PREFACE TO THE 37th EDITION

The HEATING VENTILATING AIR CONDITIONING GUIDE, 1959, has been enlarged to 8½ x 11 inch page size for the purpose of providing additional space for new technical text and for enlargement of many illustrations, working charts, and tables. The use of larger type and open spacing in tables will be of particular advantage, for instance, in selecting heat transfer coefficients for various types of building construction or finding degree days for various cities.

This edition has 286 new or revised diagrams and charts. In most cases the enlarged page size has made it possible to place illustrations very close to their first mention in the text.

Five new chapters have been added on the following subjects: (1) high-temperature water systems, (2) the heat pump, (3) evaporative apparatus for heat rejection, (4) evaporative air cooling and humidification, and (5) snow melting.

Outstanding improvements made in chapters continued from the previous edition include (1) new outdoor winter design temperatures based on probability of occurrence of various temperatures, (2) new steam pipe sizing charts and tables based on Moody friction data for steam flow, (3) a revised table on gages and construction of air ducts including low-, medium-, and high-pressure ducts, (4) revised information and illustrations for unit ventilators and their application, (5) a rewritten chapter on automatic control with new illustrations of control applications, (6) general revision of the information on sorbents, including their use at elevated pressures, (7) data on heat transfer coefficients for ventilated attics, (8) revised information on sound absorption in ducts and plenums, noise levels, and diffuser noise, (9) up-to-date values for maximum allowable concentration of contaminants in occupied spaces, (10) a new section on the absorption refrigeration system, (11) a new section on the gas-fired year-round residential air conditioner, (12) new data on duct construction for residences, (13) a revised discussion of fuel utilization, efficiency, and consumption, (14) a rewritten chapter on school systems, and (15) additions and changes in the list of codes and standards.

More detailed information regarding the changes in the various chapters:

Chapter 7—Air Contaminants. Additions and revisions have been made in the tables of maximum allowable concentration of toxic gases, vapors, dusts, fumes, and mists, in order to have these values conform to those adopted by the American Conference of Governmental Industrial Hygienists in 1958.

Chapter 9—Heat Transmission Coefficients of Building Materials. A section on ventilated attic coefficients, with examples, has been added. The section on the practical use of overall coefficients has been revised. The tables of heat transmission coefficients for various building constructions have been enlarged to facilitate their use. All wall and roof constructions have been numbered to aid in identifying and referring to the coefficient for a particular construction.

Chapter 10—Moisture in Building Construction. The information on moisture migration and its calculation has been revised. The discussion of condensation in cooled structures has been extended.

Chapter 12—Heating Load. The data on winter outdoor temperatures have been revised to show as design values for the United States the minimum average daily temperatures that have the probability of occurring once in 40, 20, 13, 10, or 5 years as determined from U. S. Weather Bureau records. The discussion of design temperatures has been rewritten to explain the use of these new values. The tables have been enlarged in type and size for easier readability.

Chapter 15—Unit Ventilators and Unit Heaters. The discussion of unit ventilators has been enlarged and thirteen new illustrations have been added. The illustrations of piping connections to unit heaters have also been revised.

Chapter 16—Unitary Air-Conditioning Equipment. A section discussing the features, design considerations, selection, and installation of room air conditioners has been added.

Chapter 17—Electric Heating. This chapter was rewritten to include information on present heating units and methods of use.

Chapter 18—Warm Air Heating Systems. The information on ducts has been revised to include recommended gages for residential systems.

Chapter 20—Air Distribution. The sections on principles of air distribution and on ventilating jets have been rewritten and simplified.

Chapter 21—Air Duct Design. A revised section on construction includes data on high-, medium-, and low-pressure ductwork, coordinated with the recommendations of the Sheet Metal and Air Conditioning Contractors National Association. The charts for friction loss in ducts and the table of equivalent sizes of round and rectangular ducts have been enlarged.

Chapter 25—Sound Control. Data on noise levels in offices have been added. The section on noise from axial-flow fans has been enlarged. New information is given on diffuser noise. The sections on sound attenuation in ducts and plenum absorption have been revised.

Chapter 26—Steam Heating Systems. The information on steam pipe sizing has been rewritten to include a new basic chart (0 to 200 psig) based on the Moody friction data which take into account the Reynolds number and its effect on the friction factor, and to include also new charts for 30, 50, 100, and 150 psig and tables for 3.5 and 12 psig. (The new information, charts, and tables were prepared by the ASHAE Research Laboratory under the direction of the Technical Advisory Committee on Hot Water and Steam Heating.) The section on pressure-reducing valves has been enlarged by the addition of information formerly given in the chapter on District Heating.

Chapter 28—Hot Water Heating Systems. A new chart for available gravity head has been added.

Chapter 29—High-Temperature Water Systems. A new chapter has been added giving a general idea of the principles and practices that apply to high-temperature systems and discussing significant considerations for designing these systems. Many new illustrations showing piping arrangements were used.

Chapter 34—Automatic Fuel-burning Equipment. There has been a general revision of this chapter to bring the information up-to-date. A new chart for calculating friction drop or capacity for gas flow in piping has been added.

Chapter 35—Heating Boilers, Furnaces, and Space Heaters. The data on steel boilers have been improved and enlarged.

Chapter 37—Estimating Fuel Consumption for Space Heating. The former section on seasonal efficiency has been replaced by a new section on Efficiency of Utilization and the section on Calculated Heat Loss Method has been rewritten.

Chapter 38—Refrigeration. The information on absorption systems has been revised and new illustrations have been added.

Chapter 39—The Heat Pump. This is a new chapter giving information on the fundamentals, types, components, performance, design, and selection of heat pumps.

Chapter 40—Evaporative Apparatus for Heat Rejection. This is a new chapter giving information on water-cooling methods and equipment. Cooling tower theory, design, selection, operation, and maintenance are discussed. New data on spray performance are included.

Chapter 41—Evaporative Air Cooling and Humidification. This is a new presentation of the operation of air washers and their use for humidification and dehumidification. New information is given on evaporative cooling, types of equipment, and design methods. Several new illustrations were used.

Chapter 42—Dehumidification by Sorbent Materials. This chapter has been rewritten to include current information on solid and liquid sorption systems. A new section has been added on use of sorbents at elevated pressures. New illustrations were included.

Chapter 43—Automatic Control. This chapter was rewritten and enlarged to include 18 new cuts showing application of controls for various operations. The description of control types and operation has been extended.

Chapter 44—Instruments and Measurements. This chapter has been brought up to date by extensive revision.

Chapter 45—Motors and Motor Controls. The section on classification of motors has been revised to indicate the nomenclature adopted by the National Electric Manufacturers Association.

Chapter 46—Residential Summer Air Conditioning. A new section on gas-fired year-round air conditioners has been added.

Chapter 47—School Systems. This chapter has been rewritten with emphasis on factors affecting the heating and cooling loads. Various types of heating, cooling, and ventilating systems are discussed.

Chapter 48—Transportation Air Conditioning. The section on control of passenger bus air conditioning has been revised.

Chapter 49—Snow Melting. A new chapter has been added giving a method of designing snow-melting systems. New tables and data are included.

Chapter 55—Corrosion and Water-formed Deposits, Causes and Prevention. The section on use of resistant metals has been improved.

Chapter 56—Water Services. The charts for friction loss have been enlarged. The section on electric water heating has been transferred to this chapter from the chapter on electric heating.

Chapter 57—Codes and Standards. Several new standards have been added and the correct editions of listed standards have been indicated.

In addition to the changes in specific chapters outlined, numerous improvements have been made in both text and illustrations.

A complete index to Technical Data is contained in a 16-page section at the front of THE GUIDE.

For convenient reference to equipment to be selected for various types of installations, this book contains a Catalog Data Section showing products of 309 manufacturers of heating, ventilating, cooling, and air-conditioning equipment. This section is preceded by a 16-page index listing equipment available under numerous headings for most convenient use.

The Guide Committee is pleased to give credit for Preparation of Guide material for this edition to the ASHAE Technical Advisory Committees, particularly those on Evaporative Cooling, Heat Pump, Heating and Air-Conditioning Loads, Hot Water and Steam Heating, Insulation, and Sorption. The staff of the ASHAE Research Laboratory has rendered valuable assistance to these committees. Many trade associations, engineering societies, and other organizations mentioned in the text, in addition to individual engineers, both Society members and nonmembers, have contributed new material or reviewed present material to establish its authenticity. While it is impossible to recognize all sources of information and help, the Guide Committee is pleased to mention the following, who have been very active in preparation of this volume:

P. R. ACHENBACH
E. R. AMBROSE
R. S. ASH
G. C. F. ASKER
D. R. BAKER
G. L. BIEHN
WILLIAM BINGHAM
R. L. BOYD, JR.
A. D. BRANDT
G. F. CARLSON
J. R. CARROLL
C. A. CARTER
J. B. CHADDOCK
D. N. CROSTHWAIT, JR.
L. F. CHRISTOFFERSON
J. H. CLARKE
S. F. DUNCAN
H. S. DUTCHER
F. R. ELLENBERGER
R. B. ENGDAHL
L. F. FLAGG
W. F. FRIEND
L. R. FULLER
R. S. FUNK
ALBERT GIANNINI
E. W. GIFFORD
H. T. GILKEY
E. A. GREENLEE
C. A. GUSTAFSON
E. G. HANSEN
W. S. HARRIS
J. M. HARTMAN
H. G. HAYS
H. R. HEIPLE
N. E. HILL
W. O. HUEBNER
C. M. HUMPHREYS
LEO HUNGERFORD
N. J. JANISSE
F. A. JOY
C. F. KAYAN
G. A. KELLEY
W. F. KERKA
W. B. KIRK
J. L. KLINE
J. D. KROEKER
H. R. LIMBACHER
R. LISSON
R. A. LOCKE
R. D. MADISON
W. L. MCGRATH
S. W. MILLER
J. T. MULLER
W. M. MYLER, JR.
EUGENE O. OLSON
C. H. PESTERFIELD

CHAPTER 1

TERMINOLOGY

Glossary of Physical and Heating, Ventilating, Refrigerating and Air Conditioning Terms Used in the Text

Absolute Zero: The zero from which absolute temperature is reckoned. Approximately −273.15 C or −459.67 F. These values were established by the Tenth General Conference on Weights and Measures (1954).

Absorbent: A sorbent which changes physically or chemically, or both, during the sorption process.

Absorption: The action of a material in extracting one or more substances present in an atmosphere or mixture of gases or liquids; accompanied by physical change, chemical change, or both, of the sorbent.

Acceleration: The time rate of change of velocity, i.e., the derivative of velocity with respect to time. In the cgs system the unit of acceleration is the centimeter per (second) (second); in the fps system the unit is the foot per (second) (second),

$$a = \frac{dv}{dt}$$

Acceleration Due to Gravity: The rate of gain in velocity of a freely falling body the value of which varies with latitude and elevation. The international gravity standard has the value of 980.665 cm per (sec) (sec) or 32.174 ft per (sec) (sec) which is the actual value of this acceleration at sea level and about 45 deg latitude.

Adiabatic: An adjective descriptive of a process such that no heat is added to, or taken from, a substance or system undergoing the process.

Adsorbent: A sorbent which does not change physically or chemically during the sorption process.

Adsorption: The action, associated with surface adherence, of a material in extracting one or more substances present in an atmosphere or mixture of gases and liquids, unaccompanied by physical or chemical change. Commercial adsorbent materials have enormous internal surfaces.

Aerosol: An assemblage of small particles, solid or liquid, suspended in air. The diameters of the particles may vary from 100 microns down to 0.01 micron or less, e.g., dust, fog, smoke.

Air Cleaner: A device designed for the purpose of removing airborne impurities such as dusts, gases, vapors, fumes, and smokes. (Air cleaners include air washers, air filters, electrostatic precipitators, and charcoal filters.)

Air Conditioning: The process of treating air so as to control simultaneously its temperature, humidity, cleanliness, and distribution to meet the requirements of the conditioned space.

Air, Dry: In psychrometry, air unmixed with, or containing no, water vapor.

Air, Saturated: A mixture of dry air and saturated water vapor, all at the same dry-bulb temperature.

Air, Standard: Air with a density of 0.075 lb per cu ft and an absolute viscosity of 0.0379×10^{-4} lb mass per (ft) (sec). This is substantially equivalent to dry air at 70 F and 29.92 in. Hg barometric pressure.

Air Washer: An enclosure in which air is drawn or forced through a spray of water in order to cleanse, humidify, or dehumidify the air.

Anemometer: An instrument for measuring the velocity of a fluid.

Aspect Ratio: In air distribution outlets, the ratio of the length of the core of a grille, face, or register to the width.
In rectangular ducts, the ratio of the width to the depth.

Atmospheric Pressure: The pressure of the atmosphere to be measured by means of the barometer. *Standard Atmospheric Pressure* or *Standard Atmosphere* is exactly 1,013,250 dynes per sq cm by recent action of the Tenth General Conference on Weights and Measures (1954). It is approximately the pressure exerted by a column of mercury 76 cm high at standard gravitational acceleration, 980.665 cm per (sec) (sec), the mercury having a density of 13.5951 g per cu cm. It is equivalent to 14.696 psi or 29.921 in. Hg at 32 F.

Baffle: A surface used for deflecting fluids, usually in the form of a plate or wall.

Blast Heater: A set of heat transfer coils or sections used to heat air which is drawn or forced through it by a fan.

Blow (throw): In air distribution, the distance an air stream travels from an outlet to a position at which air motion along the axis reduces to a velocity of 50 fpm.
For unit heaters, the distance an air stream travels from a heater without a perceptible rise due to temperature difference and loss of velocity.

Boiler Heating Surface: All of the surface of the heat-transfer apparatus in contact on one side with the water or wet steam being heated and on the other side with the gas or refractory being cooled, in which the fluid being heated forms part of the circulating system, this surface to be measured on the side receiving heat. (Stationary Steam-Generating Units, *ASME Power Test Codes*, PTC 4-1946.)
Direct Heating Surface is generally understood to be the *boiler heating surface* subject to direct radiation from the surface of the grate, or from the surfaces of oil or gas burners.
Indirect Heating Surface is the *boiler heating surface* within the flues.

Boiler Horsepower: The equivalent evaporation of 34.5 lb of water per hr from and at 212 F. This is equal to a heat output of 970.3 × 34.5 = 33,475 Btuh.

British Thermal Unit (Btu): The Btu is defined as 778.177 foot-pounds if it is related to the IT calorie in such a way that 1 IT calorie per (kg) (C deg) = 1 Btu per (lb) (F deg), with 1 lb = 453.5924 g. The Ninth General Conference on Weights and Measures (1948) recommended the absolute joule as the fundamental unit of energy thereby, in effect, liquidating the old international electrical units. This calls for a redefinition of the International Tables calorie (IT cal) according to the following conversion factor: 4.18684 joule per IT calorie.

Calorie (Gram Calorie): The IT gram calorie is equivalent to 0.003968 Btu. (See definition of Btu.)

Central Fan System: A mechanical indirect system of heating, ventilating, or air conditioning, in which the air is treated or handled by equipment located outside the rooms served, usually at a central location, and is conveyed to and from the rooms by means of a fan and a system of distributing ducts. (See Chapter 19.)

