. In indirect drying, where heat transfer and drying do not depend on the flow of heated gases, the drying rate depends either on heat conduction through retaining walls to wet material in contact with such surfaces, or on radiation, or both. This applies to drum dryers, agitated pan dryers, indirect continuous sheet dryers, steam tube rotary dryers, vacuum rotary and vacuum tray dryers, and infra-red dryers.

A principal difference between indirect drying and direct drying is that, with the former, the material is usually at a higher temperature than the surrounding air, so that heat is actually transferred to the air instead of from the air.

The Falling-Rate Period. In the discussion of the periods of drying, it was shown that the drying process is discontinuous, consisting of a period of a constant rate of evaporation and a period in which the rate continuously decreases. (See Fig. 2.) This latter period is usually designated as the falling-rate period. It begins when the constant-rate period ends at the critical moisture content. If the critical moisture content is less than the required final moisture content, the constant-rate period will constitute the whole of the drying process. On the other hand, if the initial moisture content is less than the critical moisture content, as in the case of some slow-drying materials, such as soap and wood, then no constant rate will appear, and the whole of the drying process will be in the falling-rate period. This period, in the most general case, can be divided into two zones which may be termed (1) the zone of unsaturated surface drying, and (2) the zone where internal liquid flow controls.

The zone of unsaturated surface drying follows immediately after the critical point and results from a progressively decreasing wetted surface. With the surface no longer completely wetted, dry portions of the solid protrude into the air film, so that the rate of evaporation per unit of total surface is reduced. The effective wetted surface in this zone is frequently a linear function of the water content, so that the curve representing rate of drying vs. water content of the solid is straight in this region, as shown by line AD in Fig. 2. The mechanism of drying is essentially the same as during the constant-rate period.

The zone where internal liquid flow is in control is usually the second zone of the falling-rate period. In this phase the rate of internal liquid movement by one or more of the controlling mechanisms considered previously, such as diffusion, capillarity, etc., will determine the drying rate.

When diffusion does control in the falling-rate period, it obeys the same fundamental laws of diffusion as those applying to the diffusion of heat. Thus for the case where the surface is dry or at the equilibrium moisture content, and the solid has a uniform initial moisture distribution, the following rate equation holds for relatively large values of time θ, and when $(w - w_e)/(w_o - w_e) < 0.6$

$$\frac{dw}{d\theta} = -\frac{\pi^2 d}{4L^2}(w - w_e) \qquad (4)$$

where

- w = moisture content on dry basis, at any time θ, pounds of water per pound.
- w_e = moisture content at equilibrium with external conditions, pounds of water per pound of dry material.
- w_o = initial moisture content at start of diffusional period, pounds of water per pound dry material.
- d = the liquid diffusivity, square feet per hour.
- L = one-half material thickness, feet.

Equation 4 is restricted to a slab-shaped solid, the length of which is large compared with the thickness.

For some materials the drying time in the falling-rate period varies directly with the thickness. When this occurs the falling

Table 2 .... Approximate Classification of Materials Most Likely to Obey Equations 4 and 5

Materials Obeying Equation 4
1. Single-phase solid systems such as soap, gelatin, glue.
2. Wood and similar solids below the fiber saturation point.
3. Last stages of drying starches, textiles, paper, clay, hydrophilic solids, and other materials when bound water is being removed.
Materials Obeying Equation 5
1. Coarse granular solids, such as sand, paint pigments, minerals, etc.
2. Materials in which moisture flow occurs at concentrations above the equilibrium moisture content at atmospheric saturation, or above the fiber saturation point.

rate can be expressed with *fair* accuracy by the following equation:

$$\left(\frac{dw}{d\theta}\right)_f = -\frac{(dw/d\theta)_c}{(w_c - w_e)}(w - w_e) \qquad (5)$$

where

- $(dw/d\theta)_c$ = the constant drying rate, pounds per (hour) (pound dry material).
- $\left(\frac{dw}{d\theta}\right)_f$ = falling rate, pounds of water per (hour) (pound of dry material).
- w_c = the critical moisture content, pounds per pound dry material.

The appropriate expression for $\left(\frac{dw}{d\theta}\right)_c$ obtained from Table 1, may then be substituted in Equation 5.

Table 2 gives an approximate classification of materials that are most likely to obey Equations 4 and 5.

Equilibrium Moisture Content

In the drying of solids it is important to distinguish between hygroscopic and non-hygroscopic materials. A hygroscopic material is one which retains a definite percentage of moisture under definite conditions of air humidity. This bound moisture is in a state of equilibrium with the water vapor in the surrounding air. A decrease in the water vapor content will decrease the amount of equilibrium bound water. Water so retained by a solid in equilibrium with the humidity of the surrounding air, is designated as the *equilibrium moisture content.* Such moisture may be held as adsorbed surface films or condensed in fine capillary structures at reduced vapor pressure.

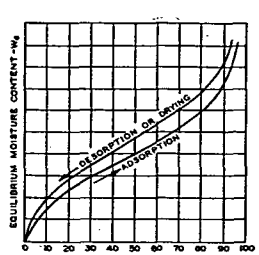

Fig. 4 .... Typical Equilibrium Moisture Content Curves[1]

The equilibrium moisture content varies with the temperature and humidity of the surrounding air. Consequently, any correlation of equilibrium moisture content should take these two factors into account. However, at low temperatures, e.g., 60 to 120 F, a plot of equilibrium moisture content *vs.* percent relative humidity, expressed as 100 (p/p_s), is essentially independent of temperature. Such a plot usually results in a curve of double curvature with a point of inflection (see Fig. 4).

APPLICATION OF HYGROMETRY TO DRYING

In analysing any particular drying problem it is sometimes advisable to consider the thermodynamic changes involving the drying medium, since in most cases the drying medium is an air-water-vapor mixture. The thermodynamic process can be traced on a psychrometric chart.

The psychrometric chart, Fig. 5, suggested by Grosvenor,[5] is suitable for most drying calculations. The adiabatic cooling lines on the chart indicate the paths along which the changes in the thermodynamic properties of the air occur in an adiabatic dryer.

The theoretical ability of air to pick up moisture corresponds to the difference between the final saturation content at the wet-bulb temperature (approximately the adiabatic cooling temperature or thermodynamic wet-bulb temperature) and the initial moisture content at the supply air dew point. The maximum possible pickup is never achieved in practical dryers because on the basis of good design, this would be undesirable. Experience has shown that there is an optimum pickup which is a function of the independent drying variables and is less than the maximum theoretical value as obtained from the psychrometric chart.

It should be noted that in practice the process will not necessarily follow exactly the adiabatic cooling line since there may be a transfer of heat to the tray or conveyor itself.

Use of the psychrometric chart for analyzing drying problems is illustrated by *Example 1.*

Example 1: Assume a dryer having a capacity of 100 lb of gelatin per hour at 11.1 percent bone-dry basis. The initial moisture content is 228 percent bone-dry basis and the final moisture content is to be 32 percent bone-dry basis. The rate of production of bone-dry gelatin is 90.5 lb per hr. Supply air is available at 120 F dry-bulb, 85 F wet-bulb, with make-up air at 80 F dry-bulb and 65 F wet-bulb. Air is exhausted from the dryer at 100 F dry-bulb and 84.5 F wet-bulb.

Find (1) the required amount of make-up and exhaust air, and (2) the percentage of recirculated air.

Solution: Refer to psychrometric chart, Fig. 5, and obtain the humidity ratio of the make-up air and of the exhaust air. In order to maintain a steady-state condition in the dryer the water which is evaporated from the material must be carried away by the exhaust air. Therefore, the difference between the humidity ratio of the exhaust air and that of the make-up air (known as pickup) is equal to the water evaporated from the material divided by the pounds per hour of dry air in the exhaust.

Step 1: The moisture in exhaust air at 100 F dry-bulb and 84.5 F wet-bulb is found to be 0.022 lb per pound of dry air. The moisture in make-up air at 80 F dry-bulb and 65 F wet-

bulb is found to be 0.010 lb per pound of dry air. Therefore the moisture pickup is 0.022–0.010, or 0.012 lb per pound of dry air.

The amount of water evaporated in the dryer = 90.5 (2.28 – 0.32) = 177 lb per hr.

The weight of dry air, make-up and exhaust, required to remove the water of evaporation = $\frac{177}{0.012}$ = 14,750 lb of dry air per hour.

Step 2: Let x = percentage of recirculated air and $100 - x$ = percentage of make-up air.

Then $\frac{x}{100}$ (humidity ratio of exhaust and recirculated air) + $\frac{100 - x}{100}$ (humidity ratio of make-up air) = humidity ratio of supply air. Hence, $\frac{x}{100}$ (0.022) + $\frac{(100 - x)}{100}$ (0.010) = 0.018 at 120 F dry-bulb, 85 F wet-bulb, or x = 66.7 percent recirculated air and therefore the required make-up air = 33.3 percent.

DETERMINATION OF DRYING TIME

In most drying problems it is necessary to obtain the drying time of a particular material. Three methods are listed below in order of preference.

1. Conduct tests in a laboratory dryer simulating conditions in the commercial machine, or obtain performance data directly from the commercial machine.
2. If the specific material is not available, obtain drying data on similar material by either of the above methods. This is subject to the experience and judgment of the investigator.
3. Estimate drying time from the theoretical equations which have been considered under *Mechanism of Drying*.

In designing commercial equipment the usual procedure is to conduct tests in a laboratory dryer in which commercial operating conditions are simulated. A representative sample in the physical form of the material as used in the laboratory tests should be identical to that which will be encountered in commercial operation. Otherwise the test results may not be an accurate indication of the drying characteristics of the commercial material.

In many cases where it is impracticable to run laboratory tests, commercial drying data are derived from the experience of the equipment manufacturer. This should not be overlooked since it can be an important source of data which would otherwise have to be obtained by less reliable methods.

Method 3, estimating drying time from the theoretical equations, should be used only as a last resort because it yields only approximate values.

Commercial Drying Time

The first step in selecting a commercial dryer is to apply the estimated drying time to determine the size of the commercial machine necessary for a given capacity. If the drying time has been derived from laboratory tests it is necessary to consider the following factors:

1. In a laboratory dryer considerable drying may have been *effected* by radiation and conduction of heat to the material, whereas in a commercial dryer these factors are usually negligible.
2. Humidity conditions in a commercial dryer may be higher than in a laboratory dryer. For drying operations with controlled humidity, this factor can be eliminated by duplicating the commercial humidity condition in the laboratory dryer.
3. Operating conditions usually cannot be kept as uniform in a commercial dryer as in a laboratory dryer.
4. Because of the relatively small sample used, the test material may not be representative of the material handled commercially.

In consideration of the preceding factors 1 to 4, it should

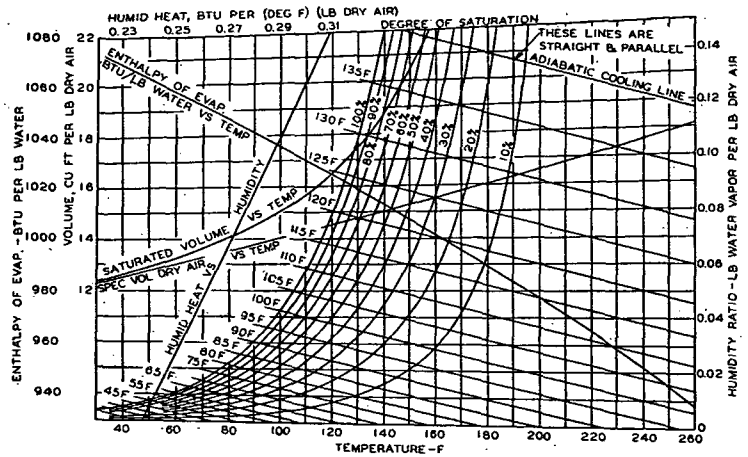

Fig. 5 .... Psychrometric Chart for Drying Calculations[5]

be stressed that the test drying time must be corrected to suit commercial conditions. This is a matter of experience and judgment on the part of the designer.

DRYER CALCULATIONS

To determine preliminary cost estimates for a commercial dryer it is usually necessary to make the following calculations:

Circulating air. The amount of circulating or supply air required is established by the optimum air velocity with reference to the material. This may be obtained from laboratory tests or previous experience, keeping in mind that there is also an optimum moisture pickup for the air, as explained in the section Application of Hygrometry to Drying.

Make-up and Exhaust. The amount of make-up and exhaust air required to maintain steady-state conditions within the dryer is discussed under the section Application of Hygrometry to Drying. In any continuously operating dryer, the relation between moisture content of the material and quantity of make-up air is given by Equation 6

$$G_T(W_2 - W_1) = M(w_1 - w_2) \text{ where } W_2 \text{ is constant.} \quad (6)$$

where

G_T = dry air supplied as make-up air to the dryer, pounds per hour.
M = stock dried in a continuous dryer, pounds per hour.
W_1 = humidity ratio of entering air, pounds of water vapor per pound of dry air.
W_2 = humidity ratio of leaving air, pounds of water vapor per pound of dry air.
w_1 = moisture content of entering material dry basis, pounds of water per pound.
w_2 = moisture content of leaving material dry basis, pounds of water per pound.

In batch type dryers, the drying operation is given by Equation 7

$$G(W_2 - W_1) = M_1 \frac{dw}{d\theta} \quad (7)$$

where

M_1 = weight of material charged in a discontinuous dryer, pounds per batch.
$\frac{dw}{d\theta}$ = the instantaneous rate of evaporation corresponding to w. W_2 is a variable during a portion of the cycle.

In actual practice the quantity of make-up air supplied is kept constant and is based on the average evaporation rate. Equation 7 then becomes identical with Equation 6 where $M = \frac{M_1}{\theta}$. Under this condition the humidity in the batch dryer will vary from a maximum to a minimum during the drying cycle; whereas, in the continuous dryer the humidity at any given point is constant with constant load.

Heat Balance. In order to estimate the fuel requirements of a dryer it is usually necessary to make a heat balance, consisting of the following:

1. Radiation and convection losses from dryer.
2. Heating of the commercial dry material to the leaving temperature (usually estimated).
3. Vaporization of the water being removed from the material (usually considered to take place at the wet-bulb temperature).
4. Heating of the vapor from the wet-bulb temperature in the dryer to the exhaust temperature.
5. Heating of the total water in the material from the entering temperature to the wet-bulb temperature in the dryer.
6. Heating of the make-up air from its initial temperature to the exhaust temperature.

The energy absorbed by items 1 to 6 must be supplied by the fuel. The proper selection and design of the heating equipment is an important part of the overall design of the dryer.

DRYING METHODS AND EQUIPMENT

Drying systems are sometimes classified according to the method of heat transfer that is employed, since the entire problem of drying resolves itself into individual problems of heat transfer and the thermodynamics of air and water vapor. The methods of heat transfer are radiation, conduction, and convection. Many types of dryers have been built on these principles for different purposes.

Drying systems can also be classified, according to the method of product handling, as batch operation, semi-continuous, and continuous.

The method of supporting or transporting the material to be dried, efficiency of operation, cost of investment, and the method of applying heat to the material are to be considered in selecting the equipment. Usually the final selection is a compromise between mechanical design, heat efficiency, quality, and product loss.

A systematic procedure is often justified when selecting a dryer for a given process. A general procedure will consist of:

1. Survey of suitable dryers
2. Preliminary cost estimates of various types
   a. Initial investment
   b. Operating cost
3. Drying tests should be conducted in prototype or laboratory units of the most promising equipment available. Sometimes a pilot plant is justified.
4. Summary of tests to evaluate quality and samples of the dried products.

Some items may overshadow the operating cost, or the investment cost, such as:

1. Product quality, which should not be sacrificed.
2. Dusting, solvent, or other product losses.
3. Space limitation.
4. Bulk density of product which may affect packaging cost.

A comprehensive bibliography for special reading will be found in the article by S. J. Friedman.[6]

Radiant Drying

In artificial systems, *radiating surfaces heated by steam*, electricity, or other means, afford a good method of heat distribution and control. Radiant heating sets up convection currents, and consequently, in low temperature dryers, only about one-third to one-half of the total heat for evaporation is actually supplied to the material by radiation. At high temperatures the radiation output increases rapidly, according to the *fourth-power law*. The total radiation may be computed by the equations and tables given in Chapter 5. In general, fins and irregular surfaces do not increase radiation, hence, the area to be used in calculations is the area of a smooth-surface envelope enclosing the radiating elements.

A certain amount of air circulation is required through a radiant dryer in order to carry off the vapor.

Radiant heat from infra-red lamps has been accepted by

certain industries as practicable for their specific problems. An example of successful application is found in the drying of laoquers.

Conduction Drying

Drying rolls or drums, Fig. 6,[7] flat surfaces, open kettles, and immersion heaters are examples of the direct-contact method. Intimate contact of the material with the heating surface is important, and in some cases agitation is desirable to increase the uniformity of heating or to prevent overheating.

A rather interesting method of conduction drying was put into practical use during the war for the drying of blood

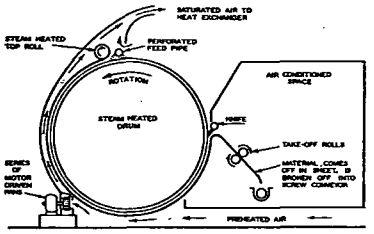

Fig. 6 .... Drum Dryer[7]

plasma, and has since been expanded to other fields such as the preservation of bacteria and other micro-organisms. This has come to be known as freeze drying or drying by sublimation. The material to be dried is first frozen and then placed in a high vacuum chamber connected to extremely low temperature condensers. The water is removed by vaporizing from the solid directly to the gas without ever becoming liquid.

Convection Drying (Direct Dryers)

A typical convection dryer is composed of an air-conditioning system, a material handling system, and the dryer housing. In normal practice it is desirable to recirculate as much as 95 percent of the air, from the standpoint of heat economy. There is an optimum point for the percentage of recirculation, depending on the temperature and evaporation rate.

A limited amount of convection drying takes place in almost any dryer such as those described in the preceding paragraphs. However, to be classified as a convection dryer the principal source of heat is the heated air or other gases circulated in the dryer. There are a number of mechanical means of accomplishing this circulation of air or gases, each of which has some particular virtue. Brief descriptions of some important types of convection dryers follow:

Rotary Dryers. These dryers are cylindrical drums which cascade the material being dried through the air stream. (See Fig. 7.) The dryers may be heated directly or indirectly, and the air circulation may be parallel or counterflow. A variation is the rotating-louver type dryer, which introduces the air beneath the flights thus securing very intimate contact.

Cabinet and Compartment Dryers. These are generally considered batch dryers wherein each charge is dried to completion before removal.[7] A wide range includes types from the heated loft with only natural convection, and usually poor and non-uniform drying, to the self-contained units with forced draft and properly designed baffles which give positive results. It is also possible to evacuate some of the systems for low temperature drying of delicate or hygroscopic materials. These dryers are usually loaded with material spread in trays to increase the exposed surface. The trays are loaded directly into the dryer or may be stacked on trucks which are wheeled in. (See Fig. 8.)

Tunnel Dryers. Tunnel dryers are a modification of the compartment dryer, and as a rule are continuous or semi-continuous in operation. Heated air or combustion gas is usually circulated by means of fans, although a few natural draft units are still in use. The material is handled on trays or racks on trucks, and moves through the dryer either intermittently or continuously. The air flow may be parallel, counterflow, or a combination of the two, obtained by center exhaust. Further, the air flow may be across the surface of the trays or up or down through the bed, or in any combination of directions. By reheating the air in this type of dryer or recirculating it, a high degree of saturation is achieved before exhausting the air. This reduces the waste of sensible heat.

A variation of this type dryer is the strictly continuous type having one or more mesh belts which travel through the dryer carrying the product, such as Fig. 9. Innumerable combinations of temperature, humidity, air direction, and velocity are possible. The labor requirement is low on such a dryer, as it can be loaded and unloaded mechanically. There is the disadvantage of hot air leaks at the entrance and exit, although these can be minimized by means of baffles or inclined ends where the material enters and leaves from the bottom.

Spray Dryers. In recent years the spray dryer has become important for the drying of liquids in many fields, especially in the food industry.

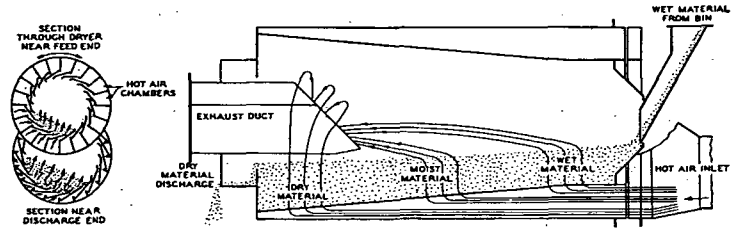

Fig. 7 .... Cross Section and Longitudinal Section Through Circulation Dryer[7]

The liquid is atomized by means of pressure nozzles, air jets, or centrifugal bowls into the air stream of a tower or chamber. Inlet air temperatures may run from 250–300 F up as high as 1200 F. Drying times are very short because of the minute particle size. Particles as small as 5 to 10 microns are formed in spray dryers. The dry powder is separated from the air by cyclone separators which are sometimes followed by cloth bags or scrubbing towers.

Because of the high inlet temperatures and the relatively large volume of air required, the efficiency of the spray dryer is relatively low and, consequently, it is seldom used for dilute solutions (less than 30 percent solid). Fig. 10 shows a typical arrangement for a spray drying system.[7]

A common and important feature of all spray processing is the direct conversion of the spray liquid to a granular product

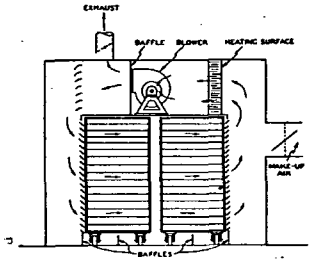

Fig. 8 .... Compartment Dryer, Showing Trucks, with Air Circulation[7]

suitable for packaging without grinding or other intermediate handling. Another aspect is the unusually high rate of drying attained. In a well designed system 15 to 30 seconds is a fair time for the passage of the sprayed particle through the drying zone; the particle temperature need not rise materially above the wet-bulb temperature of the drying air. This makes the process particularly adaptable to the drying of heat-sensitive material, some of its most important applications being the drying of milk, eggs, potato flour, soap, and blood.[8]

Tobacco Curing[9]

Considerable progress has been made recently in developing improved tobacco curing systems, through the application of heating equipment for maintaining uniform temperatures. Controlled heat and air circulation shortens the curing period and improves the quality of tobacco.

Suitable barn ventilation effected by bottom and ridge venting reduces the time and cost of curing. Orientation of barn with respect to the prevailing wind is helpful.

Tobacco Re-drying

In modern plants, tobacco is re-dried in continuous, conveyor type machines under controlled temperature and humidity conditions. One type of machine re-dries leaf tobacco in hands. This machine consists of a drying section, cooling section, and ordering section. As the hands are carried through the drying section on sticks, a high velocity of air is directed down through the heads, and a low velocity of

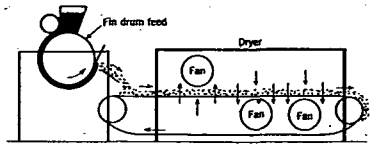

Fig. 9 .... Section of Continuous Dryer, Blow-Through Type

air passes over the body of the tobacco resulting in fast and uniform re-drying.

In the cooling section, the tobacco is quickly cooled and conveyed through the ordering section, where a controlled amount of moisture is added in this section which is maintained at almost saturated humidity ratio, so that the leaves can be packed for storage without the danger of breakage.

Agricultural Drying

Information on drying of agricultural products, such as milk, apples, flowers, tung nut, lumber, fruit juices, broom corn, grain, hay, peanuts, tobacco, and other farm crops, may be found in current issues of the *Agricultural Index*.[10]

SOLUTION OF TYPICAL DRYING PROBLEM

Since there are so many types of dryers that may be used, and so many special conditions surrounding each particular problem, it is usually recommended that those having experience with the dryer to be used be consulted. The following example, however, will serve as a guide for typical dryer calculations.

Example 2: Magnesium hydroxide is to be dried from 82 percent moisture on bone-dry basis to 4 percent moisture content on bone-dry basis. The production rate is to be 3000 lb per hr on 4 percent bone-dry basis. Previous experience indicates that a continuous single-conveyor through-circulation dryer with a fin-drum feed as illustrated in Fig. 9 should be used. The dryer is to be heated with steam at 50 psig. The optimum circulating air temperature is 160 F which is not limited by the existing steam pressure.