Chimney Effect: The tendency of air or gas in a duct or other vertical passage to rise when heated due to its lower density compared with that of the surrounding air or gas. In buildings, the tendency toward displacement (caused by the difference in temperature) of internal heated air by unheated outside air due to the difference in density of outside and inside air.

Coefficient of Performance (Heating): The ratio of the total *instantaneous* useful heating effect produced by a heat pump system at stated conditions, to the heat equivalent of the total energy input rate required to drive or operate the system.

Coefficient of Performance (Cooling): The ratio of the *instantaneous* refrigeration effect produced by a heat pump

ST LOUIS PUBLIC APR 1959

system at stated conditions, to the heat equivalent of the total energy input rate required to drive or operate the system.

Comfort Air Conditioning: The process of treating air so as to control simultaneously its temperature, humidity, cleanliness, and distribution to meet the comfort requirements of the occupants of the conditioned space. (See also general definition of *Air Conditioning* on page 1 of this chapter.)

Comfort Line: A line on the comfort chart showing relation between the effective temperature and the percentage of adults feeling comfortable.

Condensate: The liquid formed by condensation of a vapor. In steam heating, water condensed from steam; in air conditioning, water extracted from air, as by condensation on the cooling coil of a refrigeration machine.

Condensation: The process of changing a vapor into liquid by the extraction of heat. Condensation of steam or water vapor is effected in either steam condensers or in dehumidifying coils and the resulting water is called *condensate*.

Conductance, Surface (*Unit*): The amount of heat transferred by radiation, conduction, and convection from unit area of a surface to the air or other fluid in contact with it, or vice versa, in unit time for a unit difference in temperature between the surface and the fluid. The common unit is: Btu per (hour) (square foot) (Fahrenheit degree). Symbol f. The temperature of the fluid should be taken in a plane sufficiently far from the surface that it will not be affected by the temperature of the surface.

Conductance, Thermal: The time rate of heat flow through unit area of a body, of given size and shape, per unit temperature difference. Common unit is: Btu per (hour) (square foot) (Fahrenheit degree). Symbol C.

Conduction, Thermal: The process of heat transfer through a material medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Conductivity, Thermal: The time rate of heat flow through unit area of a homogeneous substance under the influence of a unit temperature gradient. Common units are: Btu per (hour) (square foot) (Fahrenheit degree per inch). Symbol k.

Conductor, Thermal: A material which readily transmits heat by means of conduction.

Convection: The motion resulting in a fluid from the differences in density and the action of gravity. In heat transmission this meaning has been extended to include both *forced* and *natural* motion or circulation.

Convective Heat Transfer: The transmission of heat by either natural or forced motion of a fluid (liquid or gas).

Convector: An agency of convection. In heat transfer, a surface designed to transfer its heat to a surrounding fluid largely or wholly by convection. The heated fluid may be removed mechanically or by gravity (Gravity Convector). Such a surface may or may not be enclosed or concealed. When concealed and enclosed the resulting device is sometimes referred to as a concealed radiator. (See also definition of *Radiator*.) (See also Chapter 14.)

Decibel: A unit used to express the relation between two amounts of power. By definition the difference in decibels between two powers P_1 and P_2, P_2 being the larger, is: db difference $= 10 \log_{10} P_2/P_1$.

In acoustics the threshold of hearing at 1,000 cycles per sec has been standardized at 10^{-16} watts per sq cm. If P_2 is the power in watts per square centimeter of a measured sound, then $10 \log_{10} P_2/10^{-16}$ is the db difference above the threshold and is known as the *intensity level*. This is a definite recognized way of describing the intensity of a sound.

Declination of Sun: The angle above or below equatorial plane. It is plus if north of the plane, and minus if below. Celestial objects are located by declination.

Degree Day: A unit, based upon temperature difference and time, used in estimating fuel consumption and specifying nominal heating load of a building in winter. For any one day, when the mean temperature is less than 65 F, there exist as many degree days as there are Fahrenheit degrees difference in temperature between the mean temperature for the day and 65 F.

Dehumidify: To reduce by any process, the quantity of water vapor within a given space.

Dehydrate: To remove water in all forms from matter. Liquid water, hygroscopic water, and water of crystallization or water of hydration are included.

Density: The ratio of the mass of a specimen of a substance to the volume of the specimen. The mass of a unit volume of a substance. When weight can be used without confusion, as synonymous with mass, density is the weight per unit volume.

Dew Point: See *Temperature, Dew Point*.

Diffusivity, Thermal: Thermal conductivity divided by product of density and specific heat $= k/pc$. Expressed in units of square feet per hour.

Direct-Indirect Heating Unit: A heating unit located in the room or space to be heated and partially enclosed, the enclosed portion being used to heat air which enters from outside the room.

Direct-Return System (*Hot Water*): A hot water system in which the water, after it has passed through a heating unit is returned to the boiler along a direct path so that the total distance traveled by the water is the shortest feasible, and so that there are considerable differences in the lengths of the several circuits composing the system.

Down-Feed One-Pipe Riser (*Steam*): A pipe which carries steam downward to the heating units and into which the condensate from the heating units drains.

Down-Feed System (*Steam*): A steam heating system in which the supply mains are above the level of the heating units which they serve.

Draft: A current of air. Usually refers to the pressure difference which causes a current of air or gases to flow through a flue, chimney, heater, or space.

Draft Head (*Side Outlet Enclosure*): The height of a gravity convector between the bottom of the heating unit and the bottom of the air outlet opening. (*Top Outlet Enclosure*): The height of a gravity convector between the bottom of the heating unit and the top of the enclosure.

Drip: A pipe, or a steam trap and a pipe considered as a unit, which conducts condensation from the steam side of a piping system to the water or return side of the system.

Dry: To separate or remove a liquid or vapor from another substance. The liquid may be water, but the term is also used for the removal of liquid or vapor forms of other substances.

Dust: An air suspension (aerosol) of solid particles of any material. (See also Chapter 7.)

Enthalpy: A term used in lieu of *total heat* or *heat content*. Expressible in Btu per pound. Mathematically defined as $h = u + pv/J$. When a change occurs at constant pressure, as when water is boiled, the change in enthalpy is equal to the heat added, in this case latent heat.

Enthalpy, Free: A thermodynamic property which serves as a measure of the available energy of a system with respect to surroundings at the same temperature and same pressure as that of the system. No process involving an increase in available energy can occur spontaneously.

Enthalpy, Specific: A term sometimes applied to enthalpy per unit weight, the English unit being Btu per pound.

Entropy: The ratio of the heat added to a substance to the absolute temperature at which it is added. Mathematically, for a reversible process, $dS = dQ/T$ or $S = \int dQ/T$.

These formulas are applicable when temperature is not constant. During a reversible adiabatic change, entropy is constant. During a reversible isothermal change, the heat absorbed by the substance is equal to the product of the absolute temperature of the substance and its change of entropy.

Entropy, Specific: A term sometimes applied to entropy per unit weight, the English unit being Btu per (Fahrenheit degree, absolute) (pound).

Equivalent Evaporation: The amount of water a boiler would evaporate, in pounds per hour, if it received feed water at 212 F and vaporized it at the same temperature and corresponding atmospheric pressure.

Fan Furnace System: See *Warm Air Heating System*.

Fog: Suspended liquid droplets generated by condensation from the gaseous to the liquid state, or by breaking up a liquid into a dispersed state, such as by splashing, foaming, and atomizing. (See also Chapter 7.)

Force: The action on a body which tends to change its relative condition as to rest or motion.

Fumes: Smoke; aromatic smoke; odor emitted, as of flowers; a smoky or vaporous exhalation, usually odorous, as that from concentrated nitric acid. The word *fumes* is so broad and inclusive that its usefulness as a technical term is very limited. Its principal definitive characteristic is that it implies an odor. The terms vapor, smoke, fog, etc., which can be more strictly defined, should be used whenever possible.

Also defined as solid particles generated by condensation from the gaseous state, generally, after volatilization from molten metals, etc., and often accompanied by a chemical reaction such as oxidation. Fumes flocculate and sometimes coalesce. (See also Chapter 7.)

Furnace: That part of a boiler or warm air heating plant in which combustion takes place. Also a complete heating unit for transferring heat from fuel being burned to the air supplied to a heating system.

Furnace Volume (*Total*): The total furnace volume for horizontal-return tubular boilers and water-tube boilers is the cubical contents of the furnace between the grate and the first plane of entry into or between tubes. It therefore includes the volume behind the bridge wall as in ordinary horizontal-return tubular boiler settings, unless manifestly ineffective (i.e., no gas flow taking place through it), as in the case of waste-heat boilers with auxiliary coal furnaces, where one part of the furnace is out of action when the other is being used. For Scotch or other internally-fired boilers, it is the cubical contents of the furnace, flues, and combustion chamber, up to the plane of first entry into the tubes. (*ASME Power Test Codes*, Series 1929.)

Grate Area: The area of the grate surface, measured in square feet, to be used in estimating the rate of burning fuel. This area is construed to mean the area measured in the plane of the top surface of the grate, except that with special furnaces, such as those having magazine feed, or special shapes, the grate area shall be the mean area of the active part of the fuel bed taken perpendicular to the path of the gases through it. For furnaces having a secondary grate, such as those in double-grate down-draft boilers, the effective area shall be taken as the area of the upper grate plus one-eighth of the area of the lower grate, both areas being estimated as previously defined.

Gravity, Specific: The ratio of the mass of a unit volume of a substance to the mass of the same volume of a standard substance at a standard temperature. Water at 39.2 F is the standard substance usually referred to. For gases, dry air at the same temperature and pressure as the gas, is often taken as the standard substance.

Gravity Warm Air Heating System: See *Warm Air Heating System*.

Head, Dynamic: Same as Total Pressure expressed in height of liquid.

Heat: *That form of energy which transfers from one system* to another, by virtue of the temperature difference which exists between the two systems, when they are placed in communication.

Heat, Humid: Ratio of increase of enthalpy per pound of dry air to rise of temperature under conditions of constant pressure and constant humidity ratio.

Heat, Latent: A term used to express the energy involved in a change of state.

Heat, Sensible: A term used in heating and cooling to indicate any portion of heat which changes only the temperature of the substances involved.

Heat of the Liquid: The increase in enthalpy per unit weight of a saturated liquid as its temperature increases from a chosen base temperature. For water, the base temperature is usually taken as 32 F.

Heat Pump: In year-round air conditioning, refrigeration equipment used in such manner that heat is taken from a *heat source* and given up to the conditioned space when heating service is wanted, and is removed from the space and discharged to a *heat sink* when cooling and dehumidification are desired.

Heat, Specific: The heat absorbed (or given up) by a unit mass of a substance when its temperature is increased (or decreased) by 1 deg. Common Units: Btu per (pound) (Fahrenheit degree), calories per (gram) (Centigrade degree). For gases, both specific heat at constant pressure (c_p) and specific heat at constant volume (c_v) are frequently used. In air conditioning, c_p is usually used.

Heat Stress Index: A numerical index of the relative degree of heat stress imposed by various combinations of metabolic heat production with environmental radiant heat, air temperature, air velocity, and moisture content of the air. A young man in good physical condition and acclimatized to heat can withstand a total heat load having an HSI = 100 for eight hours a day of simple physical work without suffering undue physiological strain. Older men and others with physiological impairments and men engaged in more exacting work require lower *HSI* values.

Heat, Total: See *Enthalpy*.

Heat Transmission, Coefficient: Any one of a number of coefficients used in the calculation of heat transmission by conduction, convection, and radiation, through various materials and structures. (See thermal conductance, thermal conductivity, thermal resistance, thermal resistivity, thermal transmittance, etc.)

Heating Element, Electric: A unit assembly consisting of a resistor, insulated supports, and terminals for connecting the resistor to electric power.

Heating Unit, Electric: A structure containing one or more heating elements, electrical terminals or leads, electric insulation, and a frame or casing, all assembled together in one unit.

Hot Water Heating System: A heating system in which water is used as the medium by which heat is carried from the boiler to the heating units.

Humidify: To increase, by any process, the density of water vapor within a given space.

Humidistat: A regulatory device, actuated by changes in humidity, used for the automatic control of relative humidity.

Humidity: Water vapor within a given space.

Humidity, Absolute: The weight of water vapor per unit volume, pounds per cubic foot, or grams per cubic centimeter.

Humidity, Relative: The ratio of the mol fraction of water vapor in a mixture to the mol fraction of water vapor in saturated air at the same dry-bulb temperature and barometric pressure. (See discussion in Chapter 3.) Also defined in various texts as the ratio of the actual partial pressure of the water vapor in a space to the saturation pressure of pure water at the same temperature.

Humidity Ratio: In a mixture of water vapor and air, the weight of water vapor per pound of dry air. Symbol W. Also called *Specific Humidity*.

Humidity, Specific: See *Humidity Ratio*.

Hygrostat: Same as *Humidistat*.

Inch of Water: A unit of pressure equal to the pressure exerted by a column of liquid water 1 in. high at a standard temperature. The standard temperature is sometimes taken as 0 C and sometimes as 62 F. One inch of water at 62 F = 5.197 lb per sq ft.

Insulation (*Thermal*): A material having a relatively high resistance to heat flow, and used principally to retard the flow of heat.

Isobaric: An adjective used to indicate a change taking place at constant pressure.

Isothermal: An adjective used to indicate a change taking place at constant temperature.

Load, Estimated Design: In a heating or cooling system, the sum of the useful heat transfer, plus heat transfer from or to the connected piping, plus heat transfer occurring in any auxiliary apparatus connected to the system. The units are Btu per hour or, in heating, equivalent direct radiation (EDR).

Load, Estimated Maximum: In a heating or cooling system, the calculated maximum heat transfer that the system will be called upon to provide.

Manometer: An instrument for measuring pressures; essentially a U-tube partially filled with a liquid, usually water, mercury, or a light oil, so constructed that the amount of displacement of the liquid indicates the pressure being exerted on the instrument.

Mass: A measure of the inertia of a body. It also measures the quantity of matter in a body. Since the only general property of a given portion of matter that cannot be changed is its inertia, it is this property by which quantities of matter are defined. Two bodies which have equal inertias are said to have equal masses, or to contain equal quantities of matter. (This definition fails at velocities approaching the velocity of light.) The mass of a body is numerically equal to the ratio of the force required to give the body a given acceleration, to the acceleration. $m = F/a$. The common units of mass are the gram and the pound.

Mechanical Equivalent of Heat: The quantity of mechanical energy equal to one unit of heat. $J = 778.177$ ft-lb per Btu $= 4.1858 \times 10^7$ ergs per g-cal.

Medium, Heating: A substance such as water, steam, air, or furnace gas used to convey heat from the boiler, furnace, or other source of heat or energy to the heating unit from which the heat is dissipated.

Micron: A unit of length, the thousandth part of 1 mm or the millionth of a meter.

Millimeter of Mercury: A unit of pressure equal to the pressure exerted by a column of mercury 1 mm high at a temperature of 0 C. One millimeter of mercury at 0 C $= 1.934 \times 10^{-2}$ psi.

Mol: A weight of a substance numerically equal to its molecular weight. If the weight is in pounds the unit is a *Pound Mol*, in grams the unit is a *Gram Mol*. For perfect gases the volume of 1 mol is constant for all gases at the same temperature and pressure. For real gases this is approximately true at moderate pressures. At 32 F and zero-pressure the value of the product, pressure times specific volume, is 359.045 ± 0.006 atmosphere cubic feet (atm ft³), *for 1 mol of any gas*. For dry air at 32 F and standard atmospheric pressure, the specific volume is 358.83 cu ft per mol (ft³ per mol).

One-Pipe Supply Riser (*Steam*): A pipe which carries steam vertically to a heating unit, and which also carries the condensate from the heating unit. In an up-feed system, steam and condensate flow in opposite directions; in an overhead or down-feed system, they flow in the same direction.

One-Pipe System (*Steam*): A steam heating system in which a single main serves the dual purpose of supplying steam to the heating unit and conveying condensate from it. Ordinarily to each heating unit there is but one connection which must serve as both the supply and the return, although separate supply and return connections may be used. (*Hot Water*)—A hot water system in which the cooled water from the heating units is returned to the supply main. Consequently, the heating units farthest from the boiler are supplied with cooler water than those near the boiler in the same circuit.

Overhead System: Any steam or hot water system in which the supply main is above the heating unit. In a steam system the return must be below the heating units; in a water system the return may be above or below the heating units.

Panel Heating: A heating system in which heat is transmitted by both radiation and convection from panel surfaces to both air and surrounding surfaces.

Panel Radiator: A heating unit placed on or flush with a flat wall surface, and intended to function essentially as a radiator.

Perimeter System: See *Warm Air Heating System*.

Permeability: Water vapor permeability is a property of a substance which permits passage of water vapor, and is equal to the permeance of a 1 in. thickness of the substance. When permeability varies with psychrometric conditions, the *Spot* or *Specific Permeability* defines the property at a specific condition. Permeability is measured in perm-inches.

Permeance: The water vapor permeance of a sheet of any thickness (or assembly between parallel surfaces) is the ratio of water vapor flow to the vapor pressure difference between the surfaces. Permeance is measured in perms.

Perm: The unit of permeance. A perm is equal to 1 grain per (sq ft) (hr) (inch of mercury vapor pressure difference).

Plenum Chamber: An air compartment maintained under pressure, and connected to one or more distributing ducts.

Potentiometer: An instrument for comparing small electromotive forces, or for measuring small electromotive forces by comparison with a known electromotive force. Its principal advantage is that during the measurement, no current flows through the source of electromotive force.

Power: The rate of performing work. Common units are horsepower, Btu per hour, and watts.

Pressure: Force per unit area. Common units are pounds per square inch, gram per square centimeter, inch of water, millimeter of mercury.

Pressure, Absolute: The sum of the gage pressure and the barometric pressure.

Pressure, Dynamic: Same as *Total Pressure*.

Pressure, Gage: Pressure measured from atmospheric pressure as a base. Gage pressure may be indicated by a manometer which has one leg connected to the pressure source and the other exposed to atmospheric pressure.

Pressure, Saturation: The saturation pressure for a pure substance for any given temperature is that pressure at which vapor and liquid, or vapor and solid, can coexist in stable equilibrium.

Pressure, Static: The normal force per unit area that would be exerted by a moving fluid on a small body immersed in it if the body were carried along with the fluid. Practically, it is the normal force per unit area at a small hole in a wall of the duct through which the fluid flows (piezometer) or on the surface of a stationary tube at a point where the disturbances, created by inserting the tube, cancel. It is supposed that the thermodynamic properties of a moving fluid depend on static pressure in exactly the same manner as those of the same fluid at rest depend upon its uniform hydrostatic pressure.

Pressure, Total: In the theory of the flow of fluids; the sum of the static pressure and the velocity pressure at the point of measurement.

Pressure, Vapor: The pressure exerted by a vapor. If a vapor is kept in confinement over its liquid so that the vapor can accumulate above the liquid, the temperature being held constant, the vapor pressure approaches a fixed limit called the maximum, or saturated, vapor pressure, dependent only on the temperature and the liquid. The term *vapor pressure* is sometimes used as synonymous with *saturated vapor pressure*.

Pressure, Velocity: In a moving fluid, the pressure capable of causing an equivalent velocity, if applied to move the same fluid through an orifice such that all pressure energy expended is converted into kinetic energy.

Psychrometer: An instrument for ascertaining the humidity or hygrometric state of the atmosphere.

Psychrometric: Pertaining to psychrometry or the state of the atmosphere with reference to moisture.

Psychrometric Chart: A graphical representation of the thermodynamic properties of moist air.

Psychrometry: The branch of physics relating to the measurement or determination of atmospheric conditions, particularly regarding the moisture mixed with the air.

Pyrometer: An instrument for measuring high temperatures.

Radiant Heating: A heating system in which only the heat radiated from panels is effective in providing the heating requirements. The term *Radiant Heating* is frequently used to include both *Panel and Radiant Heating*.

Radiation: The transmission of energy by means of electromagnetic waves.

Radiation, Thermal (Heat) Radiation: The transmission of energy by means of electromagnetic waves of very long wavelength. Radiant energy of any wavelength may, when absorbed, become thermal energy and result in an increase in the temperature of the absorbing body.

Radiation, Equivalent Direct (EDR): A unit of heat delivery of 240 Btu per hr. It does not imply 144 sq in. of surface.

Radiator: A heating unit exposed to view within the room or space to be heated. A radiator transfers heat by radiation to objects within visible range, and by conduction to the surrounding air which in turn is circulated by natural convection; a so-called radiator is also a convector, but the term radiator has been established by long usage.

Radiator, Concealed: A heating device located within, adjacent to, or exterior to the room being heated, but so covered or enclosed or concealed that the heat transfer surface of the device, which may be either a radiator or a convector, is not visible from the room. Such a device transfers its heat to the room largely by convection air currents.

Radiator, Direct: Same as *Radiator*.

Radiator, Recessed: A heating unit set back into a wall recess, but not enclosed.

Radiator, Tube or Tubular: A heating unit used as a radiator in which the heat transfer surfaces are principally tubes.

Refrigerant: A substance which produces a refrigerating effect by its absorption of heat while expanding or vaporizing.

Refrigeration, Ton of: The removal of heat at a rate of 200 Btu per min, 12,000 Btu per hr, or 288,000 Btu per 24 hr.

Resistance, Thermal: The reciprocal of thermal conductance. Symbol *R*.

Resistivity, Thermal: The reciprocal of thermal conductivity. Symbol *r*.

Resistor, Electric: A material used to produce heat by passing an electric current through it.

Return, Dry: A return pipe in a steam heating system which carries both water of condensation and air. The dry return is above the level of the water line in the boiler in a gravity system. (See *Return, Wet*.)

Return, Wet: That part of a return main of a steam heating system which is filled with water of condensation. The wet return usually is below the level of the water line in the boiler, although not necessarily so. (See *Return, Dry*.)

Return Mains: Pipes or conduits which return the heating or cooling medium from the heat transfer unit to the source of heat or refrigeration.

Reversed-Return System: A system in which the heating or cooling medium from several heat transfer units is returned along paths arranged so that all circuits composing the system or composing a major sub-division of it are of practically equal length.

Sabin: A unit of equivalent sound absorption equal to the equivalent absorption of one square foot of a surface of unit absorptivity (i.e., of one square foot of surface which absorbs all incident sound energy).

Saturation: The condition for co-existence in stable equilibrium of a vapor and liquid or a vapor and solid phase of the same substance. Example: Steam over the water from which it is being generated.

Saturation, Degree of: The ratio of the weight of water vapor associated with a pound of dry air to the weight of water vapor associated with a pound of dry air saturated at the same temperature.

Smoke: An air suspension (aerosol) of particles, usually but not necessarily solid, often originating in a solid nucleus, formed from combustion or sublimation. Also defined as carbon or soot particles less than 0.1 micron in size which result from the incomplete combustion of carbonaceous materials such as coal, oil, tar, and tobacco.

Smokeless Arch: An inverted baffle placed in an up-draft furnace toward the rear to aid in mixing the gases of combustion, and thereby to reduce the smoke produced.

Solar Constant: The solar intensity incident on a normal surface located outside the earth's atmosphere at a distance from the sun equal to the mean distance between the earth and the sun. Its value is 415, 445, or 430 Btu per (hr) (sq ft) as the July, January, or mean value, respectively. At sea level in July the solar intensity value is about 300 Btu per (sq ft) (hr) since about 28 percent is absorbed in the earth's atmosphere.

Sorbent: A material which extracts one or more substances present in an atmosphere or mixture of gases or liquids with which it is in contact, due to an affinity for such substances.

Sorption: Adsorption or absorption.

Split System: A system in which the heating is accomplished by means of radiators or convectors supplemented by mechanical circulation of air (heated or unheated) from a central point. Ventilation may be provided by the same system.

Square Foot of Heating Surface (*Equivalent*): This term is synonymous with Equivalent Direct Radiation (EDR).

Stack Height: The height of a gravity convector between the bottom of the heating unit and the top of the outlet opening.

Steam: Water in the vapor phase. *Dry Saturated Steam* is steam at the saturation temperature corresponding to the pressure, and containing no water in suspension. *Wet Saturated Steam* is steam at the saturation temperature corresponding to the pressure, and containing water particles in suspension. *Superheated Steam* is steam at a temperature higher than the saturation temperature corresponding to the pressure.

Steam Heating System: A heating system in which heat is transferred from the boiler or other source of heat to the heating units by means of steam at, above, or below atmospheric pressure.

Steam Trap: A device for allowing the passage of condensate, or air and condensate, and preventing the passage of steam.

Supply Mains: The pipes through which the heating medium flows from the boiler or source of supply to the run-outs and risers leading to the heating units.

Surface, Heating: The exterior surface of a heating unit: *Extended Heating Surface (or Extended Surface)*: Heating surface consisting of fins, pins, or ribs which receive heat by conduction from the prime surface. *Prime Surface*: Heating surface having the heating medium on one side and air (or extended surface) on the other. (See also *Boiler Heating Surface*.)

Temperature: The thermal state of matter with reference to its tendency to communicate heat to matter in contact with it. If no heat flows upon contact, there is no difference in temperature.

Temperature, Absolute: Temperature expressed in degrees above absolute zero.

Temperature, Dew-Point: The temperature at which the condensation of water vapor in a space begins for a given state of humidity and pressure as the temperature of the vapor is reduced. The temperature corresponding to saturation (100 percent relative humidity) for a given absolute humidity at constant pressure.

Temperature, Dry-Bulb: The temperature of a gas or mixture of gases indicated by an accurate thermometer after correction for radiation.

Temperature, Effective: An arbitrary index which combines into a single value the effect of temperature, humidity, and air movement on the sensation of warmth or cold felt by the human body. The numerical value is that of the temperature of still, saturated air which would induce an identical sensation.

Temperature, Mean Radiant (MRT): The temperature of a uniform black enclosure in which a solid body or occupant would exchange the same amount of radiant heat as in the existing non-uniform environment.

Temperature Scales: Three temperature scales, Centigrade, Fahrenheit, and Reaumur, derive their degree values by dividing the difference between the ice point and steam points of water as follows: Centigrade 100, Fahrenheit 180, and Reaumur 80. Only the first two are important in the United States. The value of a Fahrenheit degree is therefore 5/9 of a Centigrade degree.

The Kelvin scale, sometimes called Centigrade absolute, has its zero point at the lowest attainable temperature 273.16 Centigrade degrees below the triple-point temperature of water and exactly 273.15 below the zero of the Centigrade scale.

The Rankine scale, sometimes called Fahrenheit absolute, has its zero at the lowest attainable temperature 459.688 Fahrenheit degrees below the triple-point temperature of water and exactly 459.67 F deg below the zero of the Fahrenheit scale.

To convert Centigrade to Kelvin temperature (generally designated K) add 273.15 deg.

To convert Fahrenheit to Rankine temperature (generally designated R) add 459.67 deg.

Temperature, Wet-Bulb: Thermodynamic wet-bulb temperature is the temperature at which liquid or solid water, by evaporating into air, can bring the air to saturation adiabatically at the same temperature. Wet-bulb temperature (without qualification) is the temperature indicated by a wet-bulb psychrometer constructed and used according to specifications. (*ASME Power Test Codes*, Series 1932, Instruments and Apparatus, Part 18.)

Therm: A quantity of heat equivalent to 100,000 Btu.

Thermodynamics, Laws of: Two laws upon which rest the classical theory of thermodynamics. These laws have been stated in many different, but equivalent ways. *The First Law:* (1) When work is expended in generating heat, the quantity of heat produced is proportional to the work expended; and conversely, when heat is employed in the performance of work, the quantity of heat which disappears is proportional to the work done. (Joule)[a] (G.P.)[b]; (2) If a system is caused to change from an initial state to a final state by adiabatic means only, the work done is the same for all adiabatic paths connecting the two states. (Zemansky); (3) In any power cycle or refrigeration cycle the net heat absorbed by the working substance is exactly equal to the net work done. *The Second Law:* (1) It is impossible for a self-acting machine, unaided by any external agency, to convey heat from a body of lower to one of higher temperature. (Clausius) (G.P.); (2) It is impossible to derive mechanical work from heat taken from a body unless there is available a body of lower temperature into which the residue not so used may be discharged. (Kelvin) (G.P.); (3) It is impossible to construct an engine that, operating in a cycle, will produce no effect other than the extraction of heat from a reservoir and the performance of an equivalent amount of work (Zemansky).

Thermostat: An instrument which responds to changes in temperature, and which directly or indirectly controls temperature.

Transmittance, Thermal: The time rate of heat flow, from the fluid on the warm side to the fluid on the cold side, per (square foot) (degree temperature difference between the two fluids). Sometimes called *Overall Coefficient of Heat Transfer*.

Common unit is Btu per (hour) (square foot) (Fahrenheit degree). Symbol *U*.

Two-Pipe System (*Steam or Water*): A heating system in which one pipe is used for the supply of the heating medium to the heating unit, and another for the return of the heating medium to the source of heat supply. The essential feature of a two-pipe system is that each heating unit receives a direct supply of the heating medium, which medium cannot have served a preceding heating unit.

Up-Feed System: A heating system in which the supply *mains are below the level of the heating units which they* serve.

Vacuum Heating System: A two-pipe steam heating system equipped with the necessary accessory apparatus which will permit operating the system below atmospheric pressure when desired.

Vane Ratio: In air distributing devices the ratio of depth of vane to shortest opening width between two adjacent grille bars.

Vapor: The gaseous form of substances which are normally in the solid or liquid state, and which can be changed to these states either by increasing the pressure or decreasing the temperature. Vapors diffuse. (ASA definition.)

Vapor Heating System: A steam heating system which operates under pressures at or near atmospheric and which returns the condensate to the boiler or receiver by gravity. Vapor systems have thermostatic traps or other means of resistance on the return ends of the heating units for preventing steam from entering the return mains; they also have a pressure-equalizing and air-eliminating device at the end of the dry-return.

Velocity: A vector quantity which denotes at once the time rate and the direction of a linear motion. $V = \frac{ds}{dt}$. For uniform linear motion $V = \frac{s}{t}$. Common units are: feet per second.