Step 1: Laboratory tests or previous experience indicate that the material enters the dryer at a temperature of 60 F, with an initial moisture content of 82 percent bone-dry basis. The test drying time is 25 min and the final moisture content is 4 percent bone-dry basis. The temperature of make-up air is 70 F dry-bulb and 60 F wet-bulb. The temperature of circulating air is 160 F dry-bulb and 100 F wet-bulb. The air velocity down through the preformed bed is 250 fpm, and the static pressure drop through the bed is 0.4 in. of water. The dryer

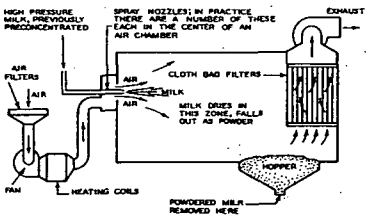

Fig. 10 .... Spray Dryer of the Pressure-Spray Rotary Type[7]

bed is to be loaded with 6.820 lb per sq ft of bone-dry material. Depth of the bed is to be 4 in.

Step 2: Previous experience indicates that the commercial drying time is 70 percent greater than the test time obtained in the particular laboratory setup used.

Therefore, the commercial drying time = $1.7 \times 25 = 42.5$ min.

Step 3: In order to dry the desired 3000 lb per hr of material the holding capacity of the dryer is $3000 \times \frac{42.5}{60} = 2125$ lb at 4 percent bone-dry basis.

The required conveyor area is $\frac{2125}{6.820} = 312$ sq ft. Assuming that a perforated plate conveyor with an 8 foot effective width is used, the length of the drying zone is $\frac{312}{8} = 39$ ft.

Step 4: The amount of water entering the dryer is $\frac{3000}{1.04} \times \frac{82}{100} = 2370$ lb per hr, while the amount of water leaving the dryer is $\frac{3000}{1.04} \times \frac{4}{100} = 115$ lb per hr. Thus, the evaporation rate in the dryer is $2370 - 115 = 2255$ lb per hr.

Step 5: Since the air circulation is perpendicular to the perforated plate conveyor, the total quantity of air that must be circulated equals the air velocity (based on the face area) multiplied by the conveyor area. Thus,

$$\text{Supply air} = 250 \times 312 = 78{,}000 \text{ cfm}$$

From Fig. 5 the humidity ratio of the supply air at 160 F dry-bulb, 100 F wet-bulb is 0.0285 lb per lb dry air. The specific volume of the supply air is 16.33 cu ft of moist air per lb of dry air, from Table 2 and Equation 27 of Chapter 3.

The quantity of dry air circulated is

$$\frac{78{,}000 \times 60}{16.33} = 286{,}500 \text{ lb per hr.}$$

Step 6: The amount of moisture pickup is $\frac{2255}{286{,}500} = 0.0079$ lb per lb of dry air. The humidity ratio of the exhaust air is $0.0079 + 0.0285 = 0.0364$ lb per lb dry air.

Substitute in Equation 6 and solve for G, the mass velocity of dry air, to determine the required quantity of make-up air. The humidity ratio of the make-up air is 0.0086 lb per lb dry air, from Fig. 5.

$$G\,(0.0364 - 0.0086) = \left(\frac{3000}{1.04}\right)\left(\frac{82 - 4}{100}\right)$$

$$G = 81{,}000 \text{ lb dry air per hr.}$$

Therefore,

$$\text{Make-up air} = \frac{81{,}000}{286{,}500} = 28.2 \text{ percent.}$$

$$\text{Recirculated air} = 71.8 \text{ percent.}$$

Step 7: Heat Balance

Sensible heat of material $= M(t_{m2} - t_{m1})c_m$
$= \frac{3000}{1.04}(100 - 60)\,0.3$
$= 34{,}600$ Btu per hr

Sensible heat of water $= Mw_1(t_w - t_{m1})c_w$
$= 2370\,(100 - 60)\,1.0$
$= 94{,}800$ Btu per hr

Latent heat of evaporation $= M(w_1 - w_2)H$
$= 2255 \times 1037$
$= 2{,}338{,}400$ Btu per hr

Sensible heat of vapor $= M(w_1 - w_2)\,(t_2 - t_w)c_v$
$= 2255\,(160 - 100)\,0.45$
$= 60{,}900$ Btu per hr

Required heat for material $= 2{,}528{,}700$ Btu per hr

The temperature drop $(t_2 - t_1)$ through the bed is

$$\frac{\text{Required heat}}{\text{Supply air, lb per hr} \times c_a} = \frac{2{,}528{,}700}{286{,}500 \times 0.24} = 37 \text{ deg}$$

Therefore, the exhaust air temperature is $160 - 37 = 123$ F

Required heat for make-up air $= G_T(t_2 - t_1)c_a$
$= 81{,}000\,(123 - 70)\,0.24$
$= 1{,}030{,}300$ Btu per hr.

The total heat required for material and make-up air is

$$2{,}528{,}700 + 1{,}030{,}300 = 3{,}559{,}000 \text{ Btu per hr.}$$

Additional heat must be provided for the radiation and convection losses, which may be calculated from the known construction of the dryer surfaces.

LETTER SYMBOLS USED IN CHAPTER 53

A = area of heat transfer and evaporation, square feet per pound of material.
a = drying area, square feet per cubic foot of bed volume.
c_a = specific heat of air, Btu per (pound) (Fahrenheit degree).
c_m = specific heat of material, Btu per (pound) (Fahrenheit degree).
c_s = humid heat, Btu per (pound of dry air) (Fahrenheit degree).
c_v = specific heat of water vapor, Btu per (pound) (Fahrenheit degree).
c_w = specific heat of water, Btu per (pound) (Fahrenheit degree).
d = diffusivity of the liquid or vapor, square feet per hour.
D_p = average diameter of particle, feet.
G = mass velocity of dry air, pounds per (hour) (square foot).
G_T = dry air supplied as make-up air to the dryer, pounds per hour.
H = enthalpy of evaporation of water at wet-bulb temperature, Btu per pound.
h = film heat transfer coefficient, Btu per (hour) (square foot) (Fahrenheit degree).
h_c = coefficient of heat transfer by convection, Btu per (hour) (square foot) (Fahrenheit degree).
h_r = coefficient of heat transfer by radiation, Btu per (hour) (square foot) (Fahrenheit degree).
h_t = total gas film heat transfer coefficient, Btu per (hour) (square foot) (Fahrenheit degree).
k_f = gas film thermal conductivity, Btu per (hour) (square foot) (Fahrenheit degree per foot).
k_g = mass transfer coefficient, pounds per (hour) (square foot) (atmosphere).
L = one-half material thickness, feet.
M = weight of stock dried in a continuous dryer, pounds per hour.
M_1 = weight of stock charged in a discontinuous dryer, pounds per batch.
$\Delta p = p_s - p_s$ = vapor-pressure difference, atmospheres.
p_a = partial pressure of water vapor in air, atmospheres.
p_s = vapor pressure of water at t_s, atmospheres.
t_a = air or gas temperature, Fahrenheit.
t_s = temperature of particle, solid, or surface of evaporation, Fahrenheit.
t_w = wet-bulb temperature of drying air, Fahrenheit.
t_1 = make-up air temperature, Fahrenheit.
t_2 = temperature of air entering stock, Fahrenheit.
t_3 = exhaust air temperature, Fahrenheit.
t_{m1} = entering stock temperature, Fahrenheit.
t_{m2} = leaving stock temperature, Fahrenheit.
$\Delta t = (t_a - t_s)$ = temperature difference between air and surface of evaporation, Fahrenheit.
Δt_m = logarithmic mean between temperature entering and leaving the bed, and the wet-bulb temperature, Fahrenheit.
W_1 = humidity ratio of entering air, pounds of water vapor per pound of dry air.
W_2 = humidity ratio of leaving air, pounds of water vapor per pound of dry air.
w = moisture content on dry basis at any time θ, pounds of water per pound.
w_c = critical moisture content, pounds water per pound dry material.
w_d = water content, dry basis, of the drop as it enters the drying chamber, pounds per pound of dry solid.
w_e = moisture content at equilibrium with external conditions, pounds per pound dry material.
w_o = initial moisture or moisture content at start of diffusional period, pounds per pound dry material.
$\frac{dw}{d\theta}$ = drying rate, pounds of water per (hour) (pound dry material).
$\left(\frac{dw}{d\theta}\right)_c$ = constant drying rate, pounds per (hour) (pound dry dry material).
$\left(\frac{dw}{d\theta}\right)_f$ = falling rate, pounds water per (hour) (pound of dry stock).
θ = time, hours.
ρ_s = bulk density of dry granular bed, density of dry particle, pounds per cubic foot.

CHAPTER 54

OWNING AND OPERATING COSTS

Fixed Charges: Amortization, Interest, Taxes, Insurance, Rent; Maintenance Costs; Labor for Operation; Energy and Water Costs: Operating Refrigerating Equipment, Condenser Water, Heating

THE total cost for the use of heating, ventilating, and air-conditioning systems may be divided into two classifications. The first of these is the relatively fixed and unvarying expense of ownership, and the second is the variable and somewhat controllable expenditure for actual operation of the equipment. Owners and prospective purchasers of this equipment are particularly concerned with both since the actual expenditure is generally predicated upon the possible return on the investment resulting from increased patronage, greater efficiency on the part of the employees, meeting of competition, or the improvement and maintenance of quality in a manufactured product. These costs may be grouped under four headings: (1) *Fixed Charges*, (2) *Maintenance Costs*, (3) *Labor for Operation*, and (4) *Energy and Water Costs*.

FIXED CHARGES

Fixed charges are the annual expenses arising from the ownership of the installation, including use of the owner's money, and protection of the equipment in the form of insurance. Such costs are usually unchanged from year to year regardless of whether the equipment is in or out of service. Fixed charges may be grouped under five headings: (1) *Amortization*, (2) *Interest*, (3) *Taxes*, (4) *Insurance*, and (5) *Rent*.

Amortization

As air-conditioning equipment becomes older, its ability or capacity to perform present and future service is reduced. Provision must be made for the owner to recover each year a portion of the initial value of the equipment as an expense to be charged against revenue, or to amortize the cost. This decrease in the value of property is usually determined by an accountant or engineer using some theoretical method and will depend upon (1) the total first cost, and (2) the amortization period.

The total first cost of an installation is the actual capital expenditure required to buy and install the air-conditioning, heating, or ventilating system ready for operation. It represents the first cost of the equipment combined with additional costs incurred because of the installation of the system.

The first cost of air-conditioning, heating, or ventilating systems includes the following:

1. Heat producing equipment including boilers, burners, controls, etc.
2. Heat distributing equipment including direct radiation, piping, etc.
3. Air handling equipment including fans, air heaters, air conditioners, filters, controls, etc.
4. Air distribution system including ducts, outlets, grilles, etc.
5. Refrigerating equipment including piping, pumps, etc.
6. Water conservation devices including towers, evaporative condensers, etc.
7. Insulation of pipes, ducts, and equipment.
8. Building alterations, furring-in ducts and pipes, structural work, etc.

To estimate the first cost of any system prior to installation, the best procedure is to determine the heating and cooling load, and then after thorough engineering study, select the type of system. The installed cost of systems will vary widely, depending upon the type of equipment selected, and the design of the distribution system, equipment and labor costs in the locality, demands for the particular installation, etc. A reasonably approximate cost may be determined for a selected design in a given locality from the sum of the estimated unit costs of the component parts of the system. A reasonably precise estimate of the cost of the components may be obtained from cost records of recent installations of a comparable design, or from quotations submitted by manufacturers and contractors.

Approximate costs are given in Table 1 for mechanical air-handling systems including heating and cooling coils for distributing 1½ cfm per square foot of floor area and refrigeration equipment based upon a requirement of one ton for every 333 sq ft of floor area. Different types of service demand may change the floor area per ton of refrigeration and air volume per square foot between wide limits and, consequently, the table should be used with caution.

Other first costs may be incurred because of the installation of the air-conditioning or heating and ventilating system. These will include such items as electrical work, plumbing, miscellaneous piping, building alterations, cutting, patching, furring-in of ducts or pipes, foundations, structural supports, remodeling or redecorating after installation, consulting engineer's fees, licenses, and permits. As these costs vary widely no approximations are practicable. Therefore, each case must be considered individually. If a quotation can be secured from a manufacturer or contractor covering the complete job, it will usually include the items that have been mentioned.

The length of the amortization period to be used depends upon (1) the type and remaining life of the building or

Table 1 .... Cost Dollars per Ton for a Complete System, Including Heating and Cooling Coils, Fan, Ducts, Refrigeration Equipment, Temperature Controls, etc.*

1	2	3	4	5	6	7	8	9	10	11	12	13
			Unit Costs		Total Cost[a]			Unit Costs[b]

75	25,000	37,500	212	0.95	15,900	35,700	51,600	690.00	2.07	1.38	120.00	
100	33,332	50,000	204	0.92	20,400	46,000	66,400	664.00	1.99	1.33	90.00	52.00
150	50,000	75,000	195	0.91	29,200	68,200	97,400	650.00	1.95	1.30	60.00	50.00
200	66,664	100,000	192	0.90	38,200	90,000	128,200	641.00	1.93	1.28		48.00
250	83,333	125,000	187	0.88	46,800	110,000	156,800	628.00	1.88	1.25		46.00
300	100,000	150,000	182	0.86	54,600	129,000	183,600	612.00	1.84	1.23		44.00
400	133,328	200,000	165	0.84	66,000	168,000	234,000	585.00	1.76	1.17		42.00
500	166,666	250,000	158	0.82	79,000	205,000	284,000	568.00	1.71	1.14		40.00

* These cost figures (based on 1954 prices which may be adjusted by using current building cost index) cover only the average type of comfort air conditioning in open spaces as in department stores, or for industrial air conditioning involving large areas. Where a multiplicity of small spaces must be individually controlled, as in office buildings, hotels, and apartment houses, these costs do not apply.

[a] Includes only final water, drain, and electrical connections within the equipment room.

[b] Columns 9, 10, and 11 represent costs where well water or city water is available for condensing purposes. Where conservation of water is required, add column 12 or 13 to column 9 to obtain total cost per ton.

[c] Does not include cost of structural reinforcing if required, to support the weight of cooling towers or evaporative condensers.

space for which the system is to be used; (2) the type of equipment to be employed as a part of the system; (3) the character of the business; and (4) the lease or ownership conditions.

Depreciation, due to deterioration or obsolescence, must be considered in arriving at the amortization period. Maintenance and deterioration usually have the effect of offsetting one or the other. If a long depreciation period is to be used, then the item for maintenance, repair, and the replacement of wearing parts must be greater than for a short depreciation period.

In determining the length of the amortization period, the owner's accounting practices will have considerable bearing upon the number of years used in the calculation. For taxation purposes, this period depends upon the use and the service to which the equipment is applied. At the present time indications are that varying interpretations on depreciation will be made by the Bureau of Internal Revenue. While most air-conditioning equipment may be considered as having a normal useful life of 20 years for depreciation purposes, no final value for depreciation should be determined without consultation with the owner's tax consultant or perhaps referral to Schedule F which is issued by the Bureau of Internal Revenue and summarized in Table 2.

Interest

The interest charged to the cost of ownership may be based upon the average interest rate for the period during which the first cost of the equipment will be amortized. While some accountants do not include interest in the annual fixed charges and consider it a negligible item, the money invested in air-conditioning, heating, or ventilating equipment, must be either borrowed or diverted from the owner's funds and converted to the purpose of making the installation. Whether it is borrowed or taken from surplus funds, the money that might have been earned as interest is properly chargeable to the operation of the system.

* Estimated for 1955.

The formulas for computing interest and amortization are given in Table 3. This table also serves as a check list for the various items to be considered in calculating the cost of ownership and operation.

Taxes

The taxes that may be charged to the property as a result of the improvement due to the installation of an air-conditioning system, will vary according to the practice of the official agencies levying property taxes.

Insurance

Insurance against losses by fire is ordinarily secured by increasing the building fire insurance coverage to cover all or part of the first cost of installing the air-conditioning and other mechanical systems. Various types of extended coverage are available for protection against a number of other types of losses.

Boiler insurance may be extended to cover the air-conditioning equipment to protect against losses due to explosion, rupture of piping, and similar hazards. Since insurance rates vary widely depending upon the type of structure in which the equipment is located and the nature of the owner's business, the rates are usually set by rating organizations specializing in this work. Exact figures on insurance cannot be determined without consultation with the owner's underwriter.

Rent

If the equipment under consideration is to be located in rented or leased quarters, or if additional space must be rented, such expense becomes a fixed charge.

MAINTENANCE COSTS

Maintenance charges consist of expense for labor and material necessary to make repairs and replace parts, as well as cleaning, painting, inspection, etc., for the purpose of eliminating or minimizing the need for repairs. Generally, routine maintenance labor requirements will be the function of an operating engineer or staff. If the responsibility of this group may extend to other facilities beyond the equipment being discussed here, it is important that only an equitable share of the group's time be charged to maintenance.

Extraordinary repairs are quite often handled by separate maintenance divisions and the expense charged back to air conditioning, heating, and ventilating. In other cases, all maintenance is handled by outside service firms and the

[a] *Modern Air Conditioning, Heating and Ventilating*, by W. H. Carrier, R. E. Cherne, and W. A. Grant (Pitman Publishing Corp., 1940, p. 73).

cost considered as maintenance. These costs vary considerably with factors such as the type of system and the proficiency of the installing and servicing organization. Therefore, any forecast of maintenance costs should include consideration of the equipment as a part of the engineering study. The charges should be based upon the entire period under study rather than the early years of operation when repairs may be expected to be at a minimum.

Various estimates of maintenance costs vary from 5 to 10 percent of the installation cost. Table 4 is based upon an average of 7½ percent for about a 75-ton installation. This probably would apply to most installations using high-quality equipment. The maintenance cost must be modified for size of job and quality of equipment. With lower-cost equipment, higher maintenance costs can be expected.

The accounting practices of the owner and the rules of the Bureau of Internal Revenue affect the charges for major overhauling or complete replacement which may restore the capital value of certain equipment items. In these cases the expenditure may not necessarily be charged as maintenance but will become a fixed charge spread over the remaining years of equipment life. Table 4 gives some approximate costs for maintaining large air-conditioning installations using high-quality equipment.

LABOR FOR OPERATION

In some cases wth the installation of automatic equipment, operating labor may be non-existent, but where such labor is required, the cost is readily calculated. Where operators are required, the expense is often considered maintenance, but since they may have other functions that are not properly charged to operation of the air-conditioning, heating, or ventilating installations, the charges should be properly allocated. The cost of experienced and competent operators is well justified in medium and larger plants by economies that can be achieved in maintenance and energy costs.

ENERGY AND WATER COSTS

Energy costs include the costs for power, water, steam, coal, oil, etc., consumed to operate the system.

From the selected equipment and type of installation, it is possible to segregate the relatively constant power loads and the total brake horsepower. Annual power cost can then be figured from the following formula:

$$\text{annual power cost} = \frac{0.746(\text{bhp})HR}{\eta} \qquad (1)$$

where

bhp = brake horsepower.
H = annual operating hours.
R = power rate, dollars per kwhr.
η = motor efficiency (decimal).

In using Equation 1 it must be pointed out that the electric rate, R, must reflect the proper combination of energy and demand rates. These vary widely between the utility companies, and sometimes the rate structure is such that it is largely the demand charge which determines the proper value of R to use in Equation 1.

Operating Refrigerating Equipment

In an air-conditioning system the refrigerating equipment is usually the largest power consuming item to be considered. Also, the prediction of operating cost is more difficult because the power required for summer cooling is affected by many factors of a variable nature.

Table 5 gives the equivalent full-load operating hours of refrigerating equipment used for summer cooling for the period of May 15th to October 15th. This table was calculated from the following equation:

$$H_e = m(b + cf) \qquad (2)$$

where

H_e = equivalent full load operating hours of refrigeration equipment used for summer cooling during period May 15 to October 15.
m = total hours during period May 15 to October 15 that the establishment is open for business.
b = fraction of maximum load from internal heat under average operating conditions.
c = fraction of maximum load that is due to external sources at maximum design conditions.
f = ratio of the number of hours for a particular city, when the outdoor wet-bulb exceeds 65 F, during the period June 1 to October 1 to the total number of hours during that same period. Total hours are assumed as 8 hr per day period for barber shops, department stores, funeral parlors, offices, short-hour restaurants, and specialty shops, and 12 hr per day period for drug stores, long-hour restaurants, and theaters.

It should be pointed out that certain southern cities may have seasons longer than the 5-month period indicated in Table 5. If it is desired to consider a longer season of operation, the ratio of full-load operating hours to hours open for business is smaller; in other words, the *refrigeration load factor* is lower. This is true because the extra increment of days added will be a relatively light load, since the table already includes the more severe part of the season.

The season electrical power cost for refrigerating equipment is then given by the following equation:

$$\text{season power costs} = \frac{0.746(\text{bhp})_l TH_e R}{\eta} \qquad (3)$$

where

$(\text{bhp})_l$ = brake horsepower per ton (see Fig. 1) for *average* load during period. (Due allowance should be made for poorer compressor efficiency at light load.)
T = maximum refrigeration design load, tons.
H_e = equivalent full load refrigeration operating time, hours (from Table 5).
R = power cost, including demand and energy charges, dollars per kwhr.
η = motor efficiency at average load (decimal).

In considering refrigeration power consumption, it should be noted that the use of weather records for a specific year may lead to large inaccuracies in estimating operating costs, since there may be wide variations from year to year, and therefore, average yearly weather records should be used rather than those for any individual year.

If the refrigeration compressor is steam-turbine driven, the same general method can be followed, taking into account average water rate per brake horsepower-hour and the cost of steam.

Condenser Water

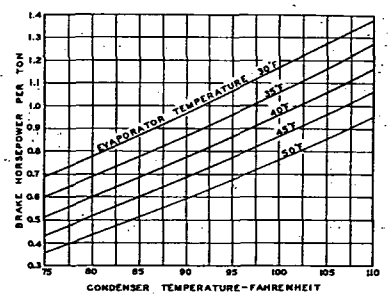
Condenser-water cost estimates can also be based on equivalent full-load operating hours of the refrigeration equipment. The varying temperature of the water at its source, as well as the temperature of the discarded water, must, however, be taken into account. In general, when water is purchased, control is provided to hold the leaving water temperature (or condensing temperature) constant; and in such case the entering water temperature becomes the major variable. The gallons per minute per ton can readily be calculated for any water temperature rise.

The following equation for cost of condenser water is useful:

$$B = 0.060\, a\, T\, H_e\, C \qquad (4)$$

where

B = cost of water for refrigeration during period, dollars.
a = average gallons per (minute) (ton).
T = tons of refrigeration at maximum design load.
H_e = equivalent full load refrigeration operating hours (Table 5).
C = water cost, dollars per 1000 gal.



The average gallons per minute per ton must take into account the variable water temperature. When well water is used as a source, and entering and leaving temperatures are considered constant, the average gallons per minute per ton obviously are equal to the design gallons per minute per ton. However, when the source is river or lake water, its maximum seasonal temperature will generally be reached at the same time that the refrigeration load factor is highest. The average gallons per minute per ton should be calculated from known or estimated water temperatures, because they vary through the season. Maximum water main temperatures are given in Chapter 41, but should always be verified locally. In lieu of this tedious work, the average gallons per (minute) (ton) may be taken as 80 percent of design gallons per (minute) (ton) with reasonable accuracy, for the condition of variable temperature of entering water obtained from rivers and lakes.

Cooling towers and evaporative condensers virtually eliminate condensing water charges since the windage and evaporation losses are seldom over two or three percent of the water circulated.

The savings in water consumed often will not in itself justify the installation of water-economizing equipment since the cost for pumping and the fixed or ownership charges may be in excess of the annual cost for once-through condensing operation. If operating costs are to be the basis for selection, then fixed charges should be determined when studying application of this equipment which usually has a shorter life than the other components.

Usually the primary factors influencing the installation of water conservation equipment are the lack of an adequate water supply or local regulations intended to conserve an existing water supply.

Another factor influencing the installation of such equipment is the increasing trend toward the enactment of taxes and service charges for condensing water wasted into city sewers. Certain municipalities will remit the sewer taxes

Values given are representative of dichlorodifluoromethane (Refrigerant 12) reciprocating machines of about 25 tons capacity in air-conditioning applications. Requirements of smaller machines are usually higher, and for larger machines may be lower. Values shown are for liquid refrigerant at condenser temperature (no subcooling). Subcooling of the liquid may decrease these values approximately 0.3 percent to 0.5 percent for each Fahrenheit degree the liquid temperature is lowered.

Fig. 1 . . . . Typical Brake Horsepower Requirements for Refrigeration[a]

or service charge if the condensing water is submetered and discharged into a storm sewer or used for process purposes.

Heating

The method of estimating fuel consumption to balance the building heat loss is given in Chapter 37. It is important to include the fuel required to heat ventilation air as used in ventilating and air-conditioning systems. In estimating fuel consumption for ventilation air, the tendency of the conventional control systems to use less than the estimated quantity of outdoor air in cold weather should be considered in its effect in lowering fuel consumption. In addition, the heat required to accomplish winter humidifying must not be neglected, when this feature is included in the equipment.