Ventilation: The process of supplying or removing air, by natural or mechanical means, to or from any space. Such air may or may not have been conditioned. (See *Air Conditioning*.)

Viscosity: That property of semi-fluids, fluids, and gases *by virtue of which they resist an instantaneous change of* shape or arrangement of parts. It is the cause of fluid friction whenever adjacent layers of fluid move with relation to each other.

The coefficient of viscosity is the resistance offered by a layer of the fluid of unit area to the motion parallel to this area of another layer of the fluid at unit distance moving with unit velocity relative to the first layer. This coefficient is known as the *absolute viscosity*, and in cgs units is the force in dynes per square centimeter at a velocity of 1 cm per second at a distance of 1 cm. This unit of absolute viscosity is the *poise*. Values of absolute viscosity are frequently listed in centipoises, a centipoise being 1/100 of 1 *poise*.

In many formulas *absolute viscosity* is expressed in pounds per foot second or pounds per foot hour. Conversion from centipoises may be made as follows: viscosity in centipoises × 0.000672 = viscosity in pounds per foot second, or viscosity in centipoises × 2.42 = viscosity in pounds per foot hour.

Kinematic viscosity is the ratio of *absolute viscosity* to the density of a fluid. The unit is the stoke which equals one poise per cu cm per gram, or 1 sq cm per sec. For conversion to English units: kinematic viscosity in stokes × 0.001076 = kinematic viscosity in square feet per second.

Volume, Specific: The volume of a substance per unit mass; the reciprocal of density. Units: cubic feet per pound, cubic centimeters per gram, etc.

Warm Air Heating System: A warm air heating plant consists of a heating unit (fuel-burning furnace) enclosed in a casing, from which the heated air is distributed to various rooms of the building through ducts.

Warm Air Heating System, Forced: A warm air heating system in which circulation of air is effected by a fan. Such a system may include air cleaning devices.

Warm Air Heating System, Gravity: A warm air heating system in which the motive head producing flow depends on the difference in weight between the heated air leaving the casing and the cooler air entering the bottom of the casing.

Warm Air Heating System, Perimeter: A warm air heating system of the combination panel and convection type. Warm air ducts embedded in the concrete slab of a basementless house, around the perimeter, received heated air from a furnace and deliver it to the heated space through registers *placed in or near the floor. Air is returned to the furnace from* registers near the ceiling.

[a] Names of authors who first stated laws are given in parentheses.
[b] From *Glossary of Physics*, by LeRoy Dougherty Weld (McGraw-Hill, 1937).

THE GREEK ALPHABET

A α	Alpha	H η	Eta	N ν	Nu	T τ	Tau
B β	Beta	Θ ϑ θ	Theta	Ξ ξ	Xi	Υ υ	Upsilon
Γ γ	Gamma	I ι	Iota	O o	Omicron	Φ φ ϕ	Phi
Δ δ	Delta	K κ	Kappa	Π π	Pi	X χ	Chi
E ϵ	Epsilon	Λ λ	Lambda	P ρ	Rho	Ψ ψ	Psi
Z ζ	Zeta	M μ	Mu	Σ σ s	Sigma	Ω ω	Omega

CHAPTER 2

ABBREVIATIONS, SYMBOLS, CONVERSION FACTORS

Standard Abbreviations; Standard Symbols; Conversion Equations; Graphical Symbols for Piping, Ductwork, Heating and Ventilating, Refrigerating; Identification of Piping by Color

THIS chapter contains information regarding abbreviations, symbols, and conversion equations, which are of particular interest to the engineer engaged in heating, ventilating, and air conditioning.

ABBREVIATIONS

Abbreviations are shortened forms of names and expressions employed in texts and tabulations, and should not generally be used as symbols in equations. Most of the following abbreviations have been compiled from a list of approved standards.[1] In general, the period has been omitted in all abbreviations, except where the omission results in the formation of an English word.

Absolute	abs
Air horsepower	air hp
Alternating-current (as adjective)	a-c
Ampere	amp
Ampere-hour	amp-hr
Atmosphere	atm
Average	avg
Avoirdupois	avdp
Barometer	bar.
Boiling point	bp
Brake horsepower	bhp
Brake horsepower-hour	bhp-hr
British thermal unit	Btu
British thermal units per hour	Btuh
Calorie	cal
Centigram	cg
Centimeter	cm
Centimeter-gram-second (system)	cgs
Cubic	cu
Cubic centimeter	cu cm or cc
Cubic foot	cu ft
Cubic feet per minute	cfm
Cubic feet per second	cfs
Decibel	db
Degree[2]	deg or °
Degree, Centigrade	C
Degree, Fahrenheit	F
Degree, Kelvin	K
Degree, Rankine	R
Diameter	dia
Direct-current (as adjective)	d-c
Electromotive Force	emf
Feet per minute	fpm
Feet per second	fps
Foot	ft
Foot-pound	*ft-lb*
Foot-pound-second (system)	fps
Freezing point	fp
Gallon	gal
Gallons per minute	gpm
Gallons per second	gps
Gram	g
Gram-calorie	g-cal
Horsepower	hp
Horsepower-hour	hp-hr
Hour	hr
Inch	in.
Inch-pound	in.-lb
Indicated horsepower	ihp
Indicated horsepower-hour	ihp-hr
Kilogram	kg
Kilowatt	kw
Kilowatt-hour	kwhr
Mass	mass
Melting point	mp
Meter	m
Micron	μ (mu)
Miles per hour	mph
Millimeter	mm
Minute	min
Molecular weight	mol wt
Mol	mol
Ounce	os
Pound	lb
Pounds per square inch	psi
Pounds per square inch, gage	psig
Pounds per square inch, absolute	psia
Revolutions per minute	rpm
Revolutions per second	rps
Second	sec
Specific gravity	sp gr
Specific heat	*sp ht*
Square foot	sq ft
Square inch	sq in.
Watt	w
Watthour	whr

[1] Abbreviations for Scientific and Engineering Terms, Z10.1-1941 (American Standards Association).
[2] It is recommended that the abbreviation for the temperature scale, F, C, K, R, be included in expressions for numerical temperatures but, wherever feasible, the abbreviation for *degree* be omitted *e.g.*, 68 F.

SYMBOLS

A letter symbol is a single character, with subscript or superscript if required, used to designate a physical magnitude in mathematical equations and expressions. Two or more symbols together always represent a product. The following have been compiled from a selected list of approved standards.[3] Additional symbols and variations in the standard symbols found necessary in the individual chapters will be found in a list at the end of Chapters 3, 4, 13, and 53.

Acceleration, due to gravity	*g*
Acceleration, linear	*a*

[3] Letter Symbols for Mechanics of Solid Bodies, Z10.3-1948, and Letter Symbols for Heat and Thermodynamics, Y10.4-1957 (American Standards Association).

Area ..... A
Change in specific volume during vaporization ..... v_{fg}
Density, Weight per unit volume, Specific weight. d or ρ (rho)

$$d = \frac{1}{v}$$

Distance, linear ..... s
Dry saturated vapor, Dry saturated gas at saturation pressure and temperature, vapor in contact with liquid ..... *Subscript g*
Efficiency ..... η
Elevation above some datum ..... z, Z
Emissivity ..... ϵ
Energy in general; work, total; work, molal ..... E
Entropy. (The capital should be used for any weight, and the small letter for unit weight) ..... S or s
Force, total load ..... F
Gas Constant, in equation $pV = nRT$ ..... R
Head ..... H or h
Heat content, Total heat, Enthalpy. (The capital should be used for any weight and the small letter for unit weight) ..... H or h
Heat content of saturated liquid, Total heat of saturated liquid, Enthalpy of saturated liquid, sometimes called heat of the liquid ..... h_f
Heat content of dry saturated vapor, Total heat of dry saturated vapor, Enthalpy of dry saturated vapor ..... h_g
Heat of vaporization at constant pressure ..... L or h_{fg}
Hydraulic radius ..... R_H
Internal energy, Intrinsic energy. (The capital should be used for any weight and the small letter for unit weight) ..... U or u
Length of path of heat flow, thickness L
Load, total ..... W
Mechanical efficiency ..... e_m
Mechanical equivalent of heat ..... J
Power, Horsepower, Work per unit time ..... P
Pressure, Absolute pressure, Gage pressure, Force per unit area ..... p
Quantity (total) of fluid, water, gas, heat; Quantity by volume; Total quantity of heat transferred ..... Q
Quality of steam, Pounds of dry steam per pound of mixture x
Reynolds Number ..... N_{Re}
Saturated liquid at saturation pressure and temperature, Liquid in contact with vapor ..... *Subscript f*
Specific heat c
Specific heat at constant pressure ..... c_p
Specific heat at constant volume ..... c_v
Specific volume, Volume per unit weight, Volume per unit mass v
Temperature (ordinary) F or C. (*Theta* is used preferably only when t is used for Time in the same discussion) ..... t or θ (*theta*)
Temperature (absolute) F abs or K. (Capital *theta* is used preferably only when small *theta* is used for ordinary temperature) ..... T or Θ (*capital theta*)
Thermal conductance: heat transferred per (unit time) (degree) C

$$C = \frac{1}{R} = \frac{kA}{L} = \frac{q}{t_1 - t_2}$$

Thermal conductance per unit area, Unit conductance: heat transferred per (unit time) (unit area) (degree) ..... C_o

$$C_o = \frac{C}{A} = \frac{1}{RA} = \frac{q}{A(t_1 - t_2)} = \frac{k}{L}$$

[4] Terms ending *ivity* designate properties independent of size or shape, sometimes called *specific properties*. Examples: conductivity, resistivity. Terms ending *ance* designate quantities depending not only on the material, but also upon size and shape, sometimes called *total quantities*. Examples: conductance, transmittance. Terms ending *ion* designate rate of heat transfer. Examples: conduction, transmission.

Thermal conductivity: heat transferred per (unit time) (unit area) (degree per unit length) ..... k

$$k = \frac{\frac{q}{A}}{\frac{(t_1 - t_2)}{L}}$$

Surface coefficient of heat transfer, Film coefficient of heat transfer, Individual coefficient of heat transfer: heat transferred per (unit time) (unit area) (degree) ..... f

$$f = \frac{\frac{q}{A}}{t_1 - t_2}$$

(In general f is not equal to k/L, where L is the actual thickness of the fluid film.)
Overall coefficient of heat transfer, Thermal transmittance per unit area: heat transferred per (unit time) (unit area) (degree overall) ..... U

$$U = \frac{\frac{q}{A}}{t_1 - t_2}$$

Thermal transmission (heat transferred per unit time) ..... q

$$q = \frac{Q}{t}$$

Thermal resistance (degree per unit of heat transferred per unit time) ..... R

$$R = \frac{t_1 - t_2}{q} = \frac{L}{kA}$$

Thermal resistivity ..... $1/k$
Vaporization values at constant pressure, Differences between values for saturated vapor and saturated liquid at the same pressure ..... *Subscript fg*
Velocity V
Viscosity, absolute ..... μ
Viscosity, kinematic ..... μ/ρ
Volume (total) V
Volume per unit time, Rate at which quantity of material passes through a machine, Quantity of heat per unit time, Quantity of heat per unit weight ..... q
Weight of a major item, Total weight ..... W
Weight rate, Weight per unit of power, Weight per unit time of ..... w
Work (total) ..... W

CONVERSION EQUATIONS[5]

Heat, Power and Work

1 ton refrigeration = { 12,000 Btu per hour; 200 Btu per minute }
Latent heat of ice = 143.4 Btu per pound
1 Btu = { 778.3 ft-lb; 0.2930 Int. whr; 252.0 I.T. calorie }
1 Int. watthour = { 2656 ft-lb; 3.413 Btu; 3600 Int. joules; 860 I.T. calories }
1 Int. kilowatthour = { 3,413 Btu; 3.517 lb water evaporated from and at 212 F }

[5] Checked in 1944 by National Bureau of Standards. Abbreviations *Int.* and *I.T.* refer to *International* and *International (Steam) Table*, respectively.

1 Int. kilowatt (1000 watts) = { 1.341 hp; 56.88 Btu per minute; 44,267 ft-lb per minute }
1000 I.T. calories / 1 I.T. kilocalorie = { 3.968 Btu; 3088 ft-lb; 1.1628 Int. whr }
1 horsepower = { 0.7455 Int. kw; 42.40 Btu per minute; 33,000 ft-lb per minute; 550 ft-lb per second }
1 boiler horsepower = { 33,475 Btu per hour; 9.809 Int. kw }

Weight and Volume

1 gal (U. S.) = { 231 cu in.; 0.1337 cu ft }
1 British or Imperial gallon = 277.42 cu in.
1 cu ft = { 7.481 gal; 1728 cu in. }
1 cu ft water at 60 F (in vacuo) = 62.37 lb
1 cu ft water at 212 F (" ") = 59.83 lb
1 gal water at 60 F (" ") = 8.338 lb
1 gal water at 212 F (" ") = 7.998 lb
1 lb (avdp) = { 16 oz; 7000 grains }
1 bushel = 1.244 cu ft
1 short ton = 2000 lb

Pressure

1 lb per square inch = { 144 lb per square foot; 2.0360 in. mercury at 32 F; 2.0422 in. mercury at 62 F; 2.309 ft water at 62 F; 27.71 in. water at 62 F }
1 oz per square inch = { 0.1276 in. mercury at 62 F; 1.732 in. water at 62 F }
1 atmosphere = { 14.696 lb per square inch; 2116 lb per square foot; 33.94 ft water at 62 F; 30.01 in. mercury at 62 F; 29.921 in. mercury at 32 F }
1 in. water at 62 F (in vacuo) = { 0.03609 lb per square inch; 0.5774 oz per square inch; 5.197 lb per square foot }
1 ft water at 62 F (in vacuo) = { 0.4330 lb per square inch; 62.37 lb per square foot }
1 in. mercury at 62 F (in vacuo) = { 0.4897 lb per square inch; 7.835 oz per square inch; 1.131 ft water at 62 F; 13.57 in. water at 62 F }
1 in. mercury at 32 F (in vacuo) = 0.49115 lb per square inch

Metric Units

1 cm = 0.3937 in. = 0.0328 ft
1 in. = 2.540 cm
1 m = 3.281 ft
1 ft = 0.3048 m
1 sq cm = 0.1550 sq in.
1 sq in. = 6.452 sq cm
1 sq m = 10.76 sq ft
1 sq ft = 0.09290 sq m
1 cu cm = 0.06102 cu in.
1 cu in. = 16.39 cu cm
1 cu m = 35.31 cu ft
1 cu ft = 0.02832 cu m
1 liter = 1000 cu cm = 0.2642 gal
1 kg = 2.205 lb (avdp)
1 lb = 0.4536 kg
1 metric ton = 2205 lb (avdp)
1 gram = 0.002205 lb (avdp)
1 kilometer per hour = 0.6214 mph
1 gram per square centimeter = { 0.02905 in. mercury at 62 F; 0.3942 in. water at 62 F }
1 kg per sq cm (metric atmosphere) = 14.22 lb per square inch
1 gram per cubic centimeter = { 0.03613 lb per cubic inch; 62.43 lb per cubic foot }
1 dyne = 0.00007233 poundals
1 absolute joule = { 10,000,000 ergs; 0.7376 ft-lb }
1 Int. joule = 0.7378 ft-lb
1 metric horsepower = { 75 kg-m per second; 0.986 hp (U. S.) }
1 I.T. kilocalorie per kilogram = 1.8 Btu per pound
1 I.T. calorie per square centimeter = 3.687 Btu per square foot
1 I.T. calorie per (second) (square centimeter) for a temperature gradient of 1 C deg per centimeter = { 2903 Btu per (hour) (square foot) for a temperature gradient of 1 F deg per inch of thickness. }

IDENTIFICATION OF PIPING SYSTEMS BY COLOR

The color scheme for identification of piping systems, based on material carried, as listed in the following table and shown in Fig. 1, is reprinted from Part V, Fourth Edition, of the Engineering Standards of the Heating, Piping and Air Conditioning Contractors National Association.[1]

Class	Color
F—Fire-protection	Red
D—Dangerous materials	Yellow or Orange
S—Safe materials	Green (or the achromatic colors, white, black, gray or aluminum)
and, when required	
P—Protective materials	Bright blue
V—Extra valuable materials	Deep purple

CHAPTER 3

THERMODYNAMICS

Mass and Energy Balances, Thermodynamic Properties of Moist Air, Formulas and Tables; Thermodynamic Properties of Water, Formulas and Tables; Degree of Saturation; ASHAE PSYCHROMETRIC CHART; Solution of Air Conditioning Problems by Use of Tables and Psychrometric Chart; U. S. Standard Atmospheres

THERMODYNAMICS is that branch of natural science which deals with energy and its transformations into various forms. In this chapter the discussion will be limited to thermodynamics as it affects the arts of heating and air conditioning. This will necessarily presume some knowledge of the fundamentals of the science on the part of the reader who may also find it desirable to refer to a standard text on the subject, preferably one published after 1930.