CHAPTER 55

CORROSION AND WATER-FORMED DEPOSITS, CAUSES AND PREVENTION

Definitions, Classification and Characteristics of Water, Causes and Prevention of Scales and Sludges, Causes and Prevention of Slimes, Underwater Corrosion, Atmospheric Corrosion, Buried Pipe Lines, Handling Water Treating Chemicals, Legal Regulations

THE purpose of this chapter is to discuss some of the common problems arising from corrosion of heating and air-conditioning equipment and to suggest methods of preventing or reducing corrosion.

DEFINITIONS

Common terms used in the field of water treatment and corrosion are defined as follows:

Alkalinity. The sum of the carbonate, bicarbonate, and hydrate ions in water. Other ions such as phosphate or silicate may also partially contribute to alkalinity. Ordinarily the difference between the total hardness of a water and the alkalinity gives the amount of permanent or non-carbonate hardness present.

Anode. A positive electrode toward which negatively charged non-metallic ions migrate and at which reduction occurs in an electrolytic cell. In corrosion processes, the anode is usually the electrode having the greater tendency to go into solution.

Biological Deposits. Biological deposits[1] are water-formed deposits of biological organisms or the products of their life processes. Biological deposits may be microscopic in nature, such as slimes, or macroscopic, such as barnacles or mussels. Slimes are usually composed of deposits of a gelatinous or filamentous nature.

Cathode. A negative electrode toward which positively charged metallic ions migrate and at which reduction occurs in the electrolytic cell. In corrosion processes, the cathode is usually the electrode tending to resist corrosion.

Corrosion. Corrosion[2] is destruction of a metal by chemical or electrochemical reaction with its environment. In the corrosion process, the reaction products formed may be soluble or insoluble in the contacting environment. Insoluble corrosion products may deposit at or near the attacked area, or be carried along and deposited at a considerable distance therefrom.

Corrosivity. Corrosivity[3] is the capacity of an environment to bring about destruction of a metal by the process of corrosion. Corrosivity is a property of the environment, but it has no significance until the metal in question is specified.

Electrolyte. A solution through which an electric current flows.

Galvanic Corrosion. Corrosion generally resulting from the contact of two dissimilar metals in an electrolyte. It is characterized by an electron flow from the metal of higher potential (anode), to the metal of the lower potential (cathode), resulting in corrosion of the anodic metal. Galvanic cell corrosion may also result from the contact of two similar metals in an electrolyte of non-uniform concentration.

Hardness. The sum of the calcium and magnesium contents in water. It is this hardness that causes the water to resist the formation of soap lather. Temporary or carbonate hardness is that portion of the total hardness which can combine with the carbonate or bicarbonate ions. The balance of the hardness, principally that which will combine with the sulfate and chloride ions, is called permanent or noncarbonate hardness.

Inhibitor. A chemical substance added to an environment to reduce corrosion.

Ion. An electrically charged atom or group of atoms.

Passivity. The tendency of a metal to become abnormally inactive in a certain environment.

pH. The logarithm of the reciprocal of the hydrogen ion concentration of a solution. The *pH* value denotes the degree of acidity or alkalinity of a solution. The value of a neutral solution, such as pure water, is 7. Values below 7 are increasingly acid, while values above 7 are increasingly alkaline.

Polarization. An effect produced on the electrode of an electrolytic cell by products formed by the passage of current through the cell. Hydrogen is the product generally formed, although other corrosion products may also cause polarization. Polarization reduces corrosive activity by offering a resistance to current flow and developing an opposing electromotive force.

Scale. Scale[4] is a deposit formed from solution directly in place upon a confining surface. It is a deposit which will retain its physical shape when mechanical means are used to remove it from the surface on which it is deposited. Scale, which may or may not adhere to the underlying surface, is usually crystalline and dense, frequently laminated, and occasionally columnar in structure.

Sludge. Sludge[4] is a water-formed sedimentary deposit. It usually does not cohere sufficiently to retain its physical shape when mechanical means are used to remove it from the surface upon which it deposits. Sludge is not always found at the place where it is formed. It may be hard and adherent, and baked to the surface on which it has been deposited.

Water-Formed Deposits. A water-formed deposit[4] is any accumulation of insoluble material derived from water or formed by the reaction of water upon surfaces in contact with water.

Deposits formed from or by water in all of its phases may be further classified as scale, sludge, corrosion products, or biological deposits.

CLASSIFICATION AND CHARACTERISTICS OF WATER

Due to the many conditions of water encountered in industry,[4] it is frequently necessary to obtain expert advice and a prescribed treatment to make the water suitable for use in a given process. The heating and air-conditioning engineer is concerned chiefly with two broad classifications of water: (1) those waters containing various amounts of mineral impurities and (2) condensates that are relatively free from mineral impurities but contain various amounts

[a] All values are parts per million of the unit cited to nearest whole number (see Reference 5).

[b] Numbers indicate location or area as follows:
(1) Catskill supply—New York City
(2) Swamp Water (Colored) Black Creek, Middleburg, Florida
(3) Niagara River (Filtered) Niagara Falls, New York
(4) Missouri River (Untreated) Average
(5) Well Waters—Public Supply—Dayton, Ohio—30-60 ft
(6) Well Water—Maywood, Illinois—2090 ft
(7) Well Water—Smithfield, Va.—330 ft
(8) Well Water—Roswell, N. Mexico
(9) Ocean Water—Average

of dissolved gases such as carbon dioxide, oxygen, and sulfur dioxide, that tend to make them corrosive.

Dissolved gases are the main factors affecting condensate corrosiveness, but they may also be present in water containing mineral impurities to an extent that will make the water corroeive.

Mineralized Waters

All the waters found in streams, wells, lakes, and the ocean are mineralized. The same is true of all municipal supplies even though they may have been *treated*. For a given area, ground waters are likely to be more highly mineralized than are surface waters. Conversely, surface waters are more likely to be contaminated with municipal sewage and trade wastes. Virtually all mineralized waters also contain biological organisms.

Mineralogical Characteristics. The character and amount of extraneous inorganic materials—including deleterious gases—dissolved and suspended therein, describe the mineralogical characteristics of any water. Revealing such information is the function of a mineralogical chemical analysis.

The analyses in Table 1 disclose the composition of the public water supplies used by about 45 percent of the total population of the cities, in the United States, having more than 20,000 inhabitants.[5]

All values recorded are in terms of parts per million.*

* Parts per million are hereinafter abbreviated ppm. A part per million signifies a unit weight of material per million unit weights of the solution.

Table 2 .... Conversion Factors for Water Analyses

To Convert	Into	Multiply by
Grains per U. S. gallon	ppm	17
Grains per Imperial gallon	ppm	14¼
Grams per liter	ppm	1000
Mg per liter	ppm	1

This is the approved standard terminology for reporting the results of mineral analyses.[5] Values reported in the other terms commonly used may be converted into the standard form by using the factors listed in Table 2.

Data for dissolved gases or *pH* values have been omitted in Table 1 because even waters of the same mineral contents may vary widely in these respects. Unpolluted natural waters usually have *pH* values within the range 5 to 8, depending upon their *free* CO_2 contents. Polluted waters, which include those derived from wells or swamps in marshy ground, may have *pH* values well below 5.

Biological Characteristics. The slime-forming organisms are mostly lower plants, grouped by botanists into the phylum thallophyta. This group is distinguished by the absence of leaves, roots, or stems from the mosses, ferns, and seed plants which comprise the three other phyla of the plant kingdom.

The thallophyta (see Table 3) are divided into algae, which can synthesize chlorophyll for the production of sugar, and the fungi which lack chlorophyll, and must therefore secure already synthesized carbohydrates.

All thallophyta are of universal distribution and many of them are slime-forming. Of the five divisions of algae, only three (the green, the blue-green, and the diatoms) are found in fresh water. Of the five divisions of fungi, all may occur in fresh water, the principal slime formers being indicated in Table 3.

The methods of analysis commonly used in the sanitary examination of a water have, as their principal object, to identify and count pathogens.

Most slime-forming organisms are not pathogens. When a water is subjected to a biochemical analysis for the purpose of evaluating its slime producing characteristics, tests, widely different from sanitary bacteriological tests, must be made. Tests upon the water itself are seldom satisfactory, and true indications of the sliming characteristics of a water can

Table 3 .... Principal Slime Formers

Phyla	Rough Division of Phyla
Algae	Single celled, sometimes forming slimy sheets. Many celled in either sheets or froods.
Fungi	*Bacteria* (Schizomycetes) frequently forming slimy surface coatings. *Slime Molds* (Myxomycetes) forming slimy sheets as one stage of their life history. *Sac fungi* (Ascomycetes) of which one division, the yeasts, occasionally form slimy aggregates. The alga-like fungi (*Phycomycetes*) and the stalked fungi (Basidomycetes) rarely form slimes but their filaments may hold together the slimes of other organisms.

only be determined by the analysis of deposits on surfaces having a temperature that approximates the operating temperature range of the final design equipment. The results of such tests are commonly used for selecting proper preventive measures.

Slime and algae micro-organisms are capable of rapid multiplication and, if not controlled, can cause shut-down or permanent damage to equipment. They can be controlled by chemical treatment of the water or in certain cases by mechanical cleaning of the surfaces affected. The chemicals used are usually toxic, and should therefore be handled only by trained personnel having a full understanding of the quantity required and their effect on operators as well as surfaces.

Chemical treatment is usually preferred to mechanical cleaning particularly where surfaces are inaccessible for cleaning or where a shut-down of the operation is necessary for mechanical cleaning.

Condensates

All condensates are caused by the cooling of vapor. Condensates resulting from the cooling of water vapor in air are *dews, sweats, rain,* and *snow,* while those formed in steam-condensing apparatus are termed condensates or return water.

In the heating and ventilating field, the biological characteristics of condensates are likely to be of concern *only* where the condensate is used as cooling water in recirculating systems. The deleterious gas contents of condensates, however, very often create serious corrosion troubles.

The data in Table 4 typify the chemical composition of

Table 4 .... Data Typifying the Deleterious Gas Content of Different Atmospheres

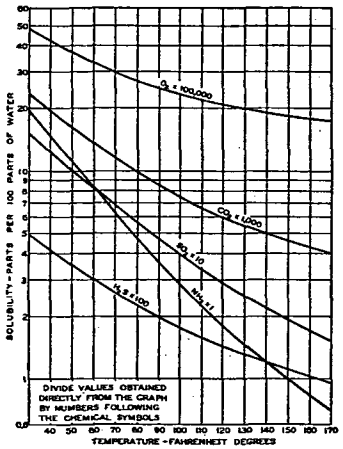

Fig. 1 .... Solubility of Gases at Partial Pressure of 1 Psi

the atmosphere in rural and metropolitan areas, and of stack gases when various types of common fuels are used. The curves in Fig. 1 disclose the solubility of the major deleterious gases present in such atmospheres in otherwise pure water, when the partial pressure of the gas is one psia.

The most common deleterious gases entrained by steam are oxygen and carbon dioxide. In rare instances, hydrogen sulfide, sulfur dioxide, or ammonia are present.

In most steam-condensing equipment,[7,8] the non-condensable gases entrained with steam accumulate so that the amount present in the vapor space is several hundred times higher than in the incoming steam and the amount dissolved in the condensate may therefore approach, or even exceed for short periods, the amount entrained by the steam.

CAUSES AND PREVENTION OF SCALES AND SLUDGES

Scales may be formed on surfaces of equipment in contact with water, and sludges in the body of the water, by the separation from the water of dissolved or suspended solids. According to the nature of a particular piece of equipment and the method of its operation, such separation may be promoted by one or more than one, of several factors:

a. The concentration of solids may be increased by the evaporation of water.

b. The dissolved solids may be rendered less soluble in the water by changes in temperature.

c. Conditions may favor the decomposition of unstable compounds with the formation of less soluble compounds.

Figs. 2 and 3 show that the solubilities of both calcium carbonate and calcium sulfate decrease with the rising temperature within a moderate range of temperatures. Surfaces transferring heat into water, such as condensers and

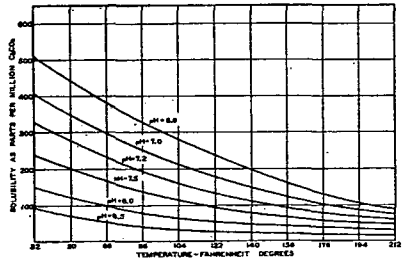

Fig. 2 Adapted from (1) *Ind. & Eng. Chem.*, 20 (1928) 1197—by Balis. (2) J.A.C.S. 60 (1929) 2086—Frear & Johnson.

Fig. 2 .... Solubility of Calcium Carbonate in Distilled Water Containing Carbon Dioxide

(*pH Values at Approximately 73 F*)

coolers, are more susceptible to scale and sludge formation than are the cold parts of the same system using the same water.

The most common of the unstable soluble salts are the bicarbonates of calcium, magnesium, and occasionally iron. Under conditions favoring the removal of carbon dioxide, as when the water is strongly aerated or when it is boiled, the bicarbonates are readily converted to the relatively insoluble carbonates. The type of scale most usually encountered is calcium carbonate (often called alkalinity) from the decomposition of calcium bicarbonate according to the following chemical reaction:

$$Ca(HCO_3)_2 + \text{heat} \rightarrow CaCO_3 + CO_2 + H_2O$$

$$\underset{\text{Bicarbonate}}{\text{Calcium}} + \text{heat} \rightarrow \underset{\text{Carbonate}}{\text{Calcium}} + \underset{\text{Dioxide}}{\text{Carbon}} + \text{water}$$

Conversely, carbonates are readily converted to the more soluble bicarbonate by the addition of carbon dioxide or other acidic materials. This explains the increase in the apparent solubility of calcium carbonate at decreasing *pH* values (increasing concentration of hydrogen ion) shown in Fig. 2, the carbonate really going into solution largely as bicarbonate.

In special cases, primarily with well waters possessing a high natural iron content, deposition of iron oxide from the decomposition of ferrous bicarbonate takes place according to the following reaction:

$$4\,Fe(HCO_3)_2 + O_2 \rightarrow 2\,Fe_2O_3 + 8\,CO_2 + 4\,H_2O$$

$$\underset{\text{Bicarbonate}}{\text{Ferrous}} + \text{Oxygen} \rightarrow \underset{\text{Oxide}}{\text{Iron}} + \underset{\text{Dioxide}}{\text{Carbon}} + \text{water}$$

Low water velocity in heat transfer equipment often causes sludges to settle out in the tubes. This has the same effect on heat transfer as scale formation. When this occurs, increasing the water velocity often cures the condition.

It is sometimes desired to evaluate the tendency in a particular water toward the separation of calcium carbonate, which may be desirable as a means of establishing a corrosion-resistant film on metal surfaces, or in other circumstances may be undesirable because of the impedance of

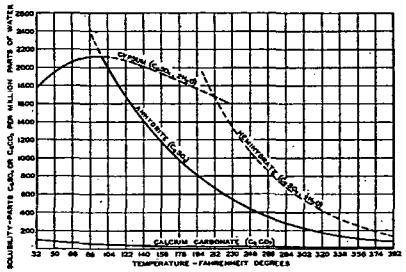

Fig. 3 Adapted from Bull. No. 15, Univ. of Mich. *Formation and Properties of Boiler Scales* by P. E. Partridge.

Fig. 3 .... Solubility of Calcium Sulfate and of Calcium Carbonate for Comparison

($CaCO_3$ *in Equilibrium with Normal* CO_2 *Content of the Atmosphere*)

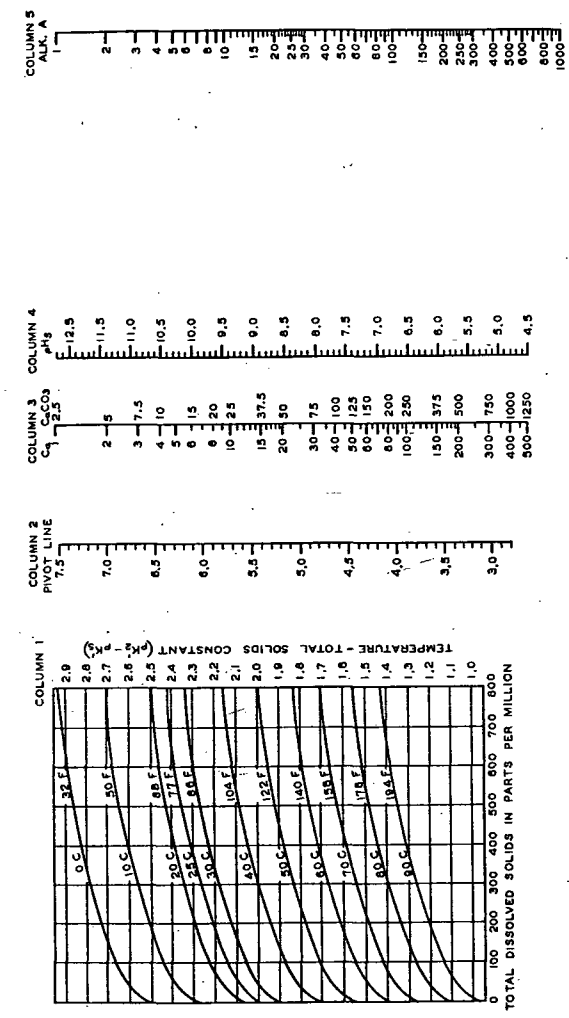
the calcium carbonate film to heat transfer. This tendency is indicated approximately by the Langelier Index,* which is obtained by subtracting the actual *pH* of a particular water from the *pH* at which it is estimated precipitation of calcium carbonate would just begin. This estimate may be made by the use of Fig. 4.

There are various expedients which may be employed for avoiding or mitigating difficulties due to scales:

a. The water may be treated before use to remove elements such as calcium, magnesium, and iron, which form relatively insoluble compounds. In the various softening processes this removal of these elements is accompanied by the addition of other elements, particularly sodium, the compounds of which are *relatively* soluble.

b. The water may be treated within the equipment to promote the separation of dissolved solids as sludges, rather than as scale which is, in most cases, more objectionable.

c. The increase in total solids, due to the evaporation of water, may be controlled by the displacement, continuously or intermittently, of some of the used water by fresh supply.



d. Substances, such as the polyphosphates, having the property of inhibiting the precipitation of calcium carbonate from solutions supersaturated with it, may be added.

e. The *pH* of the water may be lowered (hydrogen ion concentration raised) to reduce the tendency for precipitation of carbonate. This is permissible only to such an extent as will not cause a serious increase in rate of corrosion.

The choice of the best expedient or combination of expedients must be made for each type of equipment, and will be affected by operating and water considerations. Item c above must be used, regardless of which other items are used, for all recirculating water systems from which evaporation takes place.

Once-Through Equipment

Where abundant supplies of water are available at low cost, the cooling water may pass through the equipment once, undergoing a rise in temperature. Little difficulty from scale should be encountered if the Langelier Index is lower than +0.5, based on the highest water temperature encountered in the system. This often corresponds to a carbonate hardness of less than 200 ppm when water temperatures are lower than 100 F. However, since many municipal supplies are softened so that incipient calcium carbonate

Instructions for Using Chart:

1. Knowing temperature and total dissolved solids, find temperature and total solids constant on Col. 1.

2. Align this constant with given value of calcium on Col. 3 of Chart, then locate point in Col. 2 of Chart (Pivot Line).

3. Align this point on Pivot Line with given alkalinity on Col. 5; read *pH* saturation on Col. 4.

Saturation Index is *pH* actual minus *pH* saturation.

e.g.—*pH* actual, *pH* saturation, Saturation Index.

7.6	8.1	−0.5 (corrosive)
8.4	7.8	+0.6 (scale forming)

[Data required for determining *pH* saturation]

(1) Total alkalinity, as parts per million of $CaCO_3$.
(2) Calcium in parts per million.
(3) Total dissolved solids, in parts per million.
(4) Temperature, Centigrade, at which *pH* saturation desired.

Fig. 4 .... Graph and Nomogram for Determination of *pH* Saturation by Langelier's Formula

(*Applicable within pH Range 7.0–9.5*)

precipitation is induced, the Langelier Index is a more reliable indication of scaling tendency.

Prevention of scale in once-through systems is based primarily on the adjustment of pH, the application of surface-active agents, or a combination of the two. Normally the addition of a few parts per million of a surface-active agent such as a polyphosphate[20] fed proportionately to a water with a scaling tendency is all that is required to control scale.

Where a given water does not respond satisfactorily to surface-active agents, reduction of pH with sulfuric acid or carbon dioxide is often employed. The pH is reduced only sufficiently to have it fall within the effective range of the surface-active agent. The use of acid or carbon dioxide is sometimes permitted without polyphosphates when corrosion will not be severe. In this case the pH is reduced so that the Langelier Index is less than +0.5. The acid or carbon dioxide must be added with care. Use of automatic pH controllers is required if corrosion is to be prevented.

A special case of scale from ferrous bicarbonate decomposition was mentioned previously. Ferrous bicarbonate is considerably less stable than calcium bicarbonate. The prevention of this decomposition can be accomplished by the addition of polyphosphate in low concentrations.[21] The use of polyphosphate in the ratio of two parts by weight to one part by weight of iron is usually most effective. The polyphosphate must be added to the water before exposure of the water to air or chlorine if effective stabilization of the iron is to occur.

Closed Recirculating Systems

The closed recirculating system is one in which water circulates through one heat exchanger where it absorbs heat, has its temperature elevated, and circulates through another heat exchanger in which its temperature is lowered. In cold water or chilled water systems scaling is seldom a problem. In hot water systems scaling is seldom a problem unless there is a large amount of make-up water.[22] In this case surface-active agents such as polyphosphate are used.

Open Recirculating Systems

Where water from condensers and similar equipment is passed through a spray pond or cooling tower and then returned to the equipment, there is an increase in the concentration of solids because of the evaporation of some of the water into the cooling air, and, moreover, the aeration removes carbon dioxide. Both factors promote the tendency to deposit scale.

The corrosive properties of the water can also be increased through the absorption of acid gases such as sulfur dioxide (SO_2), from the air.[23] The absorption of gases from the air being processed and the concentration of solids due to evaporation are factors in air washer operation when the air is humidified.

The concentration of scale-forming minerals in open recirculated cooling water is limited by natural drift or windage loss. This is the loss of water droplets from the system. Windage losses from typical systems may be classified as follows, based on recirculating rates:

	Percent of Recirculating Rate
Evaporative Condensers and Air Washers	0 to 0.1
Mechanical Draft Cooling Towers	0.1 to 0.3
Atmospheric Cooling Towers	0.3 to 1.0
Spray Ponds	1.0 to 5.0

To show the effect of concentration in a typical mechanical draft system assume:

1. Recirculating rate = 100 gpm.
2. Drift loss = 0.2 percent of recirculating rate = 0.2 gpm.
3. Evaporation rate = 1 percent of recirculating rate = 1.0 gpm.
4. Calcium bicarbonate in make-up water = 100 ppm.
5. Calcium bicarbonate in evaporated water = 0 ppm.

Let K = concentration of calcium bicarbonate in recirculating water = concentration of calcium bicarbonate in drift loss.

The process of concentration in the system may be represented diagrammatically as follows:

Evap. = 1 gpm
$Ca(HCO_3)_2$ = 0 ppm
↑
Recirculating Water System
$K = Ca(HCO_3)_2$ conc.
→ Drift 0.2 gpm, $Ca(HCO_3)_2 = K$ ppm
↑
Make-up = 1.2 gpm
$Ca(HCO_3)_2$ = 100 ppm

The concentration may be obtained from the equation

$$\text{(Make-Up)[Ca(HCO}_3\text{)}_2\text{ conc.]} = \text{(Evap.)[Ca(HCO}_3\text{)}_2\text{ conc.]} + \text{(Drift)[Ca(HCO}_3\text{)}_2\text{ conc.]}$$

$$(1.2)\ (100) = (1)(0) + (0.2)(K)$$

substituting,

$$120 = 0 + 0.2\,K$$

whence,

$$K = 600 \text{ ppm}$$

Therefore the concentration of calcium bicarbonate in the recirculating water equals 600 ppm. This far exceeds the allowable concentration of 170 ppm at which scaling will occur.

To correct this situation, it is imperative to provide a continuous bleed-off or blowdown from the recirculating water circuit. Typical bleed-off requirements are shown in Fig. 5. Reference to the No Treatment curve shows that a

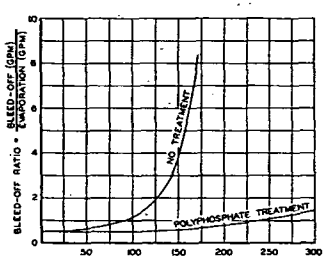

Fig. 5 .... Relation of Bleed-Off Requirement to $CaCO_3$ in Make-Up Water

bleed-off rate of 1.2 times the evaporation rate is required when a make-up water contains 100 ppm calcium bicarbonate (or alkalinity) if scale is to be prevented. Calculation by a material balance will show that the bleed-off plus drift loss will limit the calcium bicarbonate to 171 ppm.

It can be seen from Fig. 5 that very large amounts of bleed-off are required as a make-up water approaches or exceeds 150 ppm of alkalinity. When alkalinity exceeds 175 ppm, bleed-off alone is no longer effective. The use of 5 ppm or less of polyphosphate is extremely effective in reducing the required bleed-off and making possible the use of make-up waters which will not respond to bleed-off alone.

Occasionally, waters are encountered which have exceptionally high alkalinities or which develop high pH values when recirculated. The use of sulfuric acid is common in these cases to maintain pH values between 7 and 8. Polyphosphates are most always used when acid is required.

It is very important to control acid feeding carefully to avoid serious corrosion. Automatic pH controllers are often employed for such a purpose.

Heating Systems

In hot water heating systems or in steam heating boilers where all condensate is returned, troubles from scaling should not be severe. If necessary, sodium phosphate or sodium carbonate may be added to the water to prevent the formation of adherent calcium sulfate scale.

Boilers and High Temperature Equipment

Where temperature exceeds 250 F, complete softening of the water is the only practical method for minimizing sludge formation. This is usually accomplished by artificial or natural zeolites (called also ion-exchange materials) or by hot-process precipitation softeners.

In boilers operating at pressures above 100 psig virtually all the calcium, magnesium, silica, iron, and manganese salts entering with the feed water are potential scale or sludge formers.

In boilers operating at 100 to 250 psig, the formation of adherent calcium sulfate (anhydrite) scales is most to be feared. Such deposits form on the *hottest* evaporative surfaces. The scale has a low heat conductivity. Even a layer of egg shell thickness may so impede the rate of heat transfer as to bring about over-heating of the metal.

The orthophosphates of sodium are most frequently used to prevent sulfate scales. The concentration of phosphate required is such as to cause the precipitation of calcium phosphate as sludge, thus keeping the boiling water undersaturated with respect to calcium sulfate. To a lesser extent, sodium carbonate (called also soda ash and sal soda) is also used. Most of the effective boiler compounds contain either phosphates or soda ash, or both. Certain organic materials and colloids are sometimes found to minimize scale formation. Where chemicals are introduced directly into the boiler in amounts adequate to prevent scale, sludge is formed in amounts proportionate to the calcium and magnesium salts entering with the feed water. To prevent troublesome accumulation of this sludge, as well as soluble salts, as evaporation occurs, some *blowdown* of boiler water is necessary.

CAUSES AND PREVENTION OF SLIMES

A water containing slime-producing organisms will produce prohibitive amounts of slime *only* when the conditions of use are such as to propagate their life processes. Whenever sufficient food material from normal water or from airborne dust combines with optimum temperature conditions, such as exist on cooling surfaces and air washers, serious quantities of slime will be produced.

Some natural well waters do not contain sufficient foods to support luxuriant slime growths. Algae, which require light for carrying on their life processes, are likely to cause difficulty in cooling towers and other areas where sunlight is abundant. The ordinary slime-forming bacteria are capable of using a wide variety of nitrogenous and cellulose material as food sources. These bacteria thrive best under dark conditions such as exist in condensers and other heat transfer surfaces. Other organisms capable of causing similar difficulties use such a wide variety of food material as algae,[24] iron compounds,[25] and inorganic sulfates.[26]

At present, the use of toxic chemicals and irradiation are the two general means employed in slime control. The value of ultra-violet light, used so broadly in the beverage industry, is somewhat in dispute.

Anti-fouling paints have been developed and are fairly satisfactory for the prevention of the growth of macro-organisms such as *barnacles* and *mussels*, but these paints must be renewed at frequent intervals, and are not applicable to inaccessible areas such as the inside of pipe lines and cooling towers. Satisfactory *anti-sliming* paints have *not* been found.

Table 5 .... Common Chemicals Used for Slime Control

Chemical	Trade Name	Physical State*
Chlorine	Chlorine	Gas
Hypochlorites	Calcium Hypochlorites	Crystalline
	Sodium Hypochlorites	
Chlorinated Phenols	Chlorophenylphenate	Briquettes
Sodium—	Tetrachlorophenate	Briquettes
	Pentachlorophenate	Briquettes
Potassium Permanganate	Permanganate of Potash	Crystalline
Copper Sulfate	Blue Vitriol	Crystalline

* As Shipped.

Names and other pertinent data relating to some of the more common chemicals used in slime control are shown in Table 5.

Chlorine is the only chemical to which is attributed the ability to destroy slime-forming organisms. The others are presumed to poison marine organisms, most of which *recover* when the chemical is not used regularly.

While chlorine is the most generally used chemical, the use of others may occasionally prove to be more practicable. Choice of the chemical is conditioned largely by the design and operation of the system.

Open Recirculating Systems

In spray ponds and cooling towers of the open type, light-loving algae growths are likely to cause blocking of the distribution piping and troughs. These organisms are most troublesome in areas accessible to sunlight. Algae slimes are usually stringy in character.

In open recirculating systems, continuous use of small quantities of chlorine is generally most satisfactory. In once-

through systems, where large quantities of water are used, intermittent treatment a few times each day will usually result in satisfactory slime removal and chemical economies.

Neither the phenols nor copper sulfate may be used for the removal of slime already formed. For this purpose, chlorine gas or suitable chlorine liberating compounds may be used. After being cleaned, the other chemicals may be used to prevent the reestablishment of slime in the system. The removal of green algae from a cooling tower should never be used as an indication that the true slime-forming organisms on heat exchanger surfaces have been removed. The more resistant slime formers, which so materially reduce heat transfer efficiency, will often be unaffected by treatment which completely eliminates algae.

Copper sulfate must be used with care because it can cause serious corrosion of steel in a system. It is also ineffective in alkaline water because the copper is precipitated from the water.

Closed Once-Through Systems

In equipment where light is excluded, slime formations are due to fungi. Usually, they predominate on the heat exchange surfaces. Bacteria form thick, soft slime. Yeast and molds form tough rubbery slimes. Chlorine and hypochlorite solutions, fed intermittently, are usual preventatives.

UNDERWATER CORROSION

When deleterious substances are present in water, the corrosivity of the solution is increased in proportion to the amount of deleterious substances present, the temperature, and usually the rate of flow of the solution over the metal surfaces. There are other relevant factors, but their influence in general is subordinate to those mentioned. Dissolved oxygen, acid gases, and chloride salts are the corrosion accelerators most frequently encountered.

Neutral and slightly alkaline waters saturated with air, corrode iron at a rate about triple that for the same water free of air. Hot water containing oxygen will corrode iron at a rate three to four times that for the same water when cold.

Corrosion of iron decreases as the *pH* of water solutions increases, and practically ceases at a *pH* of 11. Film-forming agents such as chromium, nickel, and silicon, can be added in the manufacturing of metals to provide increased corrosion resistance. In some processes, inhibitors, such as chromates, can be added to the water to minimize corrosion.

Soft water, as for example the effluent from zeolite softeners, is likely to be several times more corrosive to iron than hard waters. In small installations, the use of copper or brass pipe usually is a practical expedient. Cement-lined pipe and tanks suitably resist attack.

Where the water contains slime-forming organisms, especially those bacteria that thrive on iron, chlorination of the water is imperative to inhibit tuberculation and subsequent pitting.

Bituminastic paints, applied at *regular* intervals upon *well cleaned* surfaces, will measurably prolong the life of equipment handling cold waters.

It is generally agreed that the rate at which oxygen reaches the surface determines the rate of corrosion of ferrous metals. Underwater, the oxygen diffusion to a surface is often restricted by films and scale that form on the surface, and consequently the rate of corrosion differs from that of surfaces exposed to the atmosphere or to alternately wet and dry conditions.

All ferrous metals will not corrode at the same rate. A thorough knowledge of the conditions to be encountered and experience gained from tests of the materials in service are required when attempting to predict performance or life in a given service.

Copper, aluminum, and other non-ferrous metals and their alloys have been found effective in resisting many types of underwater corrosion. Corrosion of ferrous metals with which these metals are in contact, may be accelerated in water of good conductivity.

The environmental conditions are responsible for length of service of any metal. No single material is suitable for all types of service.

Once-Through Systems

Where corrosion can be expected in once-through systems, it may be minimized through the use of one of the following methods:[32]

1. Forming a protective film of calcium carbonate on the metal surfaces.
2. Providing mechanical or chemical deaeration, or both, of the water.
3. Using organic or inorganic corrosion inhibitors, or both, in low concentrations.

Formation of a thin protective calcium carbonate film is accomplished by adjustment of the water until the Langelier Index has a value greater than +0.5. This is rather difficult in systems which have a wide variation in temperature. Since the Langelier Index is dependent on temperature, when a water is adjusted to form a protective film on those surfaces of higher temperature, no film will form on colder surfaces. Therefore, this method of corrosion control is more applicable to large municipal distribution systems. Where heat transfer is involved, the method is usually impractical except under unusual circumstances. When this method is used, *pH* is increased by using an inexpensive alkali such as lime, caustic soda, or soda ash. Lime is usually used for waters of low calcium content. Caustic soda or soda ash are used for waters of high calcium content.

Mechanical[33] and chemical deaeration are not often used in once-through systems because of relatively high operating costs. Mechanical deaeration also requires the use of costly equipment. Chemical deaeration is usually accomplished by raising *pH* with caustic soda and by continuously feeding catalyzed sodium sulfite in proportion to water flow. The use of catalyzed sulfite is not permitted in water to be used for potable purposes.

There are several corrosion inhibitors such as chromate, polyphosphates, and silicates which are effective in once-through systems.[34] Polyphosphate at a concentration of 2 to 5 ppm has been found useful in controlling tuberculation of iron pipe and in reducing overall corrosion. Usually, more effective treatment is to use chromate polyphosphate at concentrations of less than 60 ppm.

Sodium silicate is often used in relatively soft waters by increasing the silica content about 8 ppm. It is used primarily to reduce corrosion in potable water supply systems.

Open Recirculating Systems

Corrosion in open recirculating systems, such as air washers and cooling towers, is usually controlled by use of corrosion inhibitors such as chromates, polyphosphates, a combination of chromate and polyphosphate, and nitrites.[35, 36] Mechanical or chemical deaeration is not practicable in open systems because of the high rate of aeration. It is not practicable to use high *pH* values of 11 or more in systems containing wood. High *pH* will cause serious delignification of wood. High *pH* values also prevent control of scale. Corrosion control is usually carried out in the *pH* range of 6.5–8.

Chromates are by far the most effective corrosion inhibitors. It is extremely important, however, to maintain an adequate concentration of 300–500 ppm, which is effective for most systems. If for economic reasons substantially lower concentrations are used, serious pitting corrosion may occur.

Polyphosphates are most effective in reducing tuberculation. It is not usually possible to reduce overall corrosion to anywhere near the degree possible with chromate.

Where economy of treatment is of primary importance, a substantial reduction of pitting and overall corrosion can be obtained by using as little as 60 ppm of a mixture of polyphosphate and chromate. Close control over *pH* is a requirement for good corrosion control by this process.

Sodium nitrite has not had widespread use as a corrosion inhibitor in open recirculating systems. It has been reported that difficulty may be encountered in maintaining effective concentrations. Considerable field experience is needed to further qualify this inhibitor.

Closed Recirculating Systems

The term Closed Recirculating System is in reality a misnomer. Except for relatively small systems, most closed systems are open because they most usually require make-up water. Recently, tests conducted on 84 closed systems indicated that more than 50 percent of the systems had one or more water changes per month because of leakage. Weekly water changes were found in more than 10 percent of the systems.[37] *Continuous make-up, of course, replenishes oxygen* in the system, thus promoting corrosion. It is imperative, therefore, that corrosion control be provided for most closed systems. The age old assumption that closed systems are closed is no longer valid.

Corrosion control is usually accomplished by (1) mechanical or chemical deaeration or (2) use of corrosion inhibitors such as chromates and nitrites.

The use of polyphosphates is not generally recommended for closed systems because they will revert to ineffective orthophosphates unless there is a large replacement of water containing polyphosphate.

Higher concentrations of chromate are usually maintained in closed systems as compared with open systems. This is primarily due to the fact that, since water losses are usually small, the cost of maintaining excess chromate as a safety factor is small.

Treating Chemicals

Whenever chemicals are used to control scale, corrosion, algae, and slime, competent advice from a water chemist is desirable. Often factors considered irrelevant to the layman, will be of much importance in securing effective treatment. Very often troubles are created through improper use of chemicals and are more serious than if they were not used.[38]

Refrigerating Systems

Corrosion in refrigerating systems is confined to surfaces in contact with brines or those in contact with refrigerant.

Brines. Refrigerating brines usually are comprised of sodium chloride, calcium chloride, or calcium and magnesium chlorides. The corrosivity of dilute brines is higher than their more concentrated solutions. The corrosivity of sodium brines, other conditions being fixed, is about 1.5 times greater than brines of the alkaline earth metals.

Brines are excellent electrolytes. Contact of dissimilar metals of wide potential differences, when in contact with brines, results in rapid corrosion by galvanic action.

The leakage of air, acid refrigerants, or both, accelerates the corrosivity of brines. Ammonia precipitates calcium and magnesium salts, thus clogging the system at restricted points.

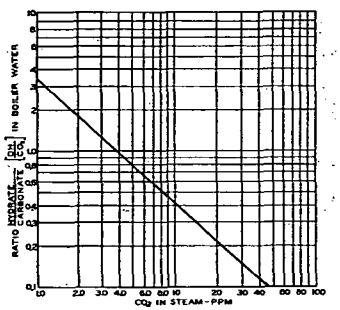
The addition of caustic soda and sodium dichromate to brine solutions to inhibit corrosion of iron, is a more or less general practice. Sodium silicate and sodium phosphate are also used at times, but tests indicate they are not as effective as is sodium dichromate. It has been suggested[39] that 125 lb of sodium bichromate per 1000 cubic feet of calcium chloride brine, and 200 lb per 1000 cubic feet of sodium chloride brine, be added to inhibit brines; that when salt or calcium chloride is added to "strengthen" brine, sodium dichromate also be added in the amounts shown in Table 6.

Table 6 . . . . Quantities of Sodium Dichromate to be Added to Maintain Initial Concentration

Specific Gravity of Brine to be Strengthened	Lb Sodium Dichromate per 100 Lb $CaCl_2$ Added
1.16	0.695
1.18	0.621
1.20	0.556
1.22	0.502
1.24	0.455
	Lb of Sodium Dichromate per 100 Lb NaCl Added
1.12	1.79
1.14	1.47
1.16	1.32
1.175	1.18

Refrigerants.[40] The common refrigerants, except those of the hydrocarbon type, will attack the common metals and alloys if *moisture is present*. Even a very small amount of water may cause severe corrosion with certain refrigerants. The amount required need only be sufficient to produce a water film on the metal surface.

With the halogenated hydrocarbons, complete elimination of water is much to be desired. Where ammonia is used, copper and its alloys, aluminum and zinc, are attacked especially at elevated temperatures. When sulfur dioxide is used, more than 50 ppm (0.005 percent) of water will cause appreciable corrosion of virtually all the common materials.



Minimizing Steam Condensate Corrosion

There are four expedients that may be utilized to minimize corrosion in steam condensate systems: (1) treatment of the boiler feed water so as to eliminate deleterious gases entrained with the steam, (2) design of the condensing equip-

ment to minimize dissolution in the condensate of the deleterious gases entrained with the steam, (3) chemical treatment of the condensate, (4) use of resistant metals.

Boiler Feedwater Treatment. Elimination of oxygen from boiler feedwater and, therefore, from the steam developed, can be accomplished either mechanically or chemically. In some steam generating stations, both expedients are employed.

Tests[28] have indicated that in small low-pressure heating boilers, where the boiler input contains less than about 50 ppm of carbonate hardness, the CO_2 in the steam can be controlled by adding calcium hydroxide to the boiler. In Fig. 6 are shown the equilibria conditions proposed for boilers operating at pressures up to about 5 psi gage. This

(All analytical values are ppm by weight)

Fig. 6. . . . . Relation of Hydrate/Carbonate Content in Hard Boiler Water and CO_2 in Steam at About 5 Psi Operating Pressure

expedient may *not* be used in higher pressure boilers, because of the possibilities of scale and sludge formations. In the latter, the only method used to date for treating the feedwater consists of removing the alkaline earth salts, i.e., softening, and subsequent acidulation followed by deaeration at temperatures near the atmospheric boiling point of water.[29]

Design of Condensing Equipment. In the design of water heaters and comparable types of condensing equipment,[27] it is possible to shift the accumulation of non-condensable gases to a location away from the condensate level and, subsequently, vent these gases to the atmosphere. The venting of an amount of steam equal to about one-half percent of the total steam entering the condenser is the optimum vent rate.

Venting is of little practical value when the CO_2 content of the incoming steam is below about 5 ppm. When the steam contains more than 5 ppm, venting provides a means of producing a condensate containing a minimum of about 3 ppm. However, even as little as 3 ppm of dissolved CO_2 can produce active corrosion if large amounts of condensate are flowing.

Chemical Treatment of Condensate. Condensates containing comparatively large amounts of oil, are practically non-corrosive, due to the protective film provided by the oil. When oil is intentionally added to condensate,[28] inadequate quantities may accelerate rather than decelerate corrosion on those surfaces not covered by the oil. Sodium silicate added to CO_2-bearing condensate has been shown to decrease, but not entirely prevent, corrosive action. It is not known whether the protection afforded by silicate solutions is due to the establishment of a protective film on the metal surface or to neutralization of the CO_2 by the alkali in the silicate solution.

It has been postulated that ammonia,[30] cyclohexylamine,[30] ethylene diamine, and morpholine[31] will retard corrosion of condensate lines. Tests with benzylamine have also been reported.[32] Where copper and its alloys are involved, the use of alkaline inhibitors is believed inadvisable. The use of small amounts of sodium hexametaphosphate has been suggested too, but tests[28] indicate that this salt accelerates rather than decelerates, the rate of attack on steel by condensate containing CO_2 and oxygen. Whether chemical treatment of steam or condensate is feasible, must be determined not only upon the basis of the acuteness of corrosion troubles, but also upon the uses made of the steam or condensate.

Use of Resistant Metals

Steam condensates vary greatly in their ability to corrode metals. The amount of gases that have been dissolved are the determining factors, with oxygen and carbon dioxide, which turns to carbonic acid, being the most common.

Steel, wrought iron, and copper are the metals ordinarily used for pipelines carrying steam condensate. All of these materials have been used with various degrees of success, but under severe corrosive conditions only a few years of service can be anticipated. With the proper metal or alloy carefully selected to suit the existing corrosive conditions, a service life of 15 to 20 years or more is not at all unusual. To obtain a long service life, an analysis must be made of the existing conditions, and if the condensate contains undue amounts of oxygen, carbon dioxide, and other harmful impurities, mechanical elimination of these gases should be a requirement. Treatment of the boiler water and the condensate itself has also proved to be somewhat effective.

Copper and ferrous metals are attacked by combinations of carbon dioxide and oxygen. When the condensate is being returned to the boiler, any copper corrosion products in the water occasionally present a serious problem. The copper that goes into solution is carried along in the condensate, and upon reaching ferrous materials in the boiler and elsewhere will plate out on the ferrous surfaces and set up galvanic corrosion due to the contact of dissimilar metals.

One of the most successful means of preventing corrosion near the junction point of copper and ferrous piping, or where copper piping is connected to steel tanks or boilers and other ferrous vessels, is to install a *throw-away* section at or near the junction. Since the corroding effect will always be found on the ferrous side of the junction rather than on the copper or copper-alloy side, and the effect is usually localized in the immediate vicinity of the joint, the installation of a ferrous pipe section 8 to 10 in. long will absorb practically all of the corrosion. When this *throw-away* section becomes corroded, it can readily be replaced. It should be noted, however, that in ordinary hot water heating systems this problem of potential corrosion at junctions of dissimilar metals seldom presents itself. Where there is any suspicion in this regard, precaution can be readily and commonly taken by separating the two metals electrically by means of a simple insulating union.

No paint or similar protective coating has thus far proven satisfactory where dissimilar metals are used in the same condensate pipe runs. Tests of cement-lined and vitreous-lined pipe have shown the linings to be readily dissolved by the hot condensates. At condensate temperatures, galvanizing on iron or steel pipe has not proved to have any advantages, and in some cases has been found to be detrimental.

ATMOSPHERIC CORROSION

Most of the problems originated by atmospheric corrosion occur in connection with the fire-side of boilers and furnaces (including their flues and stacks), sewer vents, air ducts, and coal and ash handling equipment. Usually such equipment is fabricated from common types of ferrous metals.

Generally little or no atmospheric corrosion occurs at temperatures higher than the boiling point of water, because at such temperatures little or no condensate is formed. If it does form at the higher temperatures; only negligible amounts of carbon dioxide and oxygen present in the atmosphere, will dissolve in the hot liquid, but sulfur gases may dissolve and cause rapid attack. Oxygen, sulfur dioxide, sulfur trioxide, and carbon dioxide are the deleterious gases most frequently accountable for corrosion in moist atmospheres.

Coal Storage and Handling Equipment

Virtually all coals contain sulfur in the form of pyrite, and some moisture. In storage, the pyrite is likely to be decomposed by oxidation. Moisture dissolves the products of decomposition forming sulfurous and sulfuric acid. The acid solutions vigorously attack the supporting metal.

Rubber linings have been developed for coal chutes and bins to effectively resist corrosion and the abrasive action of the coal, but they are expensive.[34] Concrete linings for steel bunkers have also been effectively employed.[35]

The use of high chromium steels is not always a sure cure, especially with coals treated with dust-allaying agents high in chlorides.

Flues, Stacks, and Fire-side of Boilers

The surfaces of flues and boilers contacting the products of combustion, seldom experience corrosive attack when the equipment is in operation. Breechings, smoke hoods, and canopies in contact with flue gas may, however, be subject to attack during the warming-up period of an appliance, or when the rate of operation is so low that the temperature of the flue gas is below the dew point. It is common practice to use cast-iron or acid-resistant vitreous enameled steel in flue gas connections to appliances, to prolong the life of these parts. The shut-down period, when condensation of moisture occurs on the metal surfaces, is usually the time when most damage is done.[36] In those sections of the stacks where flue gas temperature drops below the dew point, corrosion is inevitable during operation.

It is clear that where long shut-down periods are anticipated, a practical method for mitigating corrosion is to clean the surface thoroughly and to provide adequate clean, dry air circulation to prevent condensation. (See also Care of Idle Heating Boilers, Chapter 35.)

Protective coatings with organic binders are destroyed rather rapidly above 400 F because of the decomposition of the organic materials. The surfaces of metals, whose temperature does not exceed 400 F, may be protected by periodically applying paints such as those specified in the following paragraphs entitled Air Ducts.

Air Ducts

The most practical method for protecting air duct surfaces made of steel from atmospheric corrosion, is to apply protective paints. One of the most effective protective coatings is red lead paint.

Three coats of paint should be applied, of which the first two coats should be rust-inhibitive paint such as red lead paint, with the second coat tinted to a light brown color with carbon black, and the finishing coat may be red lead paint tinted to a black or brown color, black paint made according to *Federal Specification* TT-P-61, red iron oxide paint conforming to *Federal Specification* TT-P-31, or white or light tinted paint made according to *Federal Specification* TT-P-40.

Another paint which has had some use for priming iron and steel is zinc chromate paint.

Under some conditions, a chlorinated rubber base paint made according to *Federal Specification* TT-P-91 may be used for the finishing coat, particularly where the presence of highly corrosive gases or contact with strong alkaline water would injure the standard paints. Rubber base paints should be used only for the finishing coat over regular priming and second coats.

BURIED PIPE LINES

Lines that are cold and in intimate contact with the earth are corroded from the same causes as in mineral waters, but pitting is usually more intense due to variations in concentration of salts and oxygen in solution, acidity, drainage, and presence of solid materials (such as cinder) in contact with metal pipe. Galvanic currents, induced by contact of certain dissolved constituents in the soil, often act over a large area, and accelerate corrosion where they leave the pipe line.

Certain bacteria that thrive in the absence of oxygen have the power to obtain hydrogen and dissociate sulfates in the soil, with a resultant production of hydrogen sulfide which attacks iron to form iron sulfide.

Stray electric currents from electric power generating stations sometimes find their way into buried steel structures, and do damage in proportion to the current density where the current leaves the metal to enter the ground.