MASS AND ENERGY BALANCES

The First Law of Thermodynamics is a statement of the Principle of Conservation of Energy. It may be stated as follows: *The energy added to a system is equal to the increase or decrease of the energy stored in the system, plus the energy which leaves the system.* For a completely contained, or nonflow system, this may be restated as: The heat added to a nonflow system is equal to the change in the internal energy of the system, plus the work done by the system.

$$ {}_1q_2 = U_2 - U_1 + w \qquad (1) $$

For a constant pressure process

$$ {}_1q_2 = H_1 - H_2 \qquad (2) $$

where

${}_1q_2$ = energy added between points 1 and 2.
U = internal energy of system.
w = work done by system.
H = enthalpy of system.

Subscripts 1 and 2 refer to sections of the system between which a change takes place.

For engineering problems, a more important application of the First Law is its use in cases in which, in addition to energy, one or more fluids are crossing the boundaries of the system. The most simple of these is the steady flow system, in which the rates of energy and mass flow across the boundaries of the system are constant, and no mass or energy is stored or released by the system.

Consider a system as illustrated in Fig. 1. The fluid crossing the boundaries of the system carries with it potential energy by reason of its elevation above some convenient datum, kinetic energy by reason of its velocity, and energy in the form of enthalpy. Additional energy may cross the boundaries of the system in the forms of heat or work. The various forms of energy crossing the boundaries between the sections under consideration may be equated by applying the First Law of Thermodynamics:

$$ PE_1 + KE_1 + H_1 + {}_1q_2 = PE_2 + KE_2 + H_2 + w \qquad (3) $$

where

PE = potential energy, Btu per pound dry air.
KE = kinetic energy, Btu per pound dry air.
H = enthalpy, Btu per pound dry air.
${}_1q_2$ = heat added between sections 1 and 2, Btu per pound dry air.
w = shaft work withdrawn between sections 1 and 2, Btu per pound of dry air.

For most psychrometric problems, since the change in the potential energy and kinetic energy terms is negligible compared to the enthalpy change, Equation 3 may be written

$$ H_1 + {}_1q_2 = H_2 + w \qquad (4) $$

where

H = enthalpy of flowing medium, Btu per pound of dry air.

The enthalpy of the entire system may be broken down into constituent parts, thus:

$$ GH = Gh + Lh_{wl} + Sh_{ws} \qquad (5) $$

where

h = enthalpy of *moist* air, Btu per pound of dry air.
h_{wl} = enthalpy of liquid water, Btu per pound.
h_{ws} = enthalpy of solid water, Btu per pound.
L = flow rate of liquid water, pounds per hour.
S = flow rate of solid water, pounds per hour.
G = flow rate of dry air, pounds per hour.

Similarly, an equation expressing the conservation of mass may be written thus:

$$ \sum_{in} [G(1 + W) + L + S] = \sum_{out} [G(1 + W) + L + S] \qquad (6) $$

where

W = humidity ratio, pounds of water vapor per pound of dry air.

THERMODYNAMIC PROPERTIES OF MOIST AIR

The working substance of the air-conditioning engineer is moist air. Air is actually a mixture of oxygen, nitrogen, carbon dioxide, water vapor, and traces of other gases.

The mixture consisting of the components other than water vapor is known as *dry air*. Its composition remains essentially constant under all conditions. In moist air the amount of

water vapor varies considerably. To allow for this variation the specific properties of moist air are developed in terms of the relative amounts of water vapor and dry air. Accepted air-conditioning practice is to express this in terms of the amount of water vapor per pound of dry air.

Terms frequently used in describing the condition of a mixture of air and water vapor are *humidity ratio, relative humidity, degree of saturation, dry-bulb temperature, thermodynamic wet-bulb temperature,* and *dew-point temperature.* These terms are defined in following paragraphs.

Humidity Ratio. Weight of water vapor associated with unit weight of dry air, pounds of water vapor per pound of dry air. Humidity ratio has also been called *specific humidity,* and this term is still used in many places.

Relative Humidity. Ratio of the mol fraction of water vapor in the actual mixture to the mol fraction of water vapor in

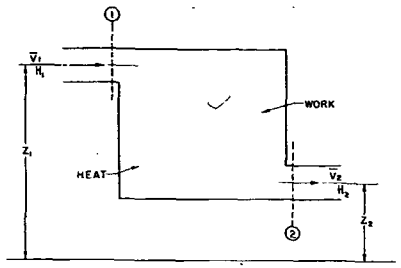

Fig. 1 . . . . Energy Change between Two Sections of a System

saturated air at the same dry-bulb temperature and barometric pressure.

Degree of Saturation. Ratio of the actual humidity ratio to the humidity ratio of saturated air at the same dry-bulb temperature and barometric pressure.

Relative humidity and degree of saturation are related according to the identity:

$$\phi = \frac{\mu}{\left[1 - (1 - \mu) f_s \frac{P_s}{P_a}\right]} \tag{7}$$

where

ϕ = relative humidity, expressed as a decimal.
μ = degree of saturation, expressed as a decimal.
P_a = observed (or barometric) pressure of the moist air.
P_s = saturation pressure of pure water at the prevailing temperature, expressed in the same units as P_a.
f_s = a dimensionless factor which may be regarded as accounting for influences arising when air and water are intermixed. Magnitudes of f_s have been reported by Goff and Gratch[1] and by Goff.[2] Table 1 gives values of f_s for a limited range of conditions.

Dry-Bulb Temperature. The temperature indicated by any type of thermometer or thermocouple not affected by the water-vapor content of the air, or by radiation.

Table 1 . . . . Magnitudes of f_s for the Range 0 to 125 F
(Standard Barometric Pressure, 29.921 in. Hg)

Temp. F	f_s	Temp. F	f_s
0	1.0048	70	1.0045
10	1.0046	80	1.0047
20	1.0046	90	1.0048
30	1.0045	100	1.0050
40	1.0044	110	1.0053
50	1.0044	120	1.0055
60	1.0044	125	1.0057

Note: The original source gives f_s to seven significant figures over the temperature range −208 F to +202 F and over the pressure range 20 to 35 in. Hg.

Thermodynamic Wet-Bulb Temperature. The temperature at which liquid or solid water, by evaporating into air, can bring the air to saturation adiabatically at the same temperature.

Consider an adiabatic system as shown in Fig. 2. Unsaturated air at the state h_1, W_1, enters the system at Section 1, and saturated air at the state h_1,* W_1,* leaves the system at Section 2. Liquid water at the state h_{w_2},* corresponding to the temperature of the saturated air leaving the system is supplied. Then, since no work is done and the system is strictly adiabatic, the energy equation becomes

$$h_1 + (W^* - W_1)h_{w^*} = h^* \tag{8}$$

where

* indicates condition at thermodynamic wet-bulb temperature.

The temperature corresponding to h^* for given values of h_1 and W_1 is called the thermodynamic wet-bulb temperature, or the temperature of adiabatic saturation.

The temperature indicated by an ordinary wet-bulb thermometer is affected by a number of factors not accounted for in Equation 8, and hence, may be quite different from the theoretical temperature obtained from its use. The measured wet-bulb temperature is influenced by (*a*) radiation from the *surroundings* to the wick; (*b*) *conduction* of heat along the stem of the thermometer; and (*c*) impact of the air on the wick or bulb of the thermometer. Arnold[3] has developed a theory which makes possible the calculation of the true thermodynamic wet-bulb temperature from observed data through the use of suitable corrections to be applied to the

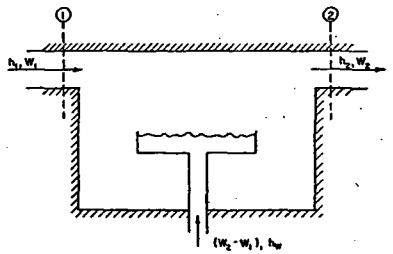

Fig. 2 . . . . Illustration of Adiabatic Saturation

readings of the wet-bulb thermometer. However, unless extreme precision is required, the observed temperature may be taken equal to the theoretical temperature for most engineering problems, if no attempt is made to shield the wick from radiation and the air velocity past the wick is about 1000 fpm.

Dew-Point Temperature. The saturation temperature corresponding to a given combination of humidity ratio W and barometric pressure is called the dew-point temperature. It is the lowest temperature at which the given humidity ratio can exist at the corresponding barometric pressure. At this temperature condensation will first start to form when moist air is cooled.

Perfect Gas Relationships

Hypotheses, based on experimental observation of the physical behavior of gases, which were advanced by Boyle, Charles, Gay-Lussac, Dalton, Gibbs, Joule, Kelvin, and others, were reduced to reasonably simple mathematical expressions and came to be regarded as physical laws. However, as scientific knowledge increased, and as more precise methods of measurement were developed, it became apparent that these simple equations did not describe the behavior of the mixtures of actual gases and vapors accurately.

The original statements have been found to be useful tools, nevertheless, in many cases. For example, the behavior of common diatomic and triatomic gases at low pressures follows these equations closely enough so that they may be used for some types of engineering problems. Many useful engineering works have been constructed through the use of approximations. The degree of approximation, however, which may be tolerated in engineering design must be decided by the engineer, based upon his study and experience in the field.

Boyle's Law. One of the original observations of the physical behavior of gases was made by Robert Boyle who noted that, if a constant weight of gas is compressed with the temperature held constant, the volume V varied inversely as the absolute pressure P. Stated mathematically,

$$PV = \text{constant} \quad \text{(temperature constant)} \tag{9}$$

Charles' Law. Experiments made independently by Charles and Gay-Lussac led to the formulation of what is now known as Charles' Law: If a constant weight of gas is heated or cooled at constant volume, the absolute pressure P varies as the absolute temperature T; if a constant weight of gas is heated or cooled at constant pressure, the volume V varies as the absolute temperature T. Stated mathematically,

$$\frac{P}{T} = \text{constant} \quad \text{(volume constant)} \tag{10}$$

$$\frac{V}{T} = \text{constant} \quad \text{(pressure constant)} \tag{11}$$

Boyle's Law and Charles' Law may be combined to form the equation of state for the ideal or perfect gas,

$$PV = RT \tag{12}$$

where

R is a constant whose value depends on the units selected for P, V, and T.

Dalton's Rule. Dalton stated that each gas in a mixture occupies the total volume of the mixture just as though the other gases were not present. Gibbs later expanded this statement for perfect gases into the following principles:

1. The pressure of a mixture of gases is the sum of the partial pressures of the individual gases when they exist at the total volume and temperature of the mixture.

2. The internal energy, enthalpy, and entropy of a mixture of gases are respectively equal to the sums of the individual internal energies, enthalpies, and entropies of the components when they exist at the total volume and temperature of the mixture.

While these relationships do not hold exactly for all systems of real gases, they may be used with a good degree of precision for many engineering applications at low pressures. Moreover, since water vapor very closely follows the perfect gas relationships in the range usually encountered in air conditioning, the Gibbs-Dalton Rule may frequently be applied to mixtures of dry air and water vapor.

Thus,
$$V_m = V_a = V_w \tag{13}$$
$$T_m = T_a = T_w \tag{14}$$
$$p_m = p_a + p_w \tag{15}$$
$$m_m h = m_a h_a + m_w h_w \tag{16}$$

where

Subscript m denotes mixture; subscript a denotes dry air; subscript w denotes water vapor.
Symbol m = weight of dry air crossing any duct section, pounds per minute.

Using Equations 12, 13, 14, and 15, the relation is obtained as follows:

$$v_T = \frac{n_a RT}{p_a} = \frac{n_w RT}{p_w} = \frac{(n_a + n_w)RT}{p} \tag{17}$$

where

v_T = total volume, cubic feet.
n_a = number of mols of dry air.
n_w = number of mols of water vapor.
R = universal gas constant, 1545 foot-pounds per (Fahrenheit degree) (mol).
p_a = partial pressure of dry air.
p_w = partial pressure of water vapor.
T = absolute temperature, Fahrenheit degrees.

The partial pressure of water vapor in the mixture is then

$$p_w = \frac{n_w}{n_a + n_w} p \tag{18}$$

or, the partial pressure of the water vapor in moist air is equal to the product of the mol fraction of the water vapor and the observed pressure of the mixture. A similar expression is obtained for the dry air.

Assuming that the perfect gas laws can be applied to water vapor at saturation at low pressures, the partial pressure of water vapor in a *saturated* mixture may be written as

$$p_s = \frac{n_s}{n_a + n_s} p \tag{19}$$

where

n_s = number of mols of water vapor at saturation.

The relative humidity may be obtained by combining

Equations 18 and 19 and solving for the ratio of mol fractions. Thus, using perfect gas relationships,

$$\phi = \frac{p_w}{p_a} \tag{20}$$

The humidity ratio W may be obtained from Equation 17:

$$W = \frac{18.016}{28.961}\frac{p_w}{p_a} = 0.622\,\frac{p_w}{p - p_w} \tag{21}$$

where 18.016 and 28.966 are the molecular weights of water and dry air, respectively.

Equation 16 may be rewritten as

$$h = h_a + Wh_w \tag{22}$$

where

h = enthalpy, Btu per pound of dry air.

In relating the enthalpy to the state of the moist air, the fact that in all applications only differences in enthalpy are involved, allows the arbitrary selection of a datum or zero enthalpy point. Accordingly, from perfect gas relationships, it is possible to write for any temperature t (Fahrenheit) greater than 0 F

$$h_a = 0.24\,t \tag{23}$$

where it is assumed that the same arbitrary datum of 0 F is used as in determining the properties of moist air in Table 2.