Pipe Materials

Some underground corrosive environments found in the air-conditioning and heating industries require special materials. The selecton of such materials must be based upon an economic evaluation, as the use of expensive first cost materials is not wise if the life of lower cost materials is adequate. On the other hand, a material low in cost and corrosion resistance should be avoided if it leads to costly shut-downs, repairs, and early replacements. Underground piping materials should be selected for their ability to resist exterior as well as interior corrosion, and careful evaluation of the soil and water should be made.

Underground corrosion of metals is particularly difficult to predict. There are many different types of soils varying in composition and in ability to corrode both ferrous and non-ferrous metals. Where excessively corrosive soils are encountered, special materials may be necessary, but gener-

ally the commonly used ferrous materials have proved to be the most economical. Copper and many of its various alloys are also used advantageously, but their use is more restricted to selected localities. It has been found that soils with high content of organic matter or alkaline soils in which the ratio of chlorides and carbonates to sulphates is high, may be corrosive to copper.[21] Copper or the commonly used ferrous metals should not be embedded directly in cinders or in tidal marshes, as they may be unduly attacked by sulphur compounds. It is also wise to avoid the embedding of any pipe materials *in soils where unusually high salt contents* are known to exist.

Galvanized wrought-iron pipe and steel will resist underground corrosion quite satisfactorily, particularly if the galvanized coating is 3 oz per sq ft or more. The National Bureau of Standards reports that where an underground piping material contains 3 oz of galvanizing per square foot, or more, the life of the pipe materially increased. The zinc used for galvanized coating is on the electrochemical protective side of the iron; and the zinc as it corrodes is changed to zinc compounds before the underlying base metal is attacked. This fact and the mechanical protection provided by the zinc coating account for the protection afforded by the galvanized coating. Once the galvanized coating has been destroyed, the base metal must then retard the corrosive attack, so the rate of attack depends upon the composition of such base metals. Lead-coated pipe[22] has had a limited application for underground service. It has been found that it corrodes chiefly in soils deficient in oxygen or containing cinders.

Protective Coating

Protective coatings for buried pipe lines are in a class by themselves because of the unusual service conditions, and because it is not possible to maintain them by recoating when necessary. Buried steel pipe lines have been protected against corrosion with considerable success by the use of very thick bituminous coatings applied in molten condition. The best results are obtained by applying the bituminous coatings over a standard priming coat such as red lead or a bituminous paint, and for long service it has been found that after the bituminous coatings are applied, a wrapping of asbestos fabric saturated with bitumens will prevent movement and displacement of the bituminous coatings, and add greatly to the length of time satisfactory protection will be maintained.

Cathodic Protection

Protection is obtained by rendering the structure cathodic to the surrounding water or soil by means of a controlled difference of potential. This method, which has proved satisfactory and economical on a number of gas and oil pipe lines underground, has also been applied with some success to the protection of the inside of water-storage tanks and other structures that are in contact continuously with water. Protective coatings that insulate a large portion of the metal surface will reduce very materially the total amount of protective current that must be impressed on bare anodic areas to arrest corrosion.

Because of differences in environmental conditions, it is necessary to determine or estimate the minimum current density required for each structure, and design the anode or anodes so that the necessary protection can be obtained most economically. In water having relatively high electrical conductivity such as in sea water, this is comparatively easy compared with fresh water. In the latter, the composition of the water is a major factor. It is therefore desirable to obtain an accurate estimate of the minimum current density required. The current is then controlled by the potential between the anode and the structure to be protected.

Rectifiers have generally proved to be the most practical means for supplying the necessary current for protection of surfaces in contact with neutral waters.[23]

HANDLING WATER TREATING CHEMICALS

Virtually all the chemicals used in water conditioning are injurious if taken internally in large doses. Many also cause severe skin irritation. Thus, they should be handled with caution.

Caustic soda, lime, and concentrated sulfuric acid will burn the flesh. In addition, if mixed with small amounts of water, sufficient heat may be generated so that spattering occurs or the container becomes too hot to handle.

The chlorophenol compounds, even in the low concentrations used in water conditioning, have been reported[24] to produce dermatitis. Chrom-itch is not uncommon among workers handling chromates. The amines are said to be absorbed through the skin.[25] Morpholine is said to cause kidney and lung trouble when so absorbed.

Chlorine gas irritates the skin, eyes, and mucous membranes. Concentrations as low as 0.004 percent by volume in air cause dangerous illness in one-half to one hour.

When relatively large amounts of the non-gaseous chemicals are to be handled, protective clothing, including goggles, should always be provided, and a shower head or its equivalent provided at or very near the point where the chemicals are mixed. *Chemicals should always be washed from the skin with large volumes of water.*

For the handling of chlorine and chlorinators, the U. S. Public Health Service[26] stipulates the following safety requirements:

1. Suitable gas masks and a small bottle of ammonia for testing for leaks should be kept at convenient points immediately outside the room or enclosure in which chlorine is being stored or is in use. Gas masks should be inspected at regular intervals and kept in serviceable condition. Note:—All-purpose masks offer adequate protection only when the concentration of acid gases does not exceed two percent—see *Safe Practices Pamphlet #64* National Safety Council.
2. Chlorinating equipment and cylinders of chlorine should be housed preferably in separate buildings above the ground level.
3. The room or building housing chlorinators in service should be maintained at a temperature above 60 F, but never in excess of the normal summer temperature. The cylinders of chlorine should be shielded, where necessary, from excessive heat or cold. Direct heat should not be applied to cylinders of chlorine, nor should hot water be poured over them or come in contact with the cylinder valve.
4. Adequate ventilation should be provided for all enclosures in which chlorine is being fed or stored.
5. All joints of tubing connecting chlorine cylinder and chlorinators should be kept absolutely tight and inspected frequently to insure tightness. Tubing should slope upward from the cylinder.

LEGAL REGULATIONS

In a number of states, the water used for humidification, even in industrial plants, is required to meet drinking water standards insofar as bacteriological quality is concerned. A ruling of the U. S. Department of Agriculture, Meat Inspection Division, prohibits the use of chromate in water used for air washing when the air later contacts foodstuffs.[27]

There is an ever growing consciousness on the part of public health officials, of the necessity for regulations to *protect* potable water supplies. Attesting this is an ordinance[28] now in effect in Detroit, Michigan, which stipulates in part:

"No physical connection shall be maintained between lines carrying city water and pipes, pumps, or tanks supplied from any other source. Where dual supplies are necessary or desired, lines carrying city water must be protected against back flow of polluted water by an *atmospheric gap*. Secondary supplies and emergency sources shall include: surface waters from rivers, lakes, ponds, lagoons, and reservoirs; well waters both deep and shallow; any supply of water which has been stored, held, or reserved after being used for industrial purposes; cooling water, or water which has in any way been treated, processed, or has been subjected or exposed to any contamination of a bacteriological or chemical nature; and water from any other source than the city supply."

The U. S. Public Health Service stipulates:

"Salts of barium, hexavalent chromium, heavy-metal glucosides, or other substances with deleterious physiological effects, shall not be allowed in the water supply system."

Table 7 .... Recommended Maximum Allowable Content in Water Supply*

Substance	Max. Concentration, ppm
Copper	3.0
Iron & Manganese (Total)	0.3
Magnesium	125.0
Zinc	15.0
Lead	0.1
Fluorine	1.0
Arsenic	0.05
Selenium	0.05
Phenols (Total)	0.001
Polyphosphate of Sodium	10.0
pH Value @ 25C	10.6

* U. S. Public Health Service.

The same agency recommends that the concentration of the substances listed be held below the values cited in Table 7. The Board of Directors of the American Water Works Association has accepted these values as standard for *all* public water supplies in the United States.[29] While their action is not binding, prudence dictates that no form of treatment should be used that will result in raising the concentration of the substances listed above the value cited.

Since virtually all of the permissible chemicals used for scale, slime, and corrosion control have deleterious physiological effects if taken internally in *relatively large doses*, they should always be carefully *proportioned*. To insure this, the Detroit ordinance stipulates that the chemical feeding device must have the following major characteristics:

"1. There shall be a visible means of checking the quantity of material being applied by the feeding device.
2. A water metering device, sealed to prevent tampering, shall be installed to measure the flow of water being treated.
3. The device shall be constructed so that in the event of back-flow or vacuums, the maximum amount of material that may be possibly back-siphoned from the device or any of its attachments or parts shall not exceed one fluid ounce.
4. Should there be a failure of the water metering device or the water supply, the feeding device shall automatically cease operating."

CHAPTER 56

WATER SERVICES

Sizing Cold Water Supply Piping, Procedure for Sizing Cold Water Systems, Cooling Water Piping, Estimating Heating Load and Storage Capacity, Methods of Heating Water, Direct-Fired, Electric, and Indirect Water Heaters, Computing Heat Transfer Surface, Hot Water Supply Piping, Control of Service Water Temperature, Safety Devices, Solar Water Heaters, Domestic Hot Water by Heat Pump

PROPER design of the water distributing system in a building is necessary in order that the various fixtures may function properly. The amount of either hot or cold water used in any building is variable, depending on the type of structure, usage, occupancy, and time of day. It is necessary to provide piping, water heating, and storage facilities of sufficient capacity to meet the peak demand without wasteful excess in either piping or equivalent cost.

SIZING COLD WATER SUPPLY PIPING

One of the important items that must be determined before any part of the water-piping system can be sized, is the probable rate of flow in any particular reach of piping. The rate of flow in the service line, risers, and main branches, however, will rarely be equal to the sum of the rates of flow of all connected fixtures. In fact, the probability that every fixture in a large group will be in use at the same time is so remote that it would be very poor engineering practice to design the piping to take care of such simultaneous flow.

The demand load in building water supply systems cannot be determined exactly and is not readily standardized. The two main problems to be considered are: (1) the satisfactory supply of water for a given fixture, and (2) the number of fixtures which may be assumed to be in use at the same time.

The minimum flow that will be satisfactory to the consumer depends greatly on the consumer, his standard of living, his professional needs, size of family, garden requirements, and similar factors. Depending on these factors, the per capita water consumption for domestic use usually varies between 20 and 80 gal per day. Experience indicates that the type of dwelling also has considerable influence on the water consumption.

In *apartment houses* the per capita daily water consumption is generally higher than in single-family houses. This is due to the use of a central metering system which is not conducive to the saving of water, and to the long hot water lines which cause high heat losses and an increase in the wasting of the cooled water. In designing water supply systems for apartment houses, a daily per capita water consumption of 50 gal may be considered a safe design figure.

Although a considerable number of *housing projects* have been developed throughout the United States, conclusive water consumption data have not yet been gathered. Nevertheless, it seems that the daily per capita water consumption in *housing projects* falls in between the consumption in apartment houses and that in single dwellings at the same geographical location. In general, a daily per capita water consumption of 40 gal can be used as a safe design figure for *housing projects*.

Table 1 gives the rate of flow desirable for many common types of fixtures, and the average pressure necessary to give this rate of flow. The pressure necessarily varies with fixture design, a much greater pressure being necessary with some fixtures to give the same rate of flow as in others. In general, the lower the quality of the faucet the greater will be the pressure required.

In estimating the load, the rate of flow is frequently computed in *fixture units*. One *fixture unit* is equivalent to 7.5 gal per min. Table 2 gives the demand weights in terms of fixture units for different plumbing fixtures under several conditions of service, and Fig. 1 gives the estimated demand in gallons per minute corresponding to any total number of *fixture units*. Fig. 2 shows an enlargement of Fig. 1 for a range up to 250 *fixture units*.

The estimated demand load for fixtures used intermittently on any supply pipe will be obtained by multiplying the number of each kind of fixture supplied through that pipe by its weight from Table 2, adding the products, and then referring to the appropriate curve of Figs. 1 or 2 to find the demand corresponding to the total fixture units. In using this method it should be noted that the demand for fixture or supply outlets other than those listed in the table of fixture units is not yet included in the estimate. The demands for outlets (such as hose connections, air-conditioning apparatus, etc.) which are likely to impose continuous demand during times of heavy use of the weighted fixtures, should be estimated separately and added to the demand for fixtures used intermittently, in order to estimate the total demand.

So far, the information presented makes possible the de-

Table 1.... Proper Flow and Pressure Required During Flow for Different Fixtures

Fixture	Flow Pressure[a]	Flow gpm
Ordinary basin faucet	8	3.0
Self-closing basin faucet	12	2.5
Sink faucet—$\frac{3}{8}$ in.	10	4.5
Sink faucet—$\frac{1}{2}$ in.	5	4.5
Bathtub faucet	5	6.0
Laundry tub cock—$\frac{1}{2}$ in.	5	5.0
Shower	12	5.0
Ball-cock for closet	15	3.0
Flush valve for closet	10–20	15–40[b]
Flush valve for urinal	15	15.0
Garden hose, 50 ft, and sill cock	30	5.0

[a] Flow pressure is the pressure in the pipe at the entrance to the particular fixture considered.
[b] Wide range due to variation in design and type of flush-valve closets.

termination of the *design rate of flow* in any particular section of piping. The next general step is to determine the *size* of piping.

As water flows through a pipe, the pressure continually decreases along the pipe, due to loss of energy from friction. The problem is then one of ascertaining the minimum pressure in the street main, and the minimum pressure required for the operation of the topmost fixture. (A pressure of 15 psi is ample for flush valves, but reference should be made to the manufacturers' requirements. A minimum of 8 psi should be allowed for other fixtures.) The pressure differential thus obtained will be available for overcoming pressure losses in the distributing system, and in overcoming the difference in elevation between the water main and the highest fixture.

The pressure loss, in pounds per square inch, caused by the difference in elevation between the street main and the highest fixture, may be obtained by multiplying the difference in elevation in feet by the conversion factor 0.43.

When water flows through a pipe, friction occurs as the result of the sliding of water particles past one another. If the pipe wall is rough, the roughness projections cause additional friction, owing to the development of increased turbulence in the flowing water. As the water flows along a uniform pipe, the pressure decreases as a result of a dissipation of energy arising from the internal friction set up by viscosity of the water. This loss in energy is shown by the loss of pressure. The pressure loss is proportional to the length of straight uniform pipes, and varies greatly with flow velocity, pipe diameter, roughness of pipe, and water temperature.

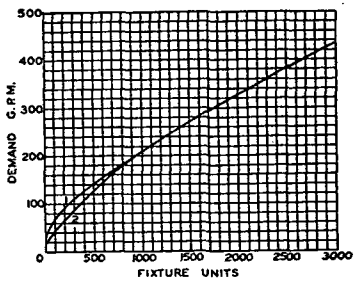

Table 2.... Demand Weights of Fixtures in Fixture Units[a]

Fixture or Group[b]	Occupancy	Type of Supply Control	Weight in Fixture Units[c]
Water closet	Public	Flush valve	10
Water closet	Public	Flush tank	5
Pedestal urinal	Public	Flush valve	10
Stall or wall urinal	Public	Flush valve	5
Stall or wall urinal	Public	Flush tank	3
Lavatory	Public	Faucet	2
Bathtub	Public	Faucet	4
Shower head	Public	Mixing valve	4
Service sink	Office, etc.	Faucet	3
Kitchen sink	*Hotel or restaurant*	Faucet	4
Water closet	Private	Flush valve	6
Water closet	Private	Flush tank	3
Lavatory	Private	Faucet	1
Bathtub	Private	Faucet	2
Shower head	Private	Mixing valve	2
Bathroom group	Private	Flush valve for closet	8
Bathroom group	Private	Flush tank for closet	6
Separate shower	Private	Mixing valve	2
Kitchen sink	Private	Faucet	2
Laundry trays (1–3)	Private	Faucet	3
Combination fixture	Private	Faucet	3

[a] For supply outlets likely to impose continuous demands, estimate continuous supply separately and add to total demand for fixtures.

[b] For fixtures not listed, weights may be assumed by comparing the fixture to a listed one using water in similar quantities and at similar rates.

[c] The given weights are for total demand. For fixtures with both hot and cold water supplies, the weights for maximum separate demands may be taken as ¾ the listed demand for the supply.

No. 1 for system predominantly for flush valves.
No. 2 for system predominantly for flush tanks.

Fig. 1.... Estimate Curves for Demand Load

On the basis of inside surface conditions, pipes may be classified as smooth, fairly rough, and rough, as follows:

Smooth. The pipe surface shows no perceptible roughness. *Pipes made of copper, brass, or lead may usually be classified as smooth.*

Fairly Rough. All ordinary pipes, such as wrought iron, galvanized iron, steel, and cast iron, after a few years of usage, may be called fairly rough.

Rough. Pipes that have deteriorated fairly rapidly for some *10 or 15 years after being laid, are classified as rough.*

Figs. 3, 4, and 5 give the pipe friction losses corresponding to these three types of pipes for various nominal diameters for a water temperature of 50 F.[1] *Example 1* will illustrate the use of the charts.

Example 1: A 2½-in. fairly rough pipe supplies 100 gpm of water. Find the friction loss in head if the pipe length is 200 ft.

Solution: Enter Fig. 4 at 100 gpm, and move along this line until it intersects the 2½-in. diameter line. From this intersection point, move vertically down and read 4.5 psi friction loss per 100 ft of pipe length. Then the *total friction* loss will be $2 \times 4.5 = 9$ psi.

The pressure losses in the distributing system will consist of the pressure losses in the piping itself, plus the pressure losses in the pipe fittings, valves, and the water meter, if any. Approximate design pressure losses for disc-type meters for various rates of flow are given in Fig. 6. Flow limits for disc-type meters, which may be regarded as the limits of recommended ranges in capacities, are given in Table 3. Manufacturers should be consulted for data on exact pressure losses and capacities since these vary for meters of different internal design.

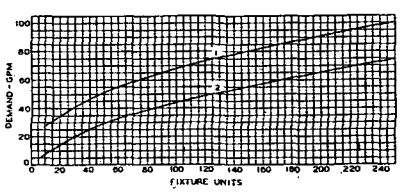

Fig. 2.... Section of Fig. 1 on Enlarged Scale

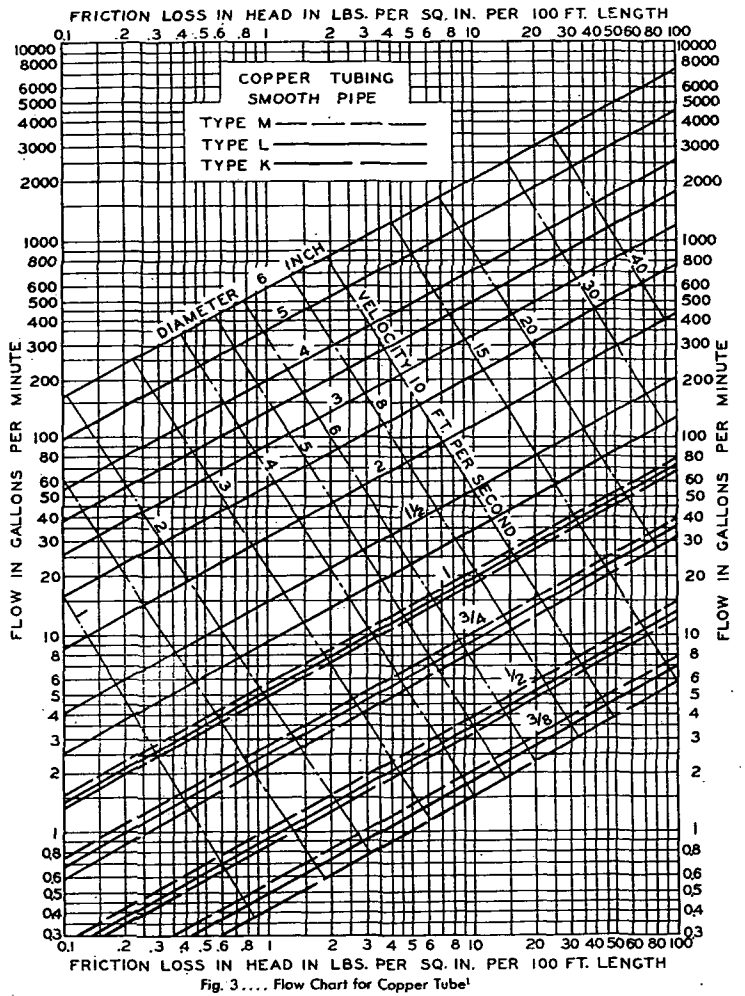

Fig. 3.... Flow Chart for Copper Tube[1]

Fig. 7 shows the variation of pressure loss with rate of flow for various types of faucets and cocks, based on experimental data obtained at the State University of Iowa.

The loss of pressure through any fitting or valve can be expressed in pounds per square inch for any given rate of flow. Experience has shown, however, that the simplest method of expressing losses in fittings and valves is to use the concept of an equivalent length of straight pipe. Thus it has

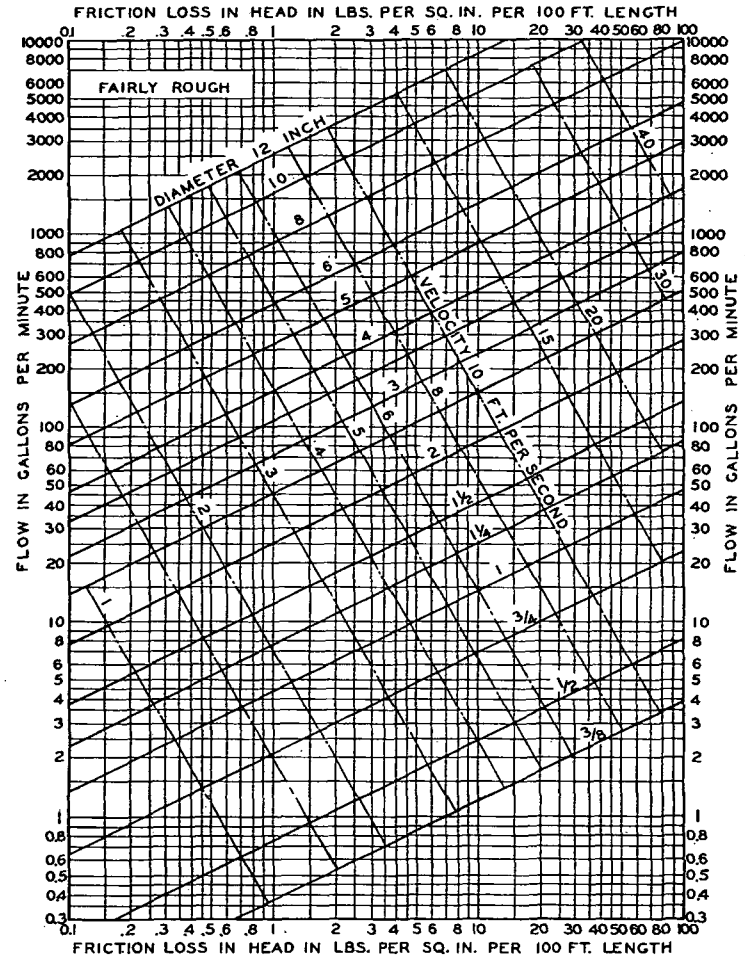

Fig. 4 .... Flow Chart for Fairly Rough Pipe[1]

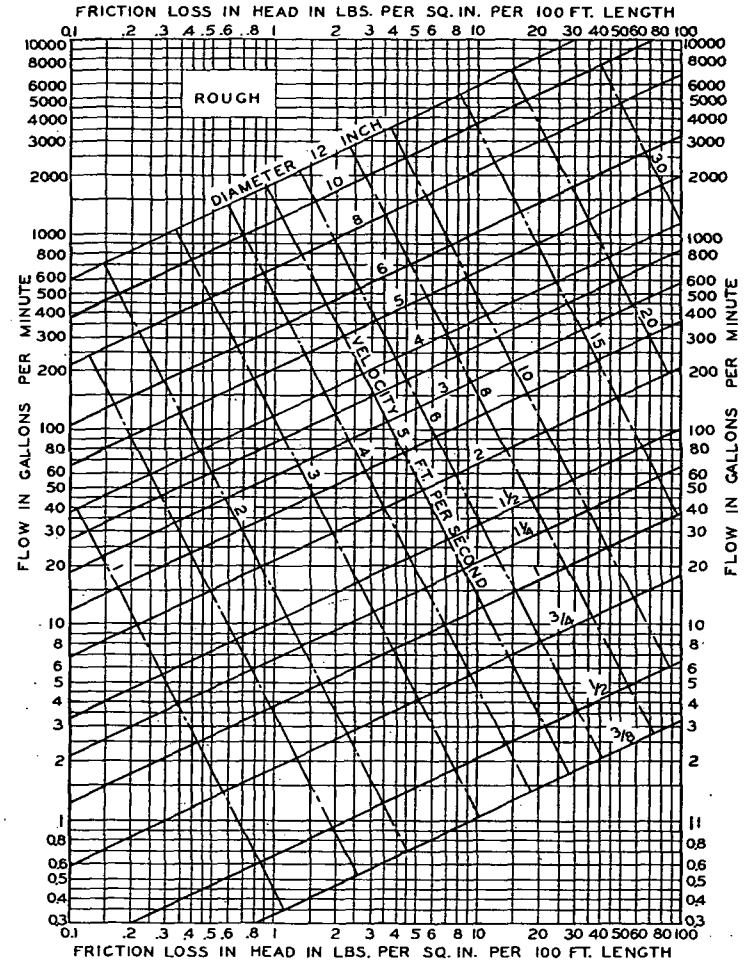
been found, for example, that a 1-in., 90-deg elbow introduces a loss equivalent to 2.2 ft of straight 1-in. pipe. Therefore, for each 1-in., 90-deg elbow, 2.2 ft of 1-in. pipe are added to the total length of 1-in. pipe.