Tables of Thermodynamic Properties of Moist Air

Research work conducted at the University of Pennsylvania and at other institutions has shown that the Gibbs-Dalton Rule is inaccurate in varying degrees, depending on temperature, pressure, and the amount of water vapor present. This inaccuracy is probably due to the effect of:

1. Chemical solution of gas molecules in the water vapor.
2. The finite size of the molecules causing interference with the free passage of other molecules toward the boundaries of the system.
3. Intermolecular forces of attraction and repulsion.

Many attempts have been made to develop an equation of state which would predict the true states of real gases and vapors. The Van der Waal, Maxwell, and Beattie-Bridgman equations are probably the best known. Unfortunately, these expressions rapidly become much too complicated to be used in everyday calculations and, therefore, engineers find it more convenient to use tables of thermodynamic properties for specific working substances, as these can be prepared by physicists using the best laboratory equipment and all the refinements of mathematics.

Mechanical engineers have long been familiar with such tables for the properties of steam. Tables of the properties of moist-air, as prepared by Goodenough and others, have been available for some time, but the latest and most precise of such tables are those which have resulted from a cooperative research agreement between the American Society of Heating and Air-Conditioning Engineers and the Towne Scientific School of the University of Pennsylvania. These properties are published herein as Table 2, and are taken from a research report by Goff and Gratch.[4] Table 2, which experimentally and mathematically takes into account deviations from perfect gas behavior, such as those listed above, makes the application of the Gibbs-Dalton Rule a less frequent necessity.

In Table 2 there are 15 columns of figures, each column being headed by a suitable symbol. In the following subparagraphs brief explanations are given of the data in Table 2 under the appropriate column headings.

t(F) = Fahrenheit temperature defined in terms of absolute temperature T by the relation,

$$T = t + 459.67 \tag{24}$$

W_s = humidity ratio at *saturation*. Saturation is the condition at which the vapor phase (moist air) may exist in equilibrium with a condensed phase (liquid or solid) at the given temperature and pressure (standard atmospheric pressure in the case of Table 2). At given values of temperature and pressure, the humidity ratio W can have any value from zero to W_s.

v_a = specific volume of dry air, cubic feet per pound.

$v_{aa} = v_s - v_a$, the difference between the volume of moist air *at saturation*, per pound of dry air, and the specific volume of the dry air itself, cubic feet per pound of dry air.

v_s = specific volume of moist air *at saturation* per pound of dry air, cubic feet per pound of dry air.

h_a = specific enthalpy of dry air, Btu per pound of dry air. The specific enthalpy of dry air has been assigned the value zero at 0 F, standard atmospheric pressure. The energy unit Btu is related to the foot-pound by definition, as follows: 1 Btu = 778.3 ft-lb.

$h_{aa} = h_s - h_a$, the difference between the enthalpy of moist air *at saturation*, per pound of dry air, and the specific enthalpy of the dry air itself, Btu per pound of dry air.

h_s = enthalpy of moist air *at saturation* per pound of dry air, Btu per pound of dry air.

s_a = specific entropy of dry air, Btu per (pound) (Fahrenheit degree). It will be noticed that the specific entropy of dry air has been assigned the value zero at 0 F and standard atmospheric pressure.

$s_{aa} = s_s - s_a$, the difference between the entropy of moist air *at saturation*, per pound of dry air, and the specific entropy of the dry air itself, Btu per (pound of dry air) (Fahrenheit degree).

s_s = entropy of moist air *at saturation* per pound of dry air, Btu per (pound of dry air) (Fahrenheit degree).

h_w = specific enthalpy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per pound of water. The specific enthalpy of liquid water has been assigned the value zero at 32 F, saturation pressure (0.088586 psia).

s_w = specific entropy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per (pound of water) (Fahrenheit degree). The specific entropy of liquid water has been assigned the value zero at 32 F, saturation pressure (0.088586 psia).

p_s = saturation pressure of pure water vapor, pounds per square inch or inches of mercury (absolute pressure). At a given pressure, moist air can be saturated at any temperature, though this requires that it have a definite humidity ratio W, and that the coexisting condensed phase contain a definite, but very small, quantity of dissolved air. On the other hand, pure water vapor (steam) below the critical temperature, can be saturated at only one temperature for a given pressure. The values of saturation pressure listed in Table 2 have been computed from the formulas of Goff and Gratch.

THERMODYNAMIC PROPERTIES OF WATER AT SATURATION

Since water vapor at low pressures acts almost as a perfect gas, the enthalpy of water vapor should also be a function only of the temperature within these limits. Therefore, the enthalpy of the water vapor may be expressed as approximately equal to the enthalpy of saturated vapor at the dry-bulb temperature of the mixture. Substituting these values in Equation 22, the enthalpy of the mixture becomes

$$h = 0.24\,t + Wh_s \tag{25}$$

where h_s is the value of the enthalpy of saturated vapor at the temperature t, and is obtained from Table 3.

Table 3 offers revisions to existing steam table data with extensions downward to −160 F. These revisions and extensions were a necessary preliminary to the construction of Table 2. A detailed explanation of the methods employed in the construction of Table 3 is given in a paper by John A. Goff and S. Gratch.[5]

As in Table 2, the temperature scale used as argument in Table 3 is the Fahrenheit scale defined in terms of absolute temperature T by Equation 24. The symbols used as column headings in Table 3 are the same as those used in steam tables, and have the same meanings.

Properties of water above 212 F from Keenan and Keyes[6] are given in Table 4.

DEGREE OF SATURATION

Degree of saturation has previously been defined as the ratio of the actual humidity ratio to the humidity ratio of saturated air at the same dry-bulb temperature and barometric pressure. This may be stated mathematically as

$$\mu = \frac{W}{W_s} \tag{26}$$

Obviously the degree of saturation μ can have any value from zero (dry air) to unity (moist air at saturation). The degree of saturation is conveniently used to interpolate values for the enthalpy, specific volume, and entropy of moist air from the data of Table 2. Within the estimated precision of the data of Table 2, at temperatures below 150 F, the volume v, enthalpy h, and entropy s, of moist air *per pound of dry air* at any degree of saturation μ may be computed from the simple relations:

$$v = v_a + \mu v_{aa} \tag{27}$$

$$h = h_a + \mu h_{aa} \tag{28}$$

$$s = s_a + \mu s_{aa} \tag{29}$$

Thus, the degree of saturation is used in conjunction with Table 2 in the same manner as the quality is used with tables of the thermodynamic properties of steam.

Correction of Table 2 for Temperatures Above 150 F

The simple relations expressed in Equations 27, 28, and 29 give the properties of unsaturated air with satisfactory precision for most engineering design problems. Above 150 F, when greater precision than that obtained by Table 2 is required, these simple relations can be adjusted by the addition of supplementary terms.

To correct the volume, it is necessary to add a correction term $\bar{v}$ which is defined as

$$\bar{v} = \frac{\mu(1-\mu)A}{1 + aW_s\mu} \tag{30}$$

where a denotes the ratio of the apparent molecular weight of dry air (28.966) to the molecular weight of water (18.016), and is equal to 1.6078. Table 5 gives the values of the coefficient A for several higher temperatures, the value of μ at which the correction term $\bar{v}$ attains its maximum value, and the maximum value of $\bar{v}$ term there attained.

The correction term for the enthalpy is

$$\bar{h} = \frac{\mu(1-\mu)B}{1 + aW_s\mu} \tag{31}$$

Table 5 gives the values of the coefficient B and maximum values of $\bar{h}$, the maximum values occurring at the same degree of saturation as $\bar{v}$.

Corrections for the entropy consist of two terms: $\bar{s}$ which is defined as

$$\bar{s} = \frac{\mu(1-\mu)C}{1 + aW_s\mu} \tag{32}$$

and s, the so-called *mixing entropy*, which contributes the larger part of the error. The *mixing entropy* is defined as

$$s = 0.1579\,[(1 + \mu aW_s)\log_{10}(1 + \mu aW_s) - \mu aW_s\log_{10}(\mu) - \mu(1 + aW_s)\log_{10}(1 + aW_s)] \tag{33}$$

Table 5 lists the values of the coefficient C, the maximum values of $\bar{s}$ and $\bar{\bar{s}}$ and the values of μ at which they occur. The maximum $\bar{s}$ occurs at the same degree of saturation as the maximum values of $\bar{v}$ and $\bar{h}$.

THE ASHAE PSYCHROMETRIC CHART

A psychrometric chart is a graphical representation of the thermodynamic properties of moist air. To be of real value in the solution of engineering problems, it must have distinctive features which aid in problem analysis.

An examination of psychrometric mass and energy balances shows that no properties other than *enthalpy* and *humidity ratio* are required for the solution of problems. It is logical, then, to use these properties as the coordinates of a psychrometric chart. This was initially done by Mollier in 1923,[7, 8] and is the arrangement followed in the chart included with The Guide. The ASHAE Psychrometric Chart is based on the best thermodynamic data available today, namely, those of Goff and Gratch, as given in Table 2. The chart is plotted on oblique coordinates of enthalpy and humidity ratio; the enthalpy axis making an angle of approximately 40 deg with the humidity ratio axis. This is shown in Fig. 3.

For practical use, the inclusion of dry-bulb and wet-bulb temperatures, volumes, and indexes of the condition of the

air in relation to saturation, is necessary for locating and describing states on the chart. The arrangement of the families of curves of constant dry-bulb temperature, wet-bulb temperature, volume, relative humidity, and degree of saturation, are shown in Fig. 4.

Mass and energy balances deal only with net changes between definite states; the detailed history of a change is not involved. A chart used to facilitate such calculations must primarily aid in clearly establishing states. Lines drawn on the chart to connect different states need have no other significance than being loci lines, that is, lines which contain the two terminal points of a change according to the particular overall conditions imposed. Loci lines are commonly called *condition lines* for the processes concerned. On the ASHAE Chart a condition line is characterized by the ratio $(h_2 - h_1)/(W_2 - W_1)$.

An abridgment of the ASHAE Psychrometric Chart appears in Fig. 5. A large size (24 x 32) chart will be found inside of the back cover.

The chart is drawn for standard atmospheric pressure. Steady flow changes commonly involve pressure drops with the flow, but so long as these pressure drops remain a small fraction of the barometric pressure, no appreciable errors need arise from using a constant pressure chart. For many design problems, the use of the standard pressure chart will not incur any undue error up to about 2000 ft above sea level.

The region above the saturation curve is a two-phase region giving equilibrium states for water in both the liquid and vapor phases. The ordinate of a point in this region is the weight of water in both phases per pound of dry air in the vapor phase, neglecting any dissolved air in the condensed phase. The ordinate at the saturation curve, or the

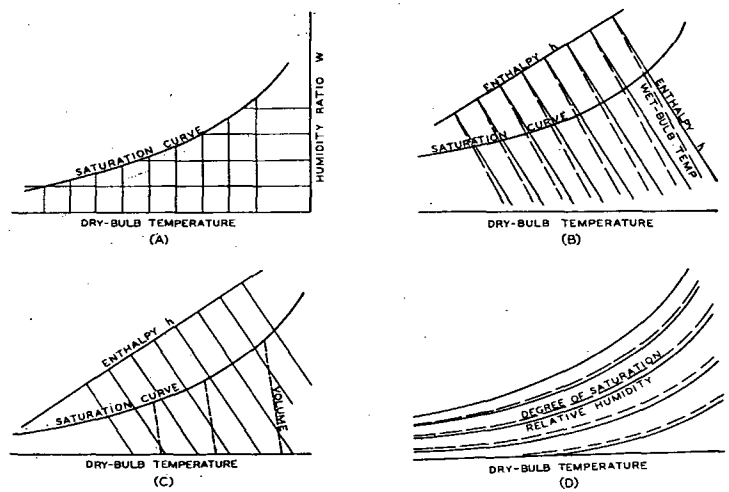

Fig. 4 .... Arrangement of Families of Curves on ASHAE Psychrometric Chart

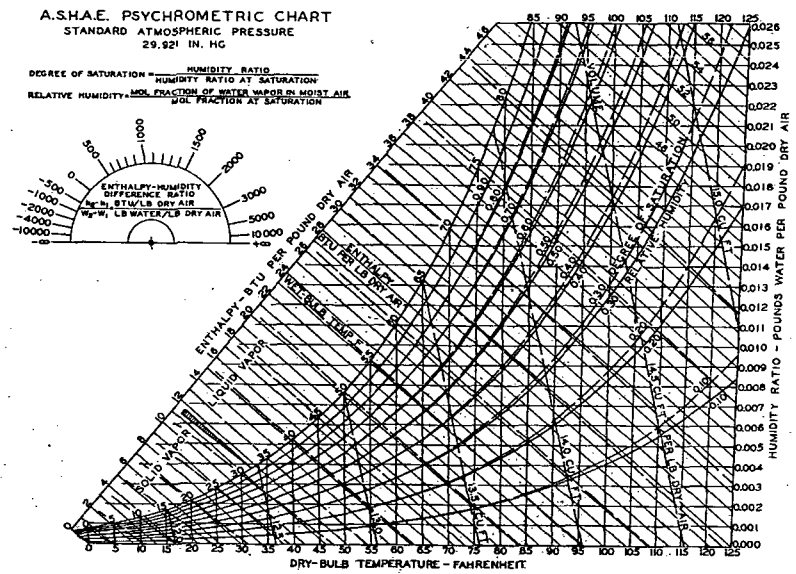

Fig. 5 . . . . Abridgment of ASHAE Psychrometric Chart

point at which the break in the isotherm through the point in question occurs, is the weight of water per pound of dry air in the vapor phase. Consequently, the difference between the two ordinates is the weight of condensed moisture per pound of dry air in the vapor phase.

The shaded solid-liquid-vapor region at 32 F is an isothermal three-phase zone, and separates the liquid-vapor zone from the solid-vapor zone. The temperature is 32 F throughout the shaded area.

It is possible to obtain two values for the wet-bulb temperature when this temperature is below 32 F. If the bulb of a thermometer is dipped into water at a temperature slightly above 32 F and held in a stream of air whose wet-bulb temperature is below 32 F, the temperature indicated by the thermometer will drop rapidly until a minimum is reached below 32 F. This will be accomplished without the formation of ice on the bulb of the thermometer. After reaching this minimum temperature, the reading will jump back to 32 F and remain there until the water on the bulb is frozen, after which it will slowly drop again until equilibrium is reached. The final temperature may be higher or lower than the first minimum reading, or it may be the same depending on the amount of moisture present in the mixture. In the absence of reliable data on the wet-bulb temperature over subcooled water, the chart, below 32 F, has been drawn for the equilibrium condition, that is, the values plotted on the ASHAE chart are for the condition where the minimum temperature is reached with ice on the bulb of the thermometer.

USE OF TABLE 2 AND THE ASHAE PSYCHROMETRIC CHART

The use of Table 2 and the ASHAE PSYCHROMETRIC CHART in analyzing typical air-conditioning problems is best explained by means of illustrative examples. In each of the following it is to be understood that the processes in question take place at a constant pressure of 29.921 in. Hg, i.e., standard atmospheric pressure.

Example 1: Determine the enthalpy of moist air at 80 F dry-bulb temperature and 0.40 degree of saturation.

Solution a: From the data of Table 2, at 80 F, h_a = 19.221 Btu per lb of dry air and h_{as} = 24.47 Btu per lb of dry air. Then h at the specified conditions is 19.221 + 0.40(24.47) = 29.01 Btu per lb of dry air.

Solution b: From the ASHAE Chart. Follow the 80 F dry-bulb line upward until it intersects the 0.40 degree of saturation line. From this intersection, follow the line of constant enthalpy to the enthalpy scale and read 29.00 Btu per lb of dry air.

Example 2: Determine the thermodynamic wet-bulb temperature of moist air at the conditions of *Example 1*.

Solution a: From the data of Table 2. Applying Equation 8, h_1 = 29.01 Btu per lb of dry air (*Example 1*). As a first approximation this is $h_1{}^*$ the enthalpy at saturation at the thermodynamic wet-bulb temperature which is, therefore, approximately 63.5 F. W^* at 63.5 F is 12.57 × 10⁻³ lb of water vapor per lb of dry air, and W_1 is 0.02233 × 0.40 = 0.00893 lb of water vapor per lb of dry air. The specific enthalpy of liquid water at 63.5 F is 31.58 Btu per lb of water. As a second approximation, h^* = 29.01 + (0.01257 − 0.00893) (31.58) = 29.12 Btu per lb of dry air. Interpolation in Table 2 gives as the final answer t^* = 63.64 F.

Solution b: From the ASHAE Chart. At the intersection of the 80 F dry-bulb temperature line and the 0.40 degree of saturation line, read the thermodynamic wet-bulb temperature.

Heating of Moist Air at Constant Pressure Without Addition of Moisture

Example 3: Air initially at 20 F, 0.80 degree of saturation, is heated to 120 F. Find the quantity of heat required to process 20,000 cfm of heated air.

The process is diagrammatically illustrated in Fig. 6. The energy equation for the process is

$$Gh_1 + {}_1q_2 = Gh_2$$

$${}_1q_2 = G(h_2 - h_1)$$

Solution a: From the data of Table 2. The initial humidity ratio, which is the same as the final humidity ratio, is 0.80 (0.002152) = 0.001722 lb of water vapor per lb of dry air; the initial enthalpy is 4.804 + 0.80(2.302) = 6.646 Btu per lb of dry air; the final degree of saturation is 0.001722/0.08149 = 0.02113; the final enthalpy is 28.841 + 0.02113(90.70) = 30.757 Btu per lb of dry air; the final volume is 14.611 + 0.02113 (1.905) = 14.651 cu ft per lb of dry air. Since 20,000 cfm of heated air are to be processed, the total quantity of heat required is

$${}_1q_2 = (20{,}000/14.651) \times 24.111 = 32{,}914 \text{ Btu per min.}$$

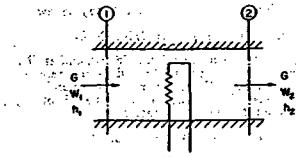

Fig. 6 . . . . Illustration of Process of *Example 3*

Solution b: From the ASHAE Chart. The process is represented by the horizontal line 1–2, Fig. 7. The initial enthalpy, at 20 F dry-bulb temperature and 0.80 degree of saturation, is 6.65 Btu per lb of dry air. Since the final humidity ratio is the same as the initial humidity ratio, the ratio $(h_2 - h_1)/(W_2 - W_1) = \infty$. The horizontal line 1–2, Fig. 7, then represents the condition line for the process, and the final state of the moist air must lie on this line. The final state is located at the point at which the 120 F dry-bulb temperature line crosses the condition line, and is labeled Point 2 on the figure. At this condition the final enthalpy is 30.8 Btu per lb of dry air and the final specific volume is 14.65 cu ft per lb of dry air. Substituting these values in the energy equation,

$${}_1q_2 = (20{,}000/14.65) \times (30.8 - 6.65) = 32{,}950 \text{ Btu per min.}$$

Cooling of Moist Air at Constant Pressure with Condensation of Water

Referring to Fig. 8, moist air cooled from State 1 passes through successive states along the line, $W = W_1$ = constant, until the saturation line is intersected. The temperature at this point of intersection is by definition the dew-point temperature for State 1.

Further cooling through successive equilibrium states is accompanied by condensation. The succession of states for the total system, moist air, and liquid water, is represented by a continuation of the $W = W_1$ line into the liquid-vapor region. (Temperatures below 32 F would involve the solid-vapor region.) Consider that the final temperature is t_3. The final enthalpy is then h_3; the liquid water formed is $(W_1 - W_3)$,

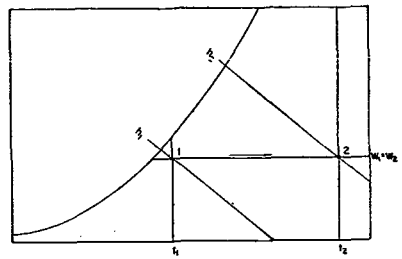

Fig. 7 . . . . Solution of *Example 3* on ASHAE Psychrometric Chart

where Point 3 is at the intersection of the isotherm through 2 and the saturation curve; the final humidity ratio of the moist air is W_3; and this final moist air has dew-point, wet-bulb, and dry-bulb temperatures all equal to t_3.

Example 4: How much heat must be removed from 20,000 cfm of air at 95 F dry-bulb temperature and 0.50 degree of saturation to cool the air to 70 F, saturated?

Solution a: From the data of Table 2. The initial humidity ratio is 0.50(0.03673) = 0.01837 lb of water vapor per lb of dry air; the initial enthalpy is 22.827 + 0.50(40.49) = 43.072 Btu per lb of dry air; the humidity ratio at saturation at the final temperature is 0.01582 lb of water vapor per lb of dry air; the quantity of liquid formed is 0.01837 − 0.01582 = 0.00255 lb of water vapor per lb of dry air; h_{ws} at 70 F is 38.11 Btu per lb of water; the initial specific volume is 13.980 + 0.50(0.822) = 14.391 cu ft per lb of dry air.

Fig. 9 illustrates the process diagrammatically. The energy equation for the process is

$$Gh_1 = Gh_3 + G(W_1 - W_3)h_{ws} + {}_1q_3$$

$${}_1q_3 = G[h_1 - h_3 - (W_1 - W_3)h_{ws}]$$

$$= \frac{20{,}000}{14.391} \times (43.072 - 34.09 - 0.00255 \times 38.07)$$

$$= 12{,}350 \text{ Btu per min.}$$

Solution b: From the ASHAE Chart. Two methods may be used to solve the problem by use of the psychrometric chart. The simpler is to use the region to the left of the saturation line (Fig. 8). From Point 1 draw a horizontal line on the chart

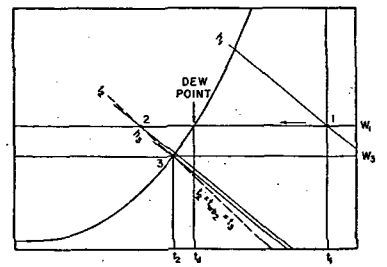

Fig. 8 . . . . Cooling of Air at Constant Pressure Shown on ASHAE Psychrometric Chart

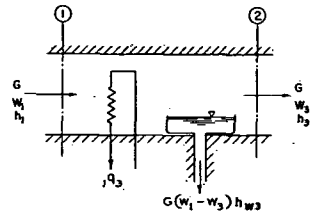

Fig. 9 .... Illustration of Process of *Example 4*

until it intersects the constant temperature line in the liquid-vapor region corresponding to the final temperature 70 F. This is shown as Point 2 on the diagram. Then,

$$_1q_3 = G(h_1 - h_3)$$

The initial enthalpy is 43 Btu per lb of dry air; the initial specific volume is 14.4 cu ft per lb of dry air; and the final enthalpy is 34.2 Btu per lb of dry air. The solution of the problem is

$$_1q_3 = \frac{20{,}000}{14.4} \times (43 - 34.2) = 12{,}200 \text{ Btu per min.}$$

The other method is to use an energy balance,

$$_1q_3 = G[h_1 - h_3 - h_{w3}(W_1 - W_3)]$$

The initial humidity ratio is 0.0183 lb of water vapor per lb of dry air, and the final humidity ratio is 0.0158 lb of water vapor per lb of dry air. Therefore, the heat to be removed is

$$_1q_3 = \frac{20{,}000}{14.4} \times (43 - 34.1 - 0.0025 \times 38.07)$$

$$= 12{,}130 \text{ Btu per min.}$$

Adiabatic Mixing of Two Steady Flow Air Streams at Constant Pressure

The process is diagrammed in Fig. 10. By applying the principles of the conservation of mass and energy, three equations may be written:

Mass balance for the dry air,

$$G_1 + G_2 = G_3$$

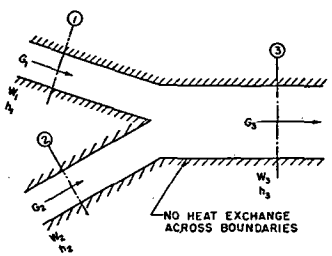

Fig. 10 .... Illustration of Mixing of Two Steady Flow Streams at Constant Pressure

Energy balance for the process,

$$G_1h_1 + G_2h_2 = G_3h_3$$

Mass balance for the water vapor,

$$G_1W_1 + G_2W_2 = G_3W_3$$

Eliminating G_3 and combining the three equations yields the equation,

$$\frac{h_2 - h_3}{h_3 - h_1} = \frac{W_2 - W_3}{W_3 - W_1} = \frac{G_1}{G_2} \tag{34}$$

Example 5: Outdoor air at 0 F dry-bulb temperature and 0.80 degree of saturation is to be mixed adiabatically with recirculated indoor air at 70 F dry-bulb temperature and 0.20 degree of saturation, in the ratio of one pound of dry air in the former to four in the latter. Find the temperature and degree of saturation in the resulting mixture.

Solution a: From the data of Table 2. The only unknown properties are the humidity ratio W_3 and the enthalpy h_3 of the resulting mixture. These may be determined from Equation 34. Thus,

$$\frac{20.270 - h_3}{h_3 - 0.668} = \frac{0.003164 - W_3}{W_3 - 0.000630} = \frac{1}{4}$$

from which $h_3 = 16.350$ and $W_3 = 0.002657$. The enthalpy of the final mixture may also be expressed by Equation 28:

$$h_3 = h_a + \mu h_{as}$$

Since μ by definition is W_3/W_s, Equation 28 may be rewritten as

$$16.350 = h_a + (0.002657/W_s) \times h_{as}$$

At 56 F the right side of the equation is 16.332, and at 57 F it is 16.582. Interpolation gives as the final dry-bulb temperature of the mixture 56.07 F. At this temperature the humidity ratio at saturation is 0.00960 lb of water vapor per lb of dry air. Therefore, the final degree of saturation is

$$\mu = 0.002657/0.00960 = 0.277$$

Solution b: From the ASHAE Chart. Equation 34 indicates that the state point of the resulting mixture lies on a straight line connecting the state points of the two streams being mixed, and divides this line into two segments whose respective lengths are inversely proportional to the rates of dry air flow in the corresponding streams. This is illustrated in Fig. 11. Points 1 and 2 are located and connected by a straight line. The state of the final mixture is set so that

$$\frac{G_1}{G_2} = \frac{D_{2-3}}{D_{3-1}} = \frac{1}{4}$$

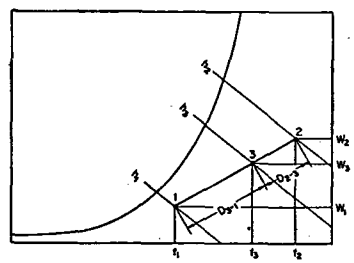

Fig. 11 .... Solution of *Example 5* on ASHAE Psychrometric Chart

Scaling the distances on the chart, the required solution to *Example 5* is 56 F dry-bulb temperature and 0.28 degree of saturation.

Addition of Moisture to an Adiabatic Stream

Consider a stream of moist air flowing adiabatically between two sections, 1 and 2, as in Fig. 12, with moisture addition at the rate $G_1(W_2 - W_1)$ and the moisture having the enthalpy h_w Btu per pound of moisture.

An energy balance yields

$$G_1h_1 + G_1(W_2 - W_1)h_w = G_1h_2 \tag{35}$$

Example 6: Liquid water chilled to 40 F is injected into an air stream initially at 95 F dry-bulb temperature and 80 F thermodynamic wet-bulb temperature. At what temperature will saturation be reached? How much water must be evaporated to reach saturation?

Solution a: From the data of Table 2. The solution of Equation 35 for h_2 yields

$$h_2 = h_1 + (W_2 - W_1)h_w$$

The initial enthalpy of the moist air h_1 must be found from Equation 8,

$$h_1 = h^* - (W^* - W_1)h_w^*$$

$$22.827 + \mu 40.49 = 43.69 - (0.02233 - 0.03673\mu) \quad (48.05)$$

from which $\mu = 0.511$.

Hence,

$$h_1 = 22.827 + 0.511(40.49)$$

$$= 43.52 \text{ Btu per lb of dry air.}$$

and

$$W_1 = 0.03673(0.511)$$

$$= 0.01877 \text{ lb per lb of dry air.}$$

The solution of Equation 35 is

$$h_2 = 43.52 + (W_2 - 0.01877)(8.09)$$

By trial and error, this equation will be satisfied at the temperature 79.87 F. At this temperature the humidity ratio W_2 is 0.02223. The weight of water evaporated is therefore $0.02223 - 0.01877 = 0.00346$ lb per lb of dry air.

Solution b: From the ASHAE Chart. Solution of Equation 35 for the ratio $(h_2 - h_1)/(W_2 - W_1)$ yields

$$\frac{h_2 - h_1}{W_2 - W_1} = h_w \tag{36}$$

The slope of the condition line is therefore determined by

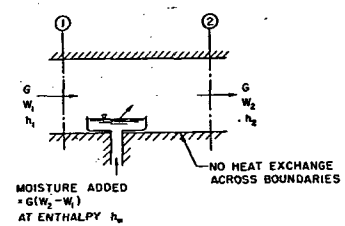

Fig. 12 .... Illustration of Addition of Moisture to an Adiabatic Stream

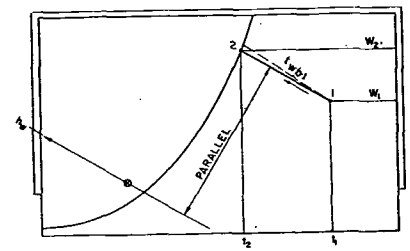

Fig. 13 .... Solution of *Example 6* on ASHAE Psychrometric Chart

the enthalpy of the water which is supplied. This slope is established on the chart by connecting the center of the protractor on the psychrometric chart with the value of h_w on the protractor. Draw a line parallel to this reference line through the initial Point 1 (Fig. 13). The second line is the condition line for the process. Since the conditions of the problem require the final point to lie on the saturation line, the intersection of the condition line with the saturation line gives the desired solution.

Adiabatic Saturation

Adiabatic saturation is the designation given any process in which the state of moist air is changed from some initial unsaturated condition to a saturated one without the addition or removal of heat. According to this definition, the addition of moisture to an adiabatic stream may become an adiabatic saturation process. *Example 6* is an illustration.