Estimated pressure losses for pipe fittings and valves in terms of equivalent pipe length are shown in Table 4.

Table 5 lists the equivalent lengths for various special types of apparatus and fittings. The loss in water meters varies considerably with the design even in meters of the same nominal size. The values given in Table 5 are ample for the well-known meters now on the market.

The water demand for hose bibbs or other large demand



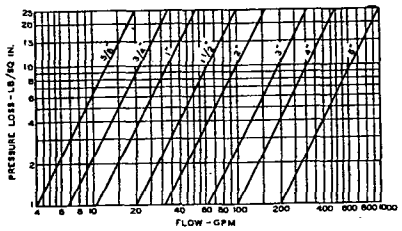


Fig. 5 .... Flow Chart for Rough Pipe[1]

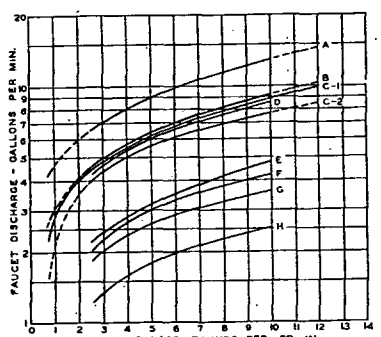
fixtures taken off the building main is frequently the cause of inadequate water supply to the upper floor of a building. This condition may be prevented by sizing the distribution system so that the pressure drops from the street main to all fixtures are the same. It is good practice to maintain the building main of ample size (not less than 1 in. where possible) until all branches to hose bibbs have been connected. Where the street main pressure is excessive and a pressure reducing valve is used to prevent water hammer or excessive pressure at the fixtures, it is frequently desirable to connect hose bibbs ahead of the reducing valve.

The principles involved in sizing either up-feed or down-

(See manufacturer's data for exact value for meter used)

Fig. 6 .... Pressure Losses in Water Meters

feed systems are the same. The principal difference in procedure is that in the down-feed system, the difference in elevation between the house tank and the fixtures provides the pressure required to overcome pipe friction.



Procedure for Sizing Cold Water Systems

The recommended procedure for sizing piping systems is outlined in following paragraphs 1 to 6, inclusive.

1. Draw a sketch of the main lines, risers, and branches, and indicate the fixtures to be served. *Indicate the rate of flow of each fixture.*

2. Using Table 2, compute the demand weights of the fixtures in fixture units.

3. Determine the total demand in fixture units and, using Fig. 1 or Fig. 2, find the expected demand in gallons per minute.

A. ½-in. laundry bibb (old style).
B. Laundry compression faucet.
C-1. ½-in. compression sink faucet (Mfr. 1).
C-2. ½-in. compression sink faucet (Mfr. 2).
D. Combination compression bathtub faucets (both open).
E. Combination compression sink faucet.
F. Basin faucet.
G. Spring self-closing faucet.
H. Slow self-closing faucet.
(Dashed lines indicate recommended extrapolation)

Fig. 7 .... Variation of Pressure Loss with Rate of Flow for Various Faucets and Cocks

Table 3 .... Performance Requirements of Water Meters[a]

Size, In.	Normal Test-Flow Limits, Gpm	Minimum Test-Flow, Gpm
⅝	1 to 20	¼
¾	2 to 34	½
1	3 to 53	¾
1½	5 to 100	1½
2	8 to 160	2
3	16 to 315	4
4	28 to 500	7
6	48 to 1,000	12

[a] *American Water Works Association Standards:*
Registration. The registration on the meter dial shall indicate the quantity recorded to be not less than 98 percent nor more than 102 percent of the water actually passed through the meter while it is being tested at *rates of flow* within the specified limits herein under normal test flow limits: There shall be not less than 90 percent of the actual flow recorded when a test is made at the rate of flow set forth under minimum test flow.

4. Determine the equivalent length of pipe in the main lines, risers, and branches. Since the sizes of the pipes are not known, the exact equivalent length for various fittings, *etc.*, cannot be made. Add the equivalent lengths, starting at the street main and proceeding along the service line, the main line in the *building, and up the riser to the top* fixture of the group served.

5. Determine the average minimum pressure in the street main and the minimum pressure required for the operation of the topmost fixture. This latter pressure should be 8 to 15 psi.

6. Calculate, by means of Equation 1, the approximate design value of the average pressure drop per 100 ft of pipe in the equivalent length determined in paragraph 4.

$$p = [P - 0.43H - 10]\frac{100}{L} \qquad (1)$$

where

p = average pressure loss per 100 ft of equivalent length of pipe, psi.
P = pressure in street main, psig.
H = height of highest fixture above street main, feet.
L = equivalent length determined in paragraph 4, feet.

If the system is of the down-feed supply from a gravity tank, the height of water in the tank, converted to pounds per square

Table 5 .... Equivalent Lengths of Iron Pipe to Give Same Loss as Special Fittings and Apparatus

Fitting Apparatus	Nominal Diameter of Pipe—Inches: ½	¾	1	1¼
30-gal Vertical hot water tank, ¾-in. pipe	4	17	56	—
30-gal Horizontal hot water tank, ¾-in. pipe	1.2	5	16	—
Water meters (No valves included)				
⅝ in. with ½-in. connections	6.7	28	90	—
⅝ in. with ¾-in. connections	4.8	20	64	—
¾ in. with ¾-in. connections	3.4	14	45	—
1 in. with 1-in. connections	—	9	30	115
1¼ in. with 1-in. connections	—	4.4	14	54
Water softener	—	50–200	—	—

inch by multiplying by 0.43, replaces the street main pressure, and the term 0.43 H in Equation 1 is added instead of subtracted in calculating the term p. In this case, H will be the vertical distance of the fixture below the bottom of the tank.

7. From the expected rate of flow, determined as in paragraph 3, and the value of p, calculated as in paragraph 6, choose the sizes of pipe from Figs. 3, 4, or 5.

Example 2: Assume a minimum street main pressure of 55 psig; a height of topmost fixture above street main of 50 ft; a developed pipe length from water main to highest fixture of 100 ft; a total load on the system of 50 fixture units; and that the water closets are flush-valve operated. Find the required size of supply main.

Solution: From Fig. 2 the estimated peak demand is found to be 51 gpm. From Table 3 it is evident that several sizes of meters would adequately measure this flow. For a trial computation choose the 1½-in. meter. From Fig. 6 the pressure drop through a 1½-in. disc-type meter for a flow of 51 gpm is found to be 6.5 psi.

Then the pressure drop available for overcoming friction in pipes and fittings is $55 - (15 + 50 \times 0.43 + 6.5) = 12$ psi.

At this point it is necessary to make some estimate of the equivalent pipe length of the fittings on the direct line from the street main to the highest fixture. The exact equivalent length of the various fittings cannot now be determined since the pipe sizes of the building main, riser, and branch leading to the highest fixture are not known as yet, but a first approximation is necessary in order to make a tentative selection of pipe sizes. If the computed pipe sizes differ from those used in determining the equivalent length of pipe fittings, a recalculation will be necessary, using the computed pipe sizes for the fittings. For the purposes of this example assume that the total equivalent length of the pipe fittings is 50 ft.

Then the permissible pressure loss per 100 ft of equivalent pipe is $12 \times 100/(100 + 50) = 8$ psi.

Assuming that the corrosive and caking properties of the water are such that Fig. 4 for fairly rough pipe is applicable, a 2-in. building main will be adequate.

Table 6 .... Computation of Branch Size in Example 2

Fixtures No. and Kind	Fixture Units (From Table 2 and Note c)	Demand (From Fig. 2) Gpm	Pipe Size (From Fig. 4) In.
3 flush valves	3 x 6 = 18		
2 bathtubs	¾ (2 x 2) = 3		
3 lavatories	¾ (3 x 1) = 2.25		
Total	23.25	38	1½

Table 7 .... Pipe Sizes for Cooling Towers[a]

Rated Tons of Refrig.	Cooling Water Gpm	Pipe Sizes (Nominal Inches): Inlet to Tower	Outlet from Tower
3 to 5	10 to 18	1½	1½
7 to 15	20 to 45	2	2
20	65	2½	3
25	86	2½	4
35	115	3	4
50	170	3	4
75	225	5	6
100	300	5	6
150	450	5	8
200	600	6	8
250	750	8	8

The sizing of the *branches* of the building main, the *risers*, and *fixture branches* follows the principles outlined. For example, assume that one of the branches of the building main carries the cold water supply for 3 water closets, 2 bathtubs, and 3 lavatories. Using the permissible pressure loss of 8 psi per 100 ft, the size of branch determined from Table 2 and Figs. 1 and 4 is found to be 1½ in. Items entering the computation of pipe size are given in Table 6.

COOLING WATER PIPING

Water is very frequently used in refrigeration systems, cooling towers, and other similar installations. In designing the piping system of such installations, the principles of hydraulics, as already outlined, are employed. Nevertheless, there are several practical items having particular application to cooling installations which are outlined in the following paragraphs. It is important that the designer be familiar with them.

In choosing pipe material, the problem of corrosion should be kept in mind to prevent failure of the system. If the water is not severely corrosive, wrought-iron or steel piping may be used; otherwise, galvanized-steel piping may be preferred. If sea water is used as the circulating medium, it is advisable to use alloys such as admiralty metal in pipe and tubing. In refrigeration condensers where water is the cooling medium, iron pipe is commonly employed.

In regard to assembly, cast-iron flanges or welded joints are to be preferred to screwed joints wherever possible.

Valves used in circulating systems may be of the globe, gate, or angle types. If water is the circulating medium, brass valves are usually used. However, if the circulating medium is an electrolyte, such as brine, then it is preferable to use valves made of the same material as the piping itself.

The friction loss in the piping may be determined from Fig. 4 for fairly rough pipe. If the coolant is brine, a correction for the proper density must be made. Experience indicates that in sizing piping for cooling systems, a pressure drop of the order of 2 to 3 psi per 100 ft of pipe length, and a fluid velocity of 3 to 8 fps, yield most economical results.

In the case of cooling towers, the amount of circulating water is about 3 gpm per ton of refrigeration, when based on a design wet-bulb temperature of about 76 F. Table 7 gives pipe sizes frequently used for various sizes of cooling towers, assuming a hot water temperature of 95 F and a cold water temperature of 85 F.[2]

ESTIMATING HEATING LOAD AND STORAGE CAPACITY

The maximum daily and the maximum hourly hot water demand form the basis for the selection of the heater and the storage tank.

In general, two-thirds of the total daily water consumption is hot water. For residential dwellings, a design value of about 20 to 30 gal per (person) (day) may be assumed, but it should be remembered that the hot water used will depend on the number of rooms and the number of bathrooms in any house or apartment. Table 8 gives estimates of the maximum hot water requirements in 24 hr in various types of buildings.

In estimating the size of hot water storage tank required, and the heating capacity to be provided, either from the boiler or from an independent domestic hot water heater, it is necessary to know the total quantity of water to be heated per day, and the maximum amount which will be used in any one hour, as well as the duration of the peak load.

In cases where the requirements for hot water are reasonably uniform, as in residences, apartment buildings, hotels, and the like, smaller storage capacity is required than in the case of factories, schools, and office buildings, where practically the entire day's usage of hot water occurs during a very short period. Correspondingly, the heating capacity must be proportionately greater with uniform usage of hot water than with intermittent usage, where there may be several hours between peak demands during which the water in the storage tank can be brought up to temperature. As a general rule, it is desirable to have a large storage capacity in order that the heating capacity, and consequently the size of the heater, or the load on the heating boiler, may be as small as possible.

Table 9.... Estimated Hot Water Demand Characteristics for Various Types of Buildings

Type of Building	Hot Water Required Per Person	Max. Hourly Demand in Relation to Day's Use	Duration of Peak Load Hours	Storage Capacity in Relation to Day's Use	Heating Capacity in Relation to Day's Use
Residences, apartments, hotels, etc.	40 gal per day[a]	1/7	4	1/5	1/7
Office buildings	2 gal per day[a]	1/5	2	1/5	1/6
Factory buildings	5 gal per day[a]	1/3	1	2/5	1/8
Restaurants				1/10	1/10
Restaurants 3 meals/day		1/10	8	1/5	1/10
Restaurants 1 meal/day		1/5	2	2/5	1/6

[a] At 140 F.

In estimating the hot water which can be drawn from a storage tank, it should be borne in mind that only about 75 percent of the volume of the tank is available, since, by the time this quantity has been drawn off, the incoming cold water has cooled the remainder down to a point where it can no longer be considered hot water.

Where steam from the heating boiler is used to heat domestic hot water, the computed load on the boiler should be increased by 4 sq ft EDR (equivalent direct radiation) for every gallon of water per hour heated through a 100 deg rise. The actual requirement is $(100 \times 8.33)/240 = 3.48$ sq ft per gal heated 100 deg. The value of 4 allows for transmission losses.

There are two methods in common use for estimating the hot water requirements of a building: (1) by the number of people, and (2) by the number of plumbing fixtures installed. Where the number of people to be served can be reasonably estimated, the data in Table 9 may be used.

Example 3: Determine the heater size and storage tank capacity for a residence housing five people.

Solution: From Table 9, a residence housing five people would have a daily requirement of $5 \times 40 = 200$ gal per day, and a maximum hourly demand of $200 \times 1/7 = 28.5$ gal. The heater should have a storage capacity of $200 \times 1/5 = 40$ gal, and a heating capacity of $200 \times 1/7 = 28.5$ gal per hr.

The conditions given in *Example 3* may be cited as average. It is possible to vary the storage and heating capacity by increasing and decreasing one over the other. Such a condition is illustrated in *Example 4*.

Example 4: Determine the required heater capacity for an apartment housing 200 people, if the storage tank has a capacity of 1000 gal. What heater capacity will be required if the storage tank is changed to 2500 gal capacity?

Solution: Assume an apartment house housing 200 people. From the data in Table 9: Daily requirements $= 200 \times 40 = 8000$ gal. Maximum hours demand $= 8000 \times 1/7 = 1140$ gal.

Duration of peak load = 4 hr. Water required for 4-hr peak $= 4 \times 1140 = 4560$.

If a 1000-gal storage tank is used, hot water available from the tank $= 1000 \times 0.75 = 750$. Water to be heated in 4 hr $= 4560 - 750 = 3710$ gal. Heating capacity per hour $= 3710/4 = 930$ gal.

If instead of a 1000-gal tank, a 2500-gal tank had been installed, the required heating capacity per hour would be $[4560 - (2500 \times 0.75)]/4 = 671$ gal.

Table 10 may be used to determine the size of water heating equipment from the number of fixtures. To obtain the *probable maximum demand*, multiply the total quantity for the fixtures by the *demand factor* in line 11. The heater or coil should have a water heating capacity equal to this *probable maximum demand*. The storage tank should have a capacity equal to the *probable maximum demand* multiplied by the storage capacity factor in line 12. *Example 5* will illustrate the procedure.

Example 5: Determination of heater and storage tank size for an apartment building from number of fixtures.

60 lavatories	× 2 =	120 gal per hr
30 bathtubs	× 20 =	600 gal per hr
30 showers	× 75 =	2250 gal per hr
60 kitchen sinks	× 10 =	600 gal per hr
15 laundry tubs	× 20 =	300 gal per hr
Possible maximum demand	=	3870 gal per hr
Probable maximum demand	=	3870 × 0.30
	=	1161 gal per hr
Heater or coil capacity	=	1161 gal per hr
Storage tank capacity	=	1161 × 1.25
	=	1450 gal

Although, in private dwellings a water temperature of 140 F is reasonable for dishwashing, in public places sanitation regulations call for 180 F water. Most of the dishwashing machines now available on the market require 180 F water. The amount of 180 F water needed in restaurants per day may be determined according to the method outlined by the American Gas Association,[a] in the following paragraphs:

1. Multiply the number of meals per day by the number of dishes per meal (6 for low-price restaurants, 8 for medium-price restaurants, and 10 for high-price restaurants) to determine the total number of dishes per day.

2. Divide the total number of dishes per day, as determined by method in paragraph 1, by the average number of dishes per rack to find the number of racks per day.

3. Multiply the number of racks per day by the gallons of 180 F water (using 1.5 for single tank machines and 0.75 for two tank machines). This product will give the gallons of 180 F water per day for rinse sprays.

4. Multiply the number of meal periods per day (one, two, or three) by the dishwashing tank capacity in gallons, giving the gallons of 180 F water per day necessary to fill the tanks.

5. Add values from paragraphs 3 and 4 to obtain the total number of gallons of 180 F water required per day.

For purposes other than dishwashing, a considerable amount of 140 F water is also used. To find the daily 140 F water requirement in a restaurant, multiply the total number of meals served per day by the gallons of 140 F water per meal. Low priced restaurants on the average utilize 0.9 gal of 140 F water per meal, while medium- and high-price restaurants use 1.2 and 1.5 gal per meal, respectively.[a]

METHODS OF HEATING WATER

Hot water may be heated either by the direct combustion of fuel, by an intermediate carrier such as steam or hot water, or by electrically heated surfaces. The simplest method is to have the fire on one side of a metal barrier and water on the other. In such a method, if the surfaces for transferring heat are small, and if the water carries a heavy proportion of precipitable salts, the water passages may soon become clogged with resultant cracking or burning of the surface. A familiar example of such trouble is the water back in the kitchen stove, or the pipe coil inserted into the firebox of a warm air furnace or small boiler. The critical water tem-

perature at which the lime, magnesia, etc., collect on hot surfaces, varies with the character and proportions of the solids, but generally such deposits are not a serious trouble below 140 F.

Direct-Fired Water Heaters

Coal-burning, direct-fired water heaters may be constructed of cored cast-iron sections, or of steel. In some cases the external appearance of the cast-iron sections is the same as in heating boilers, but internally the cores are changed to enable the sections to withstand the city water pressure. In small capacity water heaters, efficiency is not considered so important as low first cost and ability to maintain a fire at a low rate of combustion, and consequently, such heaters are generally built with a *dry* section or firebrick lining at the base of the firepot to prevent too much chilling of the fuel. While mud and scale will eventually clog the waterways of any direct-fired heater, increased life may be obtained by providing a three-way cock in the return line between the heater and the bottom of the storage tank, so that water can be blown through the heater or the tank separately, at full line pressure, to clean out loose sediment. Cleanout openings in the bottom of the heater are advantageous, if used by operators of water heaters for periodic cleaning out of sediment.

Oil-burning, direct-fired water heaters usually are of steel, and operate with higher flame temperature and better efficiency than commensurate sized coal-burning heaters. As they have the same tendency as coal boilers to accumulate lime deposits, the water passages should be large in cross-section and accessible for periodic cleaning.

Gas-burning, direct-fired water heaters may be of the instantaneous or storage type. Instantaneous heaters are generally constructed of spiral water tubes of copper, around which the products of combustion circulate upward from high capacity burners. Storage-type heaters may include in one unit an insulated storage tank, a combustion chamber, flues, burner equipment, and controls, or may consist of a separate storage tank and external direct-fired water heater, which may be a so-called *side-arm* heater for small capacity, or a gas-fired boiler for larger capacity. Gas boilers used for direct hot water supply must be able to withstand the city water operating pressure. While direct-fired gas heaters are used generally for residences and small installations of 100 gal storage capacity or less, indirect heaters are recommended for larger installations.

Chimney connections for all direct-fired, fuel-burning water heaters are an important consideration. Refer to Chapter 36.

Electric Water Heaters

Electric water heaters for hot water service in residences and commercial buildings are predominantly of the automatic storage type. These generally have a cylindrical tank mounted vertically, with a primary electric heating element or resistor near the bottom and a secondary unit located within the upper one-quarter of the tank. Water heaters of single-heating-unit type have an element only at the bottom. The first cost of automatic electric heaters is somewhat higher than that of fuel-fired types, owing to the need for larger tank storage to compensate for the limitation of recovery rate, since for economical electric service the connected load should be kept low. Large tank capacity is necessary also with off-peak operation, where there are low electric rates for this class of service.

Table 11 .... Standard Rated Capacities of Electric Water Heaters

Tank Size Gallons		Rated Input, Watts		
		Two-Unit Heater		Single-Unit Heater
Nominal	Range	Primary	Secondary	
30	30 to 35	600	1000	1500
40	35 to 45	750	1250	2000
52	45 to 55	1000	1500	2500
66	55 to 70	1250	2000	3000
80	70 to 90	1500	2500	4000
110	90 to 115	2000	3000	
120	115 to 135	2500	4000	
140	135 to 175	3000	4000	

Instantaneous heaters are used in special cases only, because of the high electric power input required, for example, 15 kw to deliver 1 gpm with 100 deg temperature rise.

Capacities of household automatic storage-type water heaters, as partially standardized within the electrical industry, range from 30 to 140 gal nominal tank capacity with input 1600 to 7000 watts. Wattage input ratings of two-unit heaters are based on approximately 30 watts per gallon of tank capacity for the secondary unit and 20 watts for the primary unit. Single-unit heaters have tank sizes up to 80 gal with an input of 4000 watts, the ratings being based on 50 watts per gallon. The schedule of heater capacities shown in *ASA Standard* C72.1-1949 is reproduced in Table 11.

The wattages listed in Table 11 are minimum recommended values for continuous service. Some departure from the standardized watts-per-gallon ratios is to be expected, as experience indicates that increased hot water use with automatic laundry machines and dishwashers may call for larger heating units than have heretofore been found desirable. With off-peak operation the watts-per-gallon ratio likewise must be raised.

Rated voltage for water heaters is 240 volts, with a range 220 volts minimum to 248 volts maximum, but specified test performance is required to be met only at the 236 volts taken as normal design voltage. Thermostats controlling the heating units are normally set for 150 F, with upper limit of adjustment range of 170 to 180 F.

Heating units are of three general types, all of which give approximately the same service efficiency if selected to suit the operating conditions, as follows:

1. Immersion element, inserted horizontally through a threaded or flanged opening in side of tank.
2. Strap-on unit, externally mounted directly against the tank shell and held in close contact by a band or strap encircling the tank.
3. Side-arm or *outside circulation* unit, consisting of a vertical cylindrical housing or heat exchanger which contains an immersion heating element, connected by pipes into top and bottom of the storage tank.

For the third type, which is less commonly used, thermostats separate from the heating units are mounted within the storage tank.

A fourth type of heater, applied only in exceptional cases and for large installations with alternating current, employs the water itself as a resistor in which electrodes are immersed. Close temperature regulation and compensation for the effect of variable amount and composition of solids and gases in the water are difficult to obtain with small unattended heaters of this kind. The electrode type of construction has in the past been used also for generating steam in so-called electric boilers, mainly for industrial plants; however, in only few instances today is electric energy obtainable at cost low enough to make it competitive with fuel-fired boilers for steam production.

Tanks of electric heaters are regularly constructed to withstand a 300 psig hydrostatic test pressure and are rated for a safe working pressure of 127.5 psig. Materials in contact with the water are selected to resist corrosion caused by solid and gaseous impurities occurring in some locations. It may be desirable also to provide *sacrificial metal* anodes of magnesium, zinc, or alloys to protect the tank and its piping connections. A safety relief valve of pressure-actuated type must be included; it may optionally be actuated also by internal temperature. A heat trap at the hot water outlet, if not provided by manufacturer within or outside the tank shell and inside the insulated jacket, may be placed in the external piping. The trap consists of vertical pipe at least 6 in. long having downward flow, to retard circulation of hot water within the distribution piping system under standby conditions.

Occasionally, an uninsulated tempering tank is installed ahead of an electric water heater, enabling the cold inlet water to absorb heat from the basement or room air—if conditions are such that objectionable sweating does not occur. The practice of connecting a tempering tank with a firebox coil, so that the electric heater furnishes heat only when there is deficiency from the boiler or furnace, is not recommended.

Delivery performance efficiency of heaters meeting the electrical-industry standard 24-hour operation test is 90 percent minimum, which allows 10 percent for thermal loss through the jacket insulation. In service, the quantity of water withdrawn from an automatic storage heater has considerable influence on overall efficiency. With increasing quantities, service efficiency rises and approaches the upper limit fixed solely by the jacket thermal loss; on the other hand, if little or no water is drawn, efficiency approaches zero since no useful work is done. Hence oversizing a water heater by having too large a tank impairs the service efficiency. Excessive heating-unit wattage causes undesirably high electric demand. Undersizing of heaters obviously results in inadequate and unsatisfactory hot water service.

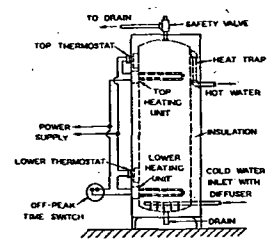

Fig. 8 .... Domestic Hot Water Heater for Off-Peak Service

Selection of electric heater capacity for residences is made by reference to rating tables which take into account the number of occupants, number of bathrooms or plumbing fixtures, and presence of appliances such as laundry equipment, dishwashers, and the like. Information of this kind is given in Tables 2, 8, 9 and 10 and in design manuals issued by the electric utility industry and by heater manufacturers. For commercial applications, the hourly hot water requirements must be analyzed and the best combination of tank capacity and heating element rating determined, with due consideration of electric power demand created in relation to the user's other electric demands.

A common type of electric service for water heating is the *off-peak* service under which the charge for energy consumed during designated hours is lower than for normal or unrestricted service. With this system, the operation of heaters is confined to such hourly intervals during the 24 hours as will (*a*) avoid creating peak electrical demands by the customer in excess of the demand resulting from the customer's other uses of electricity, or (*b*) keep the water heating load off the electric utility system during peak hours. In general, Case (*a*) occurs where rate schedules contain a demand charge component, and Case (*b*) where a special low rate applies to off-peak consumption. Water heater circuits are controlled with relays actuated by an electric-clock mechanism or by a *carrier-current* impulse impressed at suitable intervals on the electric distribution system, or by an automatic load-limiting type of control.

For general information on automatic control see Chapter 43.

One arrangement of domestic hot water heater for off-peak service, shown in Fig. 8, has the lower heating unit under control of an off-peak switch. Upper unit is connected directly to the line, so that if the reserve of hot water becomes depleted, the top thermostat brings its heating unit into operation only until the upper portion (usually about 25 percent) of tank contents reaches the thermostat temperature setting.

Indirect Water Heaters

In the indirect method, either steam or hot water is used for heating the water. With steam, the water to be heated is preferably circulated around the outside of the steam tubes which are submerged within a tank. A typical indirect heater using steam is shown in Fig. 9. The coils usually are of copper, and are U-shaped to permit expansion and contraction. The shell may be of steel, with a protective coating or with a special inside protective lining, or may be of copper or copper alloy. Where straight heating tubes are used, one end of the tube is usually expanded into a *floating* head to take

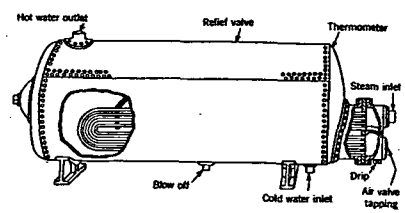

Fig. 9 .... Indirect Water Heater

care of expansion. The coils should be capable of easy withdrawal for inspection and for removal of scale. Instead of steam, the heating medium may also be hot water inside the tubes.

Another method of transferring heat from a heating boiler to the domestic water is illustrated in Fig. 10. The water heater is generally a cast-iron shell within which there is located a spiral copper coil. Hot water from the boiler circulates inside the shell and around the coil, and returns to the boiler, while domestic water from the storage tank circulates inside the coil. The storage tank should be installed with the

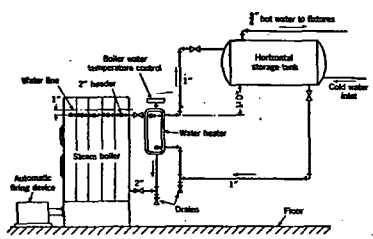

Fig. 10 .... Indirect Water Heater Mounted on Side of Boiler

bottom of the tank as far above the boiler as possible. Horizontal storage tanks of less than 18- or 20-in. diameter are not recommended because of the difficulty of preventing the hot and cold water from mixing, especially when large quantities of water are withdrawn. In Fig. 11 the heat-transfer surface is placed inside the boiler instead of in a separate vessel, but otherwise the operation is similar to that of Fig. 10. This arrangement with vertical tank is commonly used for small domestic installations.

Sometimes the heating element is located inside of the larger-type fire tube boilers and small residential boilers. In this case the heat-transfer surface is in the form of a number of straight copper tubes, with rear U-bends or a floating head, inserted through a special opening in the boiler. While the coil may be placed in the stream space above the waterline of a steam boiler, it is usually placed below the waterline. Long coils of small diameter tubing, immersed in the water, are widely used without storage tanks. The rate of flow through the coil is limited by the friction loss in the coil, and by fittings and restrictions, so that the water attains the desired temperature in one passage through the coil. This arrangement is frequently found in oil burner installations where the heating boiler, either steam or hot water type, is used to supply hot water during the summer. A thermostatic three-way mixing valve is frequently used to maintain a uniform temperature of the hot water supply to the plumbing fixtures.

In order to reduce clogging by precipitated solids, water heating plants sometimes develop steam in a closed circuit, transferring the heat through a tubular heater to the domestic water. The water in the primary heater, exposed to the high temperature of the fire, is repeatedly used and hence, has no appreciable tendency to deposit scale, while the domestic water, heated by steam at a much lower temperature than that of the fire, also exhibits a much reduced tendency to precipitate dissolved salts. Water characteristics, the effect of impurities, and means of improving the quality of the water are important items, as brought out in Chapter 55.

COMPUTING HEAT-TRANSFER SURFACE

The area of the inside surface of a heating coil may be determined from Equation 2.

$$A = \frac{Q \times 8.33(t_2 - t_1)}{U \times t_m} \qquad (2)$$

where

A = surface area of coil, square feet.
Q = quantity of water heated, gallons per hour.
t_2 = hot water outlet temperature, Fahrenheit.
t_1 = cold water inlet temperature, Fahrenheit.
U = coefficient of heat transmission, Btu per (hour) (square foot) (Fahrenheit degree logarithmic mean temperature difference).
For copper or brass coils U = 240 (steam) and 100 (hot water).
For iron coils U = 160 (steam) and 67 (hot water).

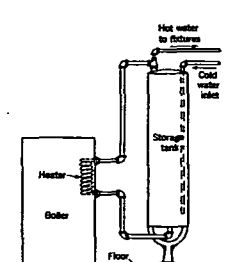

Fig. 11 .... Indirect Water Heater Placed in Boiler

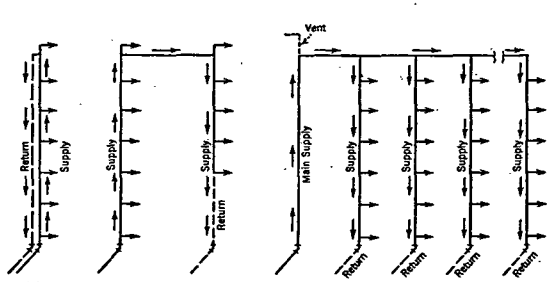

Fig. 12 .... Methods of Arranging Hot Water Circulation Lines

Table 12 .... Coefficient of Heat Transfer of Instantaneous Water Heaters

U = Btu per (hr) (sq ft) (Fahrenheit degree logarithmic mean temperature difference)

Boiler water temperature	210	200	180
U	225	175	150

t_m = logarithmic mean of the difference between the temperature of the heating medium and the average water temperature, and is *approximately*:

$$t_m = \left[\frac{(t_2 + t_1)}{2}\right]$$

t_t = temperature of the heating medium, Fahrenheit.

Equation 2 may be used to check the heating coil ratings under temperatures other than those stated in the manufacturer's published ratings.

Example 6: What area of copper transfer surface will be required to heat 70 gal of water per hour from 40 to 180 F with boiler water at 220 F?

Solution:

$$t_m = \left[220 - \frac{(180 + 40)}{2}\right] = 110$$

$$A = \frac{70 \times 8.33(180 - 40)}{100 \times 110} = 7.42 \text{ sq ft}$$

For instantaneous submerged heaters, the surface required will depend upon (1) the velocity of water in the tubes, (2) the boiler water temperature, (3) the inlet water temperature, (4) the outlet water temperature, (5) the cleanliness of the coil surface, and (6) the condition of the boiler water surrounding the coil. If the heater is located in the water of an actively steaming part of a boiler, the heat transfer may be twice as great as would be obtained if the water surrounding the coil were circulating slowly. Ratings of instantaneous water heating coils will therefore vary greatly, depending upon the assumptions made regarding the conditions of operation. The values of the coefficient of heat transmission for instantaneous heaters, shown in Table 12, are conservative.

For a coil in which heat is transferred from steam to water, the value of $U = 300\sqrt{v}$ may safely be used (v = velocity of water in feet per second).

The rate of heat transfer, between steam or water as the carrier, and the domestic water, is influenced by the rate of movement of both the carrier and the water which receives the heat. For this reason, where the transfer occurs from heating system water to domestic water, it is good practice to install a circulating pump to insure rapid movement of the boiler water.

In view of the high condensation rates obtained when steam is used with gravity circulation from the boiler, particularly when there is a sudden demand followed by an inflow of cold water, the bottom of a steam heat transfer element always should be at least 30 in. above the boiler water line, and the steam and condensate return pipes should be of liberal size. Otherwise, water hammer and reduced capacity may result, due to imperfect drainage of condensate.

When connecting a transfer-type hot water heater below the waterline of a cast-iron steam boiler having vertical sections, there should be a separate tapping for water circulation into every section of the boiler, as shown in Fig. 10, unless the boiler has large top nipple ports providing intersectional circulation. If the top nipples are entirely within the boiler steam space, no internal circulation occurs between sections. Steaming may then occur in the boiler sections not connected to the heater and, further, the unconnected sections will not deliver any heat to the water heater.

HOT WATER SUPPLY PIPING

It is common practice to provide circulating piping in all hot water supply systems in which it is desirable to have hot water available continuously at the fixtures. In average-sized and small residences and systems, in which the piping from the heater to the fixtures is short, return circulating piping is generally omitted in order to reduce installation cost, and to reduce heat loss from the piping, particularly during periods of no water demand.

The hot water supply may be distributed by either an up-feed or down-feed piping system. Three common methods of arranging the circulating lines are shown in Fig. 12. Although the diagrams apply to multi-story buildings, the arrangements (*a*) and (*b*) are sometimes used in residential designs.

A check valve should be provided in the runout from each return riser to prevent temporary reversal of flow in the piping when a faucet is open. Proper air venting of a circulating system is extremely important, particularly if gravity circulation is employed. In Fig. 12 (*a*) and (*b*), this is accomplished by connecting the circulating line below the top fixture supply. With this arrangement, air is eliminated from the system each time the top fixture is opened.

Where an overhead supply main is located above the highest fixture as in Fig. 12 (*c*), an automatic float-type air vent is installed at the highest point of the system, or a fixture branch is connected to the top of the main where air venting is desired, and then dropped to the fixture outlet.

It is sometimes necessary to make an allowance for pressure drop through the heater when sizing hot water lines, particularly where instantaneous hot water heaters are used and the available pressure is low.

The principles involved in the sizing of the hot water supply pipes are the same as those for the sizing of cold water supply lines. For small and medium sized installations a ¾-in. hot water return will be ample. For larger installations, the size of the hot water return may be computed from considerations of the heat losses in the hot water piping.[4] A throttling valve should be placed in the hot water return pipe so that the rate of circulation may be adjusted.

Where the hot water piping system is exceedingly long, a water circulator is frequently installed. It is controlled by an immersion thermostat (in the return line) set to start and stop the pump over approximately a 20 F deg temperature range. In calculating the pump capacity, the product of (1) the pounds of water circulated and (2) the temperature difference (usually 20 deg) between the flow and return, must be equivalent to the Btu heat loss from the piping at the average temperature of the water. Insulation reduces the heat loss and pump capacity required. The friction head against which the pump must operate may be calculated from the tables and charts in Chapter 28, Hot Water Heating Systems. The friction head seldom exceeds 6 to 10 feet.

Since service water is corrosive due to the high oxygen content and high temperature, circulating pumps should be made of bronze.

CONTROL OF SERVICE WATER TEMPERATURE

Coal-fired boilers are usually controlled by an immersion thermostat (located in the heated water) which opens or closes draft dampers at the boiler to adjust the rate of fuel combustion. With oil- or gas-fired boilers, the immersion thermostat controls the oil burner or the automatic gas valve. The gas pilot flame usually burns continuously. With electric heaters, the immersion thermostat operates a switch on the source of energy.

When steam or hot water is the medium for heating the water in the tank, an immersion thermostat is used to control a valve in the steam or hot water supply line. In small residence installations, using water as the carrier, a combined immersion thermostat and butterfly valve in one simple fitting may be installed in the transmitting circuit to prevent overheating of the service water.

In residences heated by pump-circulated hot water, the house temperature is controlled by operating the circulating pump intermittently, while domestic hot water is warmed by transfer from the house boiler, independent of the pump operation. The domestic water is heated from the heating boiler the year-round. Under such an arrangement, to prevent overheating the house by thermal circulation when the pump is not running, it is usual to insert a weighted check valve in the house heating main so that no circulation to the house heating system can occur unless the pump operates. In summer the fire may be controlled to maintain a boiler water temperature lower than when heating, and generally about 20 F warmer than that desired in the domestic hot water system.

The immersion thermostat in a hot water storage tank should be located no higher than the center of the tank, and possibly should be even closer to the bottom, since water in a tank stratifies proportionally to the temperature. When hot water is removed, the cold water entering to replace it quickly reduces the temperature in the lower parts of the tank.

For general information on automatic control see Chapter 43.

SAFETY DEVICES FOR HOT WATER SUPPLY SYSTEMS

There are still numerous plumbing codes which do not have regulations for the prevention of hot water storage tank explosions.

An ordinary storage tank is under certain water pressure, depending on the static pressure in the system. When the water in the tank is heated by circulation through an external heater, or by heating units in the tank, it gradually expands. For instance, if the entire contents of a 30-gal storage tank are heated from 70 F to 160 F, there will be an increase in volume of about one-half gallon. If the tank is connected to a supply line without any intervening check valve, the increase in volume causes part of the water to be pushed back into the supply line. If the hot water reaches the water meter, it may ruin the composition discs.

If back-flow cannot occur, as for example, due to the use of a check valve or a pressure-reduction valve in the line, or because of temporary shut-off of the cold water line, the pressure in the tank rises as heating continues. Such a pressure rise, if the heating continues for any length of time, may result in rupturing of the tank.

If the tank water is not confined, continued heating would, of course, cause no increase in pressure beyond ordinary line pressure. However, the temperature would continue to increase. If this should happen at elevated temperatures, the flashing of the water into steam might cause a serious tank explosion.

In order to guard against the development of excessive pressure inside a hot water storage tank (owing to the thermal expansion of the water), it is customary to install a spring-loaded pressure-relief valve which is set to open at a pressure about 20 psi higher than the normal line pressure.

The amount of water discharged by any pressure-relief device is usually quite small, since it takes only a small quantity of water to relieve any pressure rise due to the thermal expansion of the water. The rate of discharge should be such as to limit the pressure rise for any given heat input to 10 percent of the pressure at which the valve is set to open. For any given installation, the discharging capacity *should be in excess of the water to be discharged by the heater. The heater discharge* Q_m *in gallons per minute may* be computed by Equation 3:

$$Q_m = 0.00005b \quad (3)$$

where b is the heat input of heater in Btu per minute.

To prevent danger of overheating, temperature-relief devices should be used. One type of such a device has a fusible plug of metal which melts at about 212 F. The hot water then runs from the opening until the device is serviced. A better type of relief device is one which incorporates a bellows or bimetallic disc, which opens at a temperature of 210 F and closes when the temperature drops to approximately 160 F.

Another type of safety device is a fuel cut-off switch or valve in which a fusible plug is melted by excessive water temperature. The fuel supply is cut off until the fusible plug is replaced.

The capacity of temperature-relief devices may be calculated by Equation 4:

$$Q_m = 0.0008b \quad (4)$$

where Q_m and b denote the same quantities as in Equation 3.

Pressure-relief valves should be installed in the cold water line near the tank out of contact with the hot water in order to prevent excessive corrosion and lime deposit on the valve seat. *Temperature-relief* valves, in general, must be installed at the point of maximum water temperature.

SOLAR WATER HEATERS

Solar heaters utilize the energy of the sun for heating water. The successful operation of such heaters requires the availability of sunshine practically every day in the year, which has limited their use to Florida and the southern portions of California. When supplemented with some other means of gas, coal, or oil water heating, solar heaters may be used in climates where sunshine may be more or less intermittent. They have been used in summer homes as far north as Chicago. When properly installed and proportioned, solar water heaters render satisfactory service, especially in climates where the outdoor temperatures are high and extremely hot water is not necessarily desirable. Such installations consist essentially of a storage tank, heating coil, and hot box. The coil is installed in the hot box, and is arranged to circulate water to and from the storage tank. The advantage in the use of this type of heater is the fact that it requires no fuel. The same materials should be used for the coil, circulation lines, and tank. A copper coil is more efficient in absorbing heat in the box, but galvanized iron or steel may be substituted, depending on the local water conditions, cost, and other considerations.

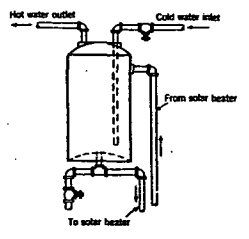

Fig. 13.... Solar Heater Tank Connections

The storage tank must be able to store sufficient heated water for the night period of about 16 hr when the coil is not functioning, or is operating under such poor sun conditions as to make its heating effect negligible. Due to the fact that the *no sun* period includes the night period when little or no hot water is used, an available storage of 50 percent of the average daily usage is considered adequate. Since about 25 percent of stored hot water cannot be drawn out of a storage tank before the incoming cold water reduces the temperature of all of the water in the tank to an unsatisfactory point for usage, the equation for calculating the storage capacity of the tank becomes:

$$S = \frac{Q_d \times 0.50}{0.75} = 0.666Q_d \quad (5)$$

where

S = storage capacity of tank, gallons.

Q_d = average daily usage, gallons.

Thus, for a family of four persons using an average of 40 gal of hot water per (person) (day), the size of the tank would be 4 persons x 40 gal x 0.666 or 106 gal, and the nearest standard size of tank would be used. The tank should be well insulated to prevent undue loss of heat during the 16-hour period when the coil is inoperative, and it should be located as high as possible in the building (under the peak of the roof if such exists) so as to secure a maximum circulation head from the coil. The hot water supply line to the house, as shown in Fig. 13, is connected to the top of the tank and serves to vent the air from the tank through the hot water faucets as fast as it accumulates.

Table 13.... Suggested Solar Heater Design Data[a]

[a] Sun Effect and the Design of Solar Heaters, by H. L. Alt (ASHVE Transactions, Vol. 41, 1935, p. 131).

Thus, for a family of four persons using an average of 40 gal of hot water per (person) (day), the size of the tank would be 4 persons x 40 gal x 0.666 or 106 gal, and the nearest standard size of tank would be used. The tank should be well insulated to prevent undue loss of heat during the 16-hour period when the coil is inoperative, and it should be located as high as possible in the building (under the peak of the roof if such exists) so as to secure a maximum circulation head from the coil. The hot water supply line to the house, as shown in Fig. 13, is connected to the top of the tank and serves to vent the air from the tank through the hot water faucets as fast as it accumulates.

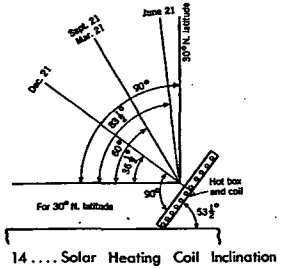

Fig. 14.... Solar Heating Coil Inclination

The coil should be of the return-bend type (square or slightly rectangular in form), and should have the pipes running east and west, with the coil on the south side of the building where it can receive the full sun effect all day long without shadows from the building itself, or from the adjacent obstructions such as trees or other structures. The coil should be placed as low as possible in relation to the storage tank level, such as on a porch roof, the roof of a one-story extension or, if necessary, even on the ground. Both the coil and the circulation lines should be designed to facilitate the circulation flow as much as possible, using long-radius copper fittings or recessed galvanized-iron fittings to match the materials of the coil, circulation lines, and tank. The coil should be inclined, as shown in Fig. 14, so that the north end is raised above the south end to secure an angle with the horizontal of about 53 deg. This will result in the inlet end of the coil being on the south side (or bottom), and the outlet end being on the north side (or top). This will satisfy conditions along the 30-deg N latitude, which includes the portions of Florida and Southern California where these heaters are most frequently used.

The hot box is usually constructed of wood on the four sides and bottom, and is insulated. Glass sash are placed over the top of the box which should be airtight. The interior surfaces should be painted white to reflect the heat, while the coil should be painted black to absorb the heat. The box need not be deeper than necessary to house the coil and to protect it from the weather.

The addition, on the bottom of the box, of a light gage copper plate to which the pipe of the coil is soldered for good metallic contact, will add to the amount of heat received by the coil, due to the fact that this plate will receive all of the sun's rays which fail to directly strike the coil. The heat from this source is transmitted to the coil through the plate rather than from the heated air surrounding the coil. Otherwise, only part of the heat enters the coil, the balance being transmitted through the glass.

Design data given in Table 13 may be used with judgment in selecting the size of solar heater coil and box for a particular application. These data are based on consumptions of 30 and 40 gal of hot water per (day) (person).

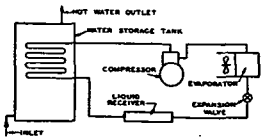

Fig. 15 .... Heat Pump Arrangement for Hot Water Supply

DOMESTIC HOT WATER BY HEAT PUMP

Hot water may suitably be obtained by using a heat-pump installation. The hot water heater may be either a heat exchanger installed just ahead of the compressor of a heat-pump installation, or may be a self-contained domestic-water heat pump.

Various designs of self-contained domestic water heat pumps are available, and one particular arrangement is shown in Fig. 15.

Hot water heating by means of a heat pump is not yet advisable where high water temperatures are desired. This is due to the fact that higher water outlet temperatures result in lower coefficients of performance.

For coefficients of performance of 4 or higher, the heat-pump water heater may be more economical to operate than a conventional water heater.

Although the first cost of domestic hot water heat pumps is somewhat high, they have the advantages of operating without products of combustion, odors, soot, or chimney. A further advantage is that they may be used for cooling purposes. With a coefficient of performance of 2½ to 3, water temperatures of 140 to 150 F may be obtained.[6]

Air Conditioning (Residential)	Design and Installation of Summer Air Conditioning for New and Existing Residences, Tentative (1955).	NWAH & ACA	NWAH & ACA Manual No. 11
Air Conditioning (Unitary Equipment)	Standard for Unitary Air Conditioning Equipment.	ARI	ARI Standard 210-57
Air Conditioning (Year-Round Residential)	Standard for Year-Round Residential Air-Conditioning.	ARI	ARI Standard 230-57
Airplane	Air Conditioning Equipment, Airplane—General Requirements for (1948).	SAE	SAE ARP 85B
Airplane	Heaters, Airplane, Internal Combustion Heat Exchanger Type (1949).	SAE	SAE ARP 143B
Airplane	Heaters, Airplane, Steam Type.	SAE	SAE ARP 87
Attic Ventilation	Residence Ventilation Guide (1950).	PFMA	PFMA
Boilers	I=B=R Testing and Rating Code for Low Pressure Cast Iron Heating Boilers, 6th Edition, 1958.	IBR	IBR
Boilers	Net Load Recommendations for Heating Boilers. Publ. semi-annually.	HP & ACCNA	MCAA
Boilers	Net Square Feet Radiation Loads in 70 Deg Fahr, Recommended for Low Pressure Heating Boilers (1948).	HP & ACCNA	MCAA
Boilers	ASME Boiler and Pressure Vessel Code (1956, 8 Sections).	ASME	ASME
Boilers	ASME Boiler and Pressure Vessel Code, Section IV, Low Pressure Heating Boilers (1956 with 1957 and 1958 addenda).	ASME	ASME
Boilers (Gas)	American Standard Approval Requirements for Central Heating Gas Appliances Vol. 1, Steam and Hot Water Boilers (1956).	A.G.A.	ASA Z21.13.1-1956
Boilers (Miniature)	ASME Boiler and Pressure Vessel Code, Section V, Miniature Boilers (1952).	ASME	ASME
Boilers (Power)	ASME Boiler and Pressure Vessel Code, Section I, Power Boilers (1956).	ASME	ASME
Boilers (Power)	ASME Boiler and Pressure Vessel Code, Section VII, Suggested Rules for Care of Power Boilers (1954).	ASME	ASME
Boilers (Steel)	Steel Boiler Institute Rating Code for Steel Boilers (1958).	SBI	SBI 7th Edition
Boilers (Steel)	Simplified Practice Recommendation for Steel Firebox Boilers and Steel Heating Boilers (Commercial and Residential Types) (1950).	BS SBI	CSD R157-50

Table 1 .... Codes and Standards—(Continued)

Subject	Title	Sponsor	Reference
Buildings	National Building Code (1955 Edition).	NBFU	NBFU
Building Requirements	American Standard Building Requirements (1946).	NHA USPHS	ASA A53.1-1946
Buildings	Basic Building Code (Also published in abridged form as Abridged Building Code) 1955.	BOCA	BOCA
Burners (Anthracite)	Commercial Standard for Domestic Burners for Pennsylvania Anthracite (Underfeed Type) (1940).	BS AIL	CSD CS48-40
Burners (Gas)	American Standard Requirements for Installation of Domestic Gas Conversion Burners (1948). Reaffirmed 1952.	A.G.A.	ASA Z21.8-1948
Burners (Gas)	American Standard Requirements for Installation of Gas Burning Equipment in Large Boilers (1950). Reaffirmed 1956.	A.G.A.	ASA Z21.33-1950
Burners (Gas)	American Standard Listing Requirements for Domestic Gas Conversion Burners (1948). Reaffirmed 1952.	A.G.A.	ASA Z21.17-1948
Burners (Oil)	Commercial Standard for Mechanical-Draft Oil Burners Designed for Domestic Installations (1956).	BS OBI	CSD CS75-56
Burners (Oil)	Standards for the Installation of Oil Burning Equipment (1956).	NFPA	NBFU or NFPA No. 31
Burners (Oil)	Standard for the Installation of Residential Oil-Fired Central Heating Equipment (1958).	OHIA	OHIA B-58
Burners (Pulverized Coal)	Standards for the Installation of Pulverized Coal Systems (1956).	NFPA	NBFU or NFPA No. 60A
Chillers	Liquid-Chilling Packages with Reciprocating Compressors (2HP and Larger) (1956).	ARI	ARI Standard 590-56
Chimneys (Flue Linings)	American Standard Sizes of Clay Flue Linings (1947).	AIA PC	ASA A62.4-1947
Cleaners (Air)	Code for Testing Air Cleaning Devices Used in General Ventilation: Section I, Unit or Panel Type Air Filtering Devices (1953).	AFI	AFI
Coal (For Stokers)	Tentative Standard Procedure for Testing and Evaluating Bituminous Stoker Coals (1952).	SMA BCR	SMA BCR
Coils	Proposed Commercial Standard for Rating and Testing Air Cooling Coils Using Nonvolatile Refrigerants (1945).	BC BS	CSD TS 4044
Coils	Joint ASRE-ASHAE Standard Methods of Testing and Rating Forced-Circulation Air Heating and Air Cooling Coils.	ASHAE ASRE	ASRE Circular No. 33-58
Color Scheme (Piping)	Scheme for Identification of Piping Systems (1956).	HP & ACCNA	MCAA Engrg. Stds. Sec. 2, Part V
Color Scheme (Piping)	Scheme for Identification of Piping Systems (1956).	ASME	ASA A13.1-1956
Compressors	ASRE Standard Methods of Rating and Testing Refrigerant Compressors.	ASRE ASHVE ACRMA	ASRE Standard 23-R
Compressors (Reciprocating)	Standard Nomenclature for Reciprocating Compressors.	ARI	ARI Standard 510-57
Condensers	ASRE Standard Methods of Rating and Testing Evaporative Condensers.	ASRE ASHVE ACRMA	ASRE Standard 20
Condensers	ASRE Standard Methods of Rating and Testing Water-Cooled Refrigerant Condensers.	ASRE ASHVE ACRMA	ASRE Standard 22
Condensing Units	ASRE Standard Methods of Rating and Testing Mechanical *Condensing Units* (1940).	ASRE ASHVE ACRMA	ASRE Standard 14-41
Conductance	Method of Test for Thermal Conductance and Transmittance of Built-up Sections by Means of Guarded Hot Box (1949).	ASTM	ASTM C 236-49 T
Conductivity	Standard Method of Test for Thermal Conductivity of Materials by Means of the Guarded Hot Plate (1945).	ASHVE ASRE ASTM NRC	ASTM C-177-45
Control Equipment (Industrial)	Underwriters' Laboratories, Inc., Standard for Industrial Control Equipment (July, 1938).	UL	UL Subject 508
Controls	Underwriters' Laboratories, Inc., Standard for Temperature Indicating and Regulating Equipment (June 1953).	UL	UL Subject 873
Controls Temperature	NEMA Standards for Automatic Temperature Controls (1953).	NEMA	NEMA DC1-1953
Controls Temperature	Temperature Control Equipment, Automatic, Airplane Cabin	SAE	SAE ARP 89A
Convectors	*Commercial Standard for Testing and Rating Convectors* (1947).	BS CMA IBR	CSD CS 140-47

Table 1 .... Codes and Standards—(Continued)

Subject	Title	Sponsor	Reference
Coolers (Air)	ASRE Standard Methods of Rating and Testing Forced Circulation and Natural Convection Air Coolers for Refrigeration (1945).	ASRE ASHVE ACRMA REMA	ASRE Standard 25-44
Coolers (Air)	Forced-Circulation Free-Delivery Air Coolers for Refrigeration.	ARI	ARI Standard 420-57
Coolers	ASRE Standard Methods of Rating and Testing Liquid Coolers.	ASRE	ASRE Standard 24-57
Cooling Towers	Accepted Test Procedure for Water Cooling Towers, Mechanical Draft, Industrial Type (1955).	CTI	CTI Bulletin ATP-105
Cooling Towers (Mechanical Draft)	Method of Testing for Rating Mechanical Draft Cooling Towers Under Controlled Conditions.	ASRE	ASRE Standard 38-57
Cooling Towers	Standard for Mechanical Draft Cooling Towers	ARI	ARI Standard 910-58
Ducts and Fittings	Simplified Practice Recommendation for Pipes, Ducts and Fittings for Warm Air Heating and Air Conditioning (1945).	Mfrs. BS	CSD R207-49
Exchangers (Heat)	Standards of *Tubular Exchanger Manufacturers Association* (1941).	TEMA	TEMA
Exhaust Systems	American Standard for Grinding, Polishing, and Buffing Equipment Sanitation (1941).	AFA	ASA Z43-1941
Exhaust Systems	Tentative Code of Recommended Practices for Testing and Measuring Air Flow in Exhaust Systems (1937).	AFA	AFA Preprint 36-27
Exhaust Systems	Tentative Recommended Good Practice Code and Handbook on the Fundamentals of Design, Construction, Operation and Maintenance of Exhaust Systems.	AFA	AFA
Exhaust Systems	Standards for Blower and Exhaust Systems (1949).	NFPA	NFPA or NBFU No. 91
Exhaust Systems (Open Tanks)	American Standard Safety Code for Ventilation and Operation of Open-Surface Tanks (1951).	AIHA ASHVE NAFM	ASA Z9.1–1951
Fans	Definitions and Terms in Use by the Blower Industry (1950) (Was NAFM Bulletin No. 105).	NAFM	NAFM-AMCA Bulletin No. 110
Fans	Standard Test Code for Testing Centrifugal and Axial Fans (1950) (Was NAFM Bulletin No. 103).	NAFM* ASHVE	NAFM-AMCA Bulletin No. 110
Fans	Standard Code for Testing Centrifugal, Axial, and Propeller Fans. (Having Wheels Less than 12-in. Dia). 1953.	NAFM	NAFM-AMCA Bulletin No. 116
Fans	Standards, Definitions, Terms and Test Codes for Centrifugal, Axial and Propeller Fans.	NAFM ASHVE**	NAFM-AMCA Bulletin 110 2nd Edition, 1952
Fans	Standards Publication Electric Fans (1955).	NEMA	NEMA FM1-1955
Fans	Test Code for Fans (1946).	ASME	ASME PTC 11-1946
Fans	Testing and Rating Ventilating Fans (Axial and Propeller Type).	CSD	CSD
Fire Prevention	National Fire Codes (1954). Vol. I—Flammable Liquids and Gases, Vol. II—Combustible Solids, Dusts, Chemicals, and Explosives, Vol. III—Building Construction and Equipment, Vol. IV—Extinguishing Equipment, Vol. V—Electrical, Vol. VI—Transportation.	NFPA	NFPA
Furnaces (Duct)	American Standard Approval Requirements for Gas-Fired Duct Furnaces (with 1956 and 1957 Addenda).	A.G.A.	ASA Z21.34-1955
Furnaces (Gas)	American Standard Approval Requirements for Central Heating Gas Appliances Vol. II, Gravity and Forced Air Central Furnaces (1956).	A.G.A.	ASA Z21.13.2 1956
Furnaces (Forced Air, Solid-Fuel)	Commercial Standard for Solid-Fuel-Burning Forced Air Furnaces (1944).	FHA NWAH & ACA AIL	CSD CS109-44
Furnaces (Heavy Duty)	Code for Testing and Rating Heavy Duty Furnaces and Direct-Fired Unit Heaters (1955).	ASHAE	ASHAE
Furnaces (Oil-Fired)	Commercial Standard for Warm Air Furnaces Equipped with Vaporising Type Oil Burners (1949).	Mfrs. BS	CSD CS104-49
Furnaces (Oil-Fired)	Recommended Commercial Standard for Warm Air Furnaces Equipped with Pressure Atomizing or Rotary Type Oil Burners.	BS NWAH & ACA	CSD CS195-54
Furnaces (Oil)	Commercial Standard for Oil Burning Floor Furnaces Equipped with Vaporizing Type Burners (1951).	BS OPA	CSD CS113-51

* Also endorsed by PFMA.

** Refers to Test Code for Centrifugal and Axial Fans.

Table 1 .... Codes and Standards—(Continued)

Subject	Title	Sponsor	Reference
Furnaces (Oil)	A Tentative Code for Testing Oil-Fired Furnaces.	NWAH & ACA	NWAH & ACA
Garage Ventilation	Recommended Good Practice Requirements for the Construction and Protection of Garages (1932, Reprint 1952)	NFPA	NFPA Pamphlet No. 88
Garages	Code of Minimum Requirements for Heating and Ventilating Garages (1935).	ASHVE	ASHAE
Gas Equipment (Large Boilers)	American Standard Requirements for Installation of Gas Equipment in Large Boilers (1950). Reaffirmed 1956.	A.G.A.	ASA Z21.33-1950
Gases (Toxic) and Dust	American Standard Allowable Concentration of Harmful Gases:	ASA	ASA
	Carbon Monoxide		Z37.1-1941
	Hydrogen Sulfide		Z37.2-1941
	Carbon Disulfide		Z37.3-1941
	Benzene		Z37.4-1941
	Manganese		Z37.6-1948
	Chromic Acid and Chromates		Z37.7-1943
	Mercury		Z37.8-1943
	Xylene		Z37.10-1948
	Lead and Certain Inorganic Lead Compounds		Z37.11-1943
	Toluene		Z37.12-1943
	Oxides of Nitrogen		Z37.13-1944
	Methanol		Z37.14-1944
	Styrene Monomer		Z37.15-1944
	Formaldehyde		Z37.16-1944
	Carbon Tetrachloride		Z37.17-1957
	Methyl Chloride		Z37.18-1949
	Trichloroethylene		Z37.19-1946
Hangars Aircraft	Standard for the Construction and Protection of Aircraft Hangars (1954).	NFPA	NBFU or NFPA No. 409
Heat Pumps (Unitary Equipment)	Standard for Unitary Heat Pump Equipment.	ARI	ARI Standard 510-57
Heat Transfer (Walls)	Thermal Conductance and Transmittance of Built-up Sections by Means of Guarded Hot Box (1949).	ASTM	ASTM C-236-49 T
Heaters (Recessed Gas Fired)	American Standard Approval Requirements for Central Heating Gas Appliances, Vol. IV Gravity and Fan Type Vented Recessed Heaters (1955 with 1956 and 1957 Addenda).	A.G.A.	ASA Z21.13.4-1955
Heaters (Room Gas Fired)	American Standard Approval Requirements for Gas-Fired Room Heaters (formerly called Space Heaters) (1956).	A.G.A.	ASA Z21.11-1956
Homes (Prefabricated)	Commercial Standard for Prefabricated Homes	PHMI BS	CSD CS125-47
Mineral Wool	Commercial Standard for Mineral Wool Insulation for Heated Industrial Equipment (1949).	BS IMWI	CSD CS117-49
Mineral Wool	Commercial Standard for Mineral Wool Insulation for Low Temperature Installations (1948).	BS IMWI	CSD CS105-48
Mineral Wool	Recommended Commercial Standard for Industrial Mineral Wool Products—All Types—Testing and Reporting (1946).	IMWI BS	CSD CS131-46
Motors	Nema Motor and Generator Standards (June 1945).	NEMA	NEMA 45-102
Motors	Test Code for Single-Phase Motors (1941).	AIEE	AIEE Report 502
Panel System (Warm Air)	Code and Manual for the Design and Installation of Warm Air Ceiling Panel Systems (1950).	NWAH & ACA	NWAH & ACA Manual No. 7-A 3rd Edition
Perimeter (Warm Air Small Pipe)	4-Inch Pipe Warm Air Perimeter Heating (1956).	NWAH & ACA	NWAH & ACA Manual No. 10 4th Edition
Perimeter (Warm Air)	Warm Air Perimeter Heating (1956, 5th Edition).	NWAH & ACA	NWAH & ACA Manual No. 4
Pipe & Tubing (Copper & Brass)	Simplified Practice Recommendation for Copper Water Tubes and Brass Pipe.	Mfrs. BS	CSD R217-49
Piping	American Standard Code for Pressure Piping (1955).	ASME	ASA B31.1-1955
Piping (Gas)	American Standard for Installation of Gas Piping and Gas Appliances in Buildings (1954).	A.G.A.	ASA Z21.30-1954
Pumps	Hydraulic Institute Test Code for Centrifugal Pumps. Hydraulic Institute Test Code for Rotary Pumps (1943).	HI	HI Section F
Radiation (Baseboard)	I=B=R Testing and Rating Code for Baseboard Type of Radiation (1950).	IBR	IBR

Table 1 .... Codes and Standards—(Continued)

Subject	Title	Sponsor	Reference
Radiation (Finned-Type)	I=B=R Testing and Rating Code for Finned-Type Radiation (First Edition 1951, with Addenda 1954).	IBR	IBR
Radiators	Simplified Practice Recommendation for Cast Iron Radiators (1943).	IBR BS	CSD R174-47
Refrigerants	Standard Designation of Refrigerants.	ASRE	ASRE Standard 34-57
Refrigeration (Equipment)	Underwriters' Laboratories, Inc., Standard for Air Conditioning and Commercial Refrigerating Equipment (Feb. 1946).	UL	UL Subject 207A
Refrigeration (Mechanical)	American Standard Safety Code for Mechanical Refrigeration (1958).	ASRE	ASA B9.1-1958***
Refrigeration (Unit Systems)	Underwriters' Laboratories, Inc., Standard for Unit Refrigerating Systems (Feb. 1946).	UL	UL Subject 207C
Refrigerators (Gas-Fired)	American Standard Approval Requirements for Refrigerators Using Gas Fuel (1942, Reaffirmed 1950).	A.G.A.	ASA Z21.19-1941
Refrigerators (Household)	American Standard Test Procedures for Household Electric Refrigerators (Mechanically Operated) (1944). Reaffirmed 1953.	ASRE USDA	ASA B38.2-1944
Sound (Measurement)	American Standard for Sound Level Meters for Measurement of Noise and Other Sounds.	AS of A	ASA Z24.3-1944
Sound (Measurement)	American Standard Method for the Pressure Calibration of Laboratory Standard Pressure Microphones.	AS of A	ASA Z24.4-1949
Sound (Measurement)	Sound Measurement Test Code for Centrifugal and Axial Fans (1950) (Was NAFM Bulletin No. 104).	NAFM	NAFM-AMCA Bulletin No. 110, 1950
Sound (Measurement)	Sound Measurement Test Code for Unit Heaters (1955).	IUHA	IUHA-AMCA Bulletin No. 13
Space Heaters	Commercial Standard for Flue Connected Oil-Burning Space Heaters Equipped with Vaporizing Pot-Type Burners (1943).	ICHAM	CSD CS101-43
Stokers	Code for Determination of Rated Capacities of Anthracite *Underfeed Stokers (1944).*	SMA	SMA
Stokers	Code for Determination of Rated Capacities of Bituminous Underfeed Stokers (1944).	SMA	SMA
Stokers	Recommended Minimum Firebox Dimensions and Base Heights (1944).	SMA	SMA
Stokers	*Recommended Standards Governing Minimum Setting* Heights (1944).	SMA	SMA
Tubing (Seamless Copper and Copper Alloy)	Simplified Practice Recommendation for Copper and Copper-Alloy Round Seamless Tube (1948).	Mfrs. BS	CSD R235-48
Tubing (Seamless Copper Water Tube)	Standard Specifications for Seamless Copper Water Tube (1956).	ASTM	ASA H23.1-1956
Unfired Pressure Vessels	ASME Boiler and Pressure Vessel Code Section VIII, Unfired Pressure Vessels (1956).	ASME	ASME
Unit Heaters	American Standard Approval Requirements for Gas Unit Heaters (1957).	A.G.A.	ASA Z21.16-1957
Unit Heaters	Standard Code for Testing and Rating Steam Unit Heaters (1950).	ASHVE IUHA	IUHA-AMCA Bulletin 10
Unit Heaters	Standard Code for Testing Hot Water Unit Heaters (1942).	IUHA	IUHA-AMCA Bulletin 11
Unit Ventilators	ASHVE Standard Code for Testing and Rating Steam Unit Ventilators (1934).	ASHVE	ASHAE
Vacuum Pumps	ASHVE Standard Code for Testing and Rating Return Line Low Vacuum Heating Pumps (1934).	ASHVE	ASHAE
Warm Air (Gravity)	Gravity Code and Manual for the Design and Installation of Gravity Warm Air Heating Systems (1954).	NWAH & ACA	NWAH & ACA Manual No. 5 5th Edition
Water Heaters	American Standard Household Automatic Electric Storage-type Water Heaters.	NEMA	ASA C72.1-1949
Water Heaters	American Standard Approval Requirements for Gas Water Heaters Volume I (1956).	A.G.A.	ASA Z21.10.1-1956
Water Heaters	NEMA Standards for Electric Water Heaters (1945).	NEMA	NEMA 45-104
Water Heaters	Testing and Rating Hand-Fired Hot Water Supply Boilers (1948).	FHA	CSD CS145-47
Wiring	Interior Wiring Design for Commercial Buildings.	AIEE	AIEE
Wiring	National Electrical Code (1956).	NFPA	NFPA or NFBU No. 70

*** Also designated ASRE Standard No. 15-58.

ABBREVIATIONS AND ADDRESSES

The Codes and Standards listed in preceding pages of this table can be obtained from the organizations listed in the *Reference Column*.

ACMA	Air Conditioning Manufacturers Association, superseded 1940 by ACRMA.
ACRMA	Air Conditioning and Refrigerating Machinery Association, Southern Bldg., Washington, D. C. superseded 1953 by ARI.
AFA	American Foundrymen's Association, 616 S. Michigan Ave., Chicago, Ill.
AFI	Air Filter Institute, 3 Center Park, Rochester 3, N. Y.
A.G.A.	American Gas Association, 420 Lexington Ave., New York 17, N. Y.
AGAEM	Association of Gas Appliance and Equipment Manufacturers, superseded 1945 by GAMA.
AIA	American Institute of Architects, 1741 New York Ave., N. W., Washington 6, D. C.
AIEE	American Institute of Electrical Engineers, 33 West 39th St., New York 18, N. Y.
AIHA	American Industrial Hygiene Association, 14125 Prevost, Detroit 27, Mich.
AIL	Anthracite Industries Laboratory, 237 Old River Rd., Wilkes-Barre, Pa.
AMCA	Air Moving and Conditioning Association, 2159 Guardian Building, Detroit 26, Mich.
ARI	Air-Conditioning and Refrigeration Institute, 1346 Connecticut Ave., N. W. Washington, D. C.
ASA	American Standards Association, 70 East 45th St., New York 17, N. Y.
AS of A	Acoustical Society of America, 57 East 55th St., New York 22, N. Y.
ASHAE	American Society of Heating and Air-Conditioning Engineers, 62 Worth St., New York 13, N. Y.
ASHVE	American Society of Heating and Ventilating Engineers, name changed to American Society of Heating and Air-Conditioning Engineers, Dec. 8, 1954.
ASME	American Society of Mechanical Engineers, 29 West 39th St., New York 18, N. Y.
ASRE	American Society of Refrigerating Engineers, 234 Fifth Ave., New York 1, N. Y.
ASTM	American Society for Testing Materials, 1916 Race St., Philadelphia 3, Pa.
BCMI	Blast Coil Manufacturers Institute, superseded by Heating and Cooling Coil Manufacturers Association HCCMA.
BCR	Bituminous Coal Research, Inc., 121 Meyran Ave., Pittsburgh 13, Pa.
BOCA	Building Officials Conference of America, 110 East 42nd St., New York 17, N. Y.
BS	National Bureau of Standards, Washington, D. C.
CSD	Commodity Standards Division, U. S. Dept. of Commerce, Washington, D. C.
CMA	Convector Manufacturers Association, 2159 Guardian Bldg., Detroit 26, Mich.
CTI	Cooling Tower Institute, 444 Emerson St., Palo Alto, Calif.
FHA	Federal Housing Administration, Washington, D. C.
GAMA	Gas Appliance Manufacturers' Association, 60 East 42nd St., New York 17, N. Y.
HCCMA	Heating and Cooling Coil Manufacturers Association, superseded by Air Moving and Conditioning Association, AMCA.
HI	Hydraulic Institute, 122 East 42nd St., New York 17, N. Y.
HP & ACCNA	Heating, Piping and Air Conditioning Contractors National Association, superseded 1956 by Mechanical Contractors Association of America, MCAA.
IBR	Institute of Boiler and Radiator Manufacturers, 608 Fifth Ave., New York 20, N. Y.
ICHAM	Institute of Cooking and Heating Appliance Manufacturers, Shoreham Hotel, Washington, D. C.
IMFI	Industrial Mineral Fiber Institute, 441 Lexington Ave., New York 17, N. Y.
MWI	Industrial Mineral Wool Institute, superseded 1953 by IMFI.
IUHA	Industrial Unit Heater Association, superseded 1956 by Air Moving and Conditioning Association, AMCA.
MCAA	Mechanical Contractors Association of America, Suite 570, 45 Rockefeller Plaza, New York 20, N. Y.
NAFM	National Association of Fan Manufacturers, superseded 1956 by Air Moving and Conditioning Association, AMCA.
NBFU	National Board of Fire Underwriters, 85 John St., New York 33, N. Y.
NEMA	National Electrical Manufacturers Association, 155 East 44th St., New York 17, N. Y.
NFPA	National Fire Protection Association, 60 Batterymarch St., Boston 10, Mass.
NHA	National Housing Agency, Washington, D. C.
NRC	National Research Council, 2101 Constitution Ave., Washington, D. C.
NWAH & ACA	National Warm Air Heating and Air Conditioning Association, 640 Engineers Bldg., Cleveland 14, Ohio.
OBI	Oil Burner Institute, superseded 1942 by OHIA
OHIA	Oil Heat Institute of America, Room 1618 (Lower Level) 500 Fifth Ave., New York 36, N. Y.
OPA	Office of Price Administration, Washington, D. C.
PC	Producers Council, 2029 K St., N.W., Washington 6, D. C.
PFMA	Propeller Fan Manufacturers Association. Became Power Fan Manufacturers Association before merger with AMCA.
PHMI	Prefabricated Home Manufacturers Institute, 908 20th St., N.W., Washington 6, D. C.
REMA	Refrigeration Equipment Manufacturers Association, superseded 1953 by ARI.
RMA	Refrigerating Machinery Association. See ACRMA.
SAE	Society of Automotive Engineers, 29 West 39th St., New York 18, N. Y.
SBI	Steel Boiler Institute, 1308 Land Title Bldg., Philadelphia 10, Pa.
SMA	Stoker Manufacturers Association, 307 N. Michigan Ave., Chicago 1, Ill.
TEMA	Tubular Exchanger Manufacturers Association, 53 Park Place, New York, N. Y.
UL	Underwriters' Laboratories, 207 East Ohio St., Chicago 11, Ill.
USDA	United States Department of Agriculture, Washington, D. C.
USPHS	United States Public Health Service, Washington, D. C.