A type of adiabatic saturation of further practical interest is the use of continually recirculated spray water in a saturating air washer. Here the spray water will ultimately come to the same temperature as the saturated leaving air; this temperature is, by definition, the thermodynamic wet-bulb temperature. Hence, adiabatic saturation in this manner will have the final state point on the saturation curve, with the same thermodynamic wet-bulb temperature as the original state point.

In a process such as this, the moist air enthalpy changes very slightly. The moisture added and temperature change may be obtained from the psychrometric chart as sketched in Fig. 14.

Example 7: Moist air at 75 F dry-bulb temperature and 0.60 degree of saturation, is saturated adiabatically with recircu-

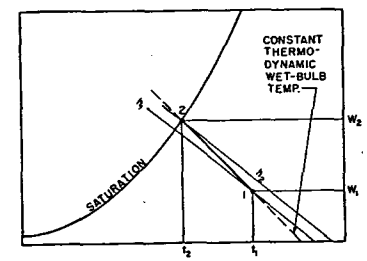

Fig. 14 .... Moisture Added and Temperature Change

lating spray water. Find the amount of water added and the change in enthalpy.

Solution a: From the data of Table 2. As previously stated, the final temperature of the mixture will be the thermodynamic wet-bulb temperature at the initial state. This must first be determined by the method of *Example 2*, and is 65.51 F. At this temperature the humidity ratio at saturation and enthalpy at saturation are 0.01350 and 30.45, respectively. The humidity ratio at the initial state is 0.60(0.01882) = 0.01129; the initial enthalpy is 0.60(20.59) + 18.018 = 30.372. The weight of water added is therefore 0.01350 − 0.01129 = 0.00221 lb per lb of dry air; the enthalpy change is 30.45 − 30.372 = 0.078 Btu per lb of dry air.

Solution b: From the ASHAE Chart. Since the initial and final states have the same thermodynamic wet-bulb temperature, the results may be read directly from the chart.

Addition of Heat and Water Vapor to an Air Stream in Steady Flow

Fig. 15 is a schematic representation of a system operating at constant pressure, *where*

G_1 is the rate of flow of dry air, pounds per minute.

G_w is the rate of evaporation of the water, pounds per minute.

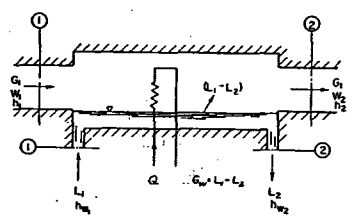

Fig. 15 .... Illustration of Addition of Heat and Water Vapor to an Air Stream in Steady Flow

h_w is the enthalpy of the liquid water entering, Btu per pound.

Q is the rate of heat addition, Btu per minute.

An energy balance for the system gives

$$G_1h_1 + Q + G_wh_w = G_1h_2 \tag{37}$$

A mass balance gives

$$G_1 + G_1W_1 + G_w = G_1 + G_1W_2$$

or

$$G_1W_1 + G_w = G_1W_2 \tag{38}$$

Combining Equations 37 and 38 and solving for the ratio $(h_2 - h_1)/(W_2 - W_1)$,

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{Q}{G_w} + h_w \tag{39}$$

Example 8: Moist air at 20 F dry-bulb temperature and 0.80 degree of saturation is heated and humidified until it is at 120 F dry-bulb temperature and 71.5 F thermodynamic wet-bulb temperature. Water at 55 F is supplied. If the air-flow rate is 20,000 cfm at the initial conditions, how much heat is required?

Solution a: From the data of Table 2. The initial humidity ratio is 0.80(0.002152) = 0.00172; the initial enthalpy is 4.804 + 0.80(2.302) = 6.6456; the initial specific volume is 12.084 + 0.80(0.042) = 12.118. The degree of saturation at the final

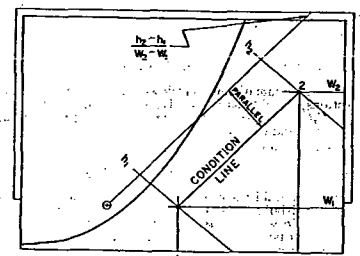

Fig. 16 .... Solution of *Example 8* on ASHAE Psychrometric Chart

state may be determined from Equation 8 which may be rewritten as

$$h_{as} + \mu h_{as_2} + h_w^*(W^* - \mu W_{s_2}) = h^*$$

The values of these properties are: $h^* = 35.39$; $W^* = 0.01668$; $h_w^* = 39.61$; $h_{as_2} = 90.70$; $W_{s_2} = 0.08149$; $h_{s_2} = 28.84$.

Making the proper substitutions and solving for degree of saturation,

$$\mu = 0.0681$$

The final humidity ratio is therefore 0.0681(0.08149) = 0.005549; the final enthalpy is 28.84 + 0.0681(90.70) = 35.02 Btu per lb dry air.

The rate of water addition is obtained from Equation 38.

$$G_w = \frac{20{,}000}{12.12}(0.005549 - 0.00172)$$

$$= 6.32 \text{ lb per min.}$$

The heat supplied is obtained from Equation 37.

$$Q = G_1(h_2 - h_1) - G_wh_w$$

$$= \frac{20{,}000}{12.12}(35.02 - 6.65) - 6.32(28.08)$$

$$= 46{,}667 \text{ Btu per min.}$$

Solution b: From the ASHAE Chart. Locate the initial and final states on the chart and connect them with a straight line. Through the reference point on the chart, draw a line parallel to the line connecting the initial and final state points, the condition line, and read the value of the ratio $(h_2 - h_1)/(W_2 - W_1)$ as 7500 from the protractor on the chart (Fig. 16). From Equation 39

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{Q}{G_w} + h_w = 7500$$

The rate of water supply was determined in *Solution a*, but will be found from the chart. It is

$$G_w = \frac{20{,}000}{12.1}(0.0055 - 0.0017)$$

$$= 6.28 \text{ lb per min}$$

$$Q = G_w(7500 - h_w)$$

$$= 6.28(7500 - 23)$$

$$= 46{,}900 \text{ Btu per min.}$$

U. S. STANDARD ATMOSPHERE

The definition of the U. S. Standard Atmosphere is important to the air-conditioning engineer as an essential standard of reference. The basic assumptions in defining the Standard Atmosphere are:

1. There is a linear decrease in temperature T with altitude up to the limit of the isothermal atmosphere at 35,332 ft. Thus,

$$T = T_s - 0.003566\,Z \tag{40}$$

2. The air is dry.
3. Air is a perfect gas obeying the laws of Charles and Boyle:

$$PV = RT$$

4. Gravity is constant at all altitudes with the standard value.
5. The temperature of the isothermal atmosphere is −66 F.

Table 6 .... Pressure and Temperature for Altitudes in U. S. Standard Atmosphere

Altitude Feet Z	Pressure In. of Hg P	Temp F t
−1,000	31.02	+62.6
−500	30.47	+60.8
0	29.921	+59.0
+500	29.38	+57.2
+1,000	28.86	+55.4
+5,000	24.89	+41.2
10,000	20.58	+23.4
15,000	16.88	+5.5
20,000	13.75	−12.3
25,000	11.10	−30.1
30,000	8.88	−47.9
35,000	7.04	−65.8
40,000	5.54	−67.0
45,000	4.36	−67.0
50,000	3.436	−67.0

Standard values at sea level, which are part of the definition of the Standard Atmosphere, are:

Pressure	29.921 in. Hg
Temperature	59 F
Absolute Temperature	518.67 F abs
Gravity	32.1740 ft per (sec) (sec)
Density	0.076505 lb per cu ft

Values of pressure and temperature are listed in Table 6 for altitudes in the standard atmosphere from −1000 to 50,000 ft above sea level. For further explanation, References 9 and 10 should be consulted.

LETTER SYMBOLS USED IN CHAPTER 3

μ = degree of saturation (decimal).
ρ = density of fluid, pounds per cubic foot.
ϕ = relative humidity (decimal).
a = ratio of apparent molecular weight of dry air (28.966) to the molecular weight of water (18.016) = 1.6078.
A = coefficient from Table 5 for use in Equation 30 (obtained from Table 5).
B = coefficient to be used in Equation 31 (obtained from Table 5).
C = coefficient for use in Equation 32 (obtained from Table 5).
f_s = factor accounting for effect of mixing air and water, dimensionless.
G = flow rate of dry air, pounds per hour.
G_1 = flow rate of dry air, pounds per minute.
G_w = rate of evaporation of water, pounds per minute.
H = enthalpy of the system.
H = enthalpy of the flowing medium, Btu per pound of dry air.
h = enthalpy of moist air, Btu per pound of dry air.
$\bar{h}$ = enthalpy correction term to be added above 150 F, to enthalpy.
h_a = specific enthalpy of dry air, Btu per pound.
$h_{as} = h_s - h_a$ = the difference between the enthalpy of moist air *at saturation* per pound of dry air, and the specific enthalpy of the dry air itself, Btu per pound of dry air.
h_g = enthalpy of saturated water vapor, Btu per pound.
h_s = enthalpy of moist air at saturation per pound of dry air, Btu per pound of dry air.
$h_s{}^*$ = enthalpy of moist air at saturation at *thermodynamic wet-bulb temperature* $t_s{}^*$ Btu per pound of dry air.
h_w = specific enthalpy of condensed water (liquid or solid) at standard pressure, Btu per pound water.
$h_w{}^*$ = specific enthalpy of water as added at the *thermodynamic wet-bulb temperature* $t_s{}^*$ Btu per pound of dry air.
h_{wl} = enthalpy of liquid water, Btu per pound.
h_{ws} = enthalpy of solid water, Btu per pound.
KE = kinetic energy, Btu per pound.
$\overline{KE}$ = average kinetic energy, Btu per pound.
L = flow rate of liquid water, pounds per hour.
m = weight of dry air crossing any duct section, pounds per minute.
n_a = mols dry air.
n_s = mols of water vapor at saturation.
n_w = mols of water vapor.
P = absolute pressure.
P_a = atmospheric pressure, inches Hg.
P_s = standard atmospheric pressure by definition 29.921 in. Hg.
P_s = saturation pressure of pure water at prevailing temperature.
p = total pressure of a mixture of air and water vapor, pounds per square inch or inches Hg.
p_a = partial pressure of dry air, pounds per square inch or inches Hg.
p_s = saturation pressure of pure water vapor, pounds per square inch or inches Hg.
p_w = partial pressure of water vapor in mixture of air and water vapor, pounds per square inch or inches Hg.
PE = potential energy, Btu per pound dry air.
$\overline{PE}$ = average potential energy, Btu per pound dry air.
Q = total heat added or subtracted, between sections, Btu per minute.
q = ratio of energy added (or removed) to water added (or removed), Btu per pound. Also called specific enthalpy of *water added*.
$_1q_2$ = energy added between points 1 and 2.
$_1q_2$ = heat added between sections 1 and 2, Btu per pound dry air.
R = universal gas constant, 1545 foot-pounds per (Fahrenheit degree) (mol).
R_a = gas constant for dry air.
R_w = gas constant for water vapor.
S = flow rate of solid water, pounds per hour.
s = entropy of moist air per pound of dry air, Btu per (pound) (Fahrenheit degree).

LETTER SYMBOLS (Continued)

$\bar{s}$ = correction to be added to entropy of moist air obtained from Table 2.
$\bar{\bar{s}}$ = additional correction to be added to entropy because of "mixing entropy" (obtained from Table 5). Correction to be added to value of s obtained from Table 2.
s_a = specific entropy of dry air, Btu per (pound) (Fahrenheit degree, absolute).
s_{as} = the difference between the entropy of moist air *at saturation* per pound of dry air, and the specific entropy of the dry air itself, Btu per (pound of dry air) (Fahrenheit degree, absolute).
s_s = entropy of moist air at saturation per pound of dry air, Btu per (pound of dry air) (Fahrenheit degree, absolute).
s_w = specific entropy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per (pound of water) (Fahrenheit degree, absolute).
T = absolute temperature, Fahrenheit degrees.
T_a = standard atmospheric temperature, by definition 518.4 F absolute.
t = temperature, Fahrenheit degrees.
t^* = thermodynamic wet-bulb temperature, Fahrenheit degrees.
U = internal energy of system.
U = internal energy.
V = volume.
$\overline{V}$ = average velocity, feet per minute.
v = volume of moist air per pound of dry air, cubic feet per pound.
$\bar{v}$ = correction to be added to volume of moist air per pound of dry air, above 150 F.
v_a = specific volume of dry air, cubic feet per pound.
$v_{as} = v_s - v_a$, the difference between volume of moist air *at saturation*, per pound of dry air, and the volume of the dry air itself, cubic feet per pound of dry air.
v_s = volume of moist air at saturation per pound of dry air, cubic feet per pound of dry air.
v_T = total volume, cubic feet.

LETTER SYMBOLS (Concluded)

W = humidity ratio of moist air, pounds of water per pound of dry air.
W_s = humidity ratio, *at saturation*, weight of water vapor per pound of dry air, pound per pound.
W_s^* = *humidity ratio* corresponding to *thermodynamic wet-bulb temperature* t,* pounds of water per pound of dry air.
w = work done by system.
w = shaft work withdrawn between sections 1 and 2, Btu per pound of air.
Z = elevation above any datum, feet.
$\bar{Z}$ = average elevation, feet.

Subscripts with symbols have following meanings: 1, 2, 3 indicate section of flow; a = air, w = water, wl = liquid water, ws = solid water, s = saturation, m = mixture; * indicates that the value is at thermodynamic wet-bulb temperature.

CHAPTER 4

FLUID FLOW

Theory of Fluid Flow, Pressure Loss in Circular Pipes, Pressure Loss in Non-Circular Pipes; Flow of Compressible Fluids, Ideal Flow Through Nozzle or Orifice; Flow Measurement, Head Meters, Location of Head Meters and Pressure Taps Pitot Tube, Variable Area Flow Meters

THE flow of fluids which is part of the branch of engineering science known as fluid mechanics will be discussed here insofar as it applies to the work of engineers in the fields of heating, ventilating, and air conditioning. Probably air is the most frequently handled fluid, but other gases and liquids are often involved. Compressible fluids (gases) and incompressible fluids (liquids) vary somewhat in behavior, though in cases where pressure and density changes are small, the gases may be treated as incompressible fluids.

THEORY OF FLUID FLOW

The following energy equation for one dimensional steady flow processes will serve as a basis for the theory of the flow of fluids. This equation is presented in several ways in various texts, but a suitable form is

$$\frac{V_1^2}{2g_c} + Ju_1 + p_1v_1 + Jq + \frac{g}{g_c}z_1 = \frac{V_2^2}{2g_c} + Ju_2 + p_2v_2 + W + \frac{g}{g_c}z_2 \quad (1)$$

where

V = velocity, feet per second.
g = gravitational acceleration, feet per (second) (second).
g_c = gravitational conversion factor = 32.174 (pounds mass per pound force) × ft per (second) (second).
J = mechanical equivalent of heat = 778 foot pounds per Btu.
u = internal energy, Btu per pound of fluid.
p = pressure per square foot, pounds.
v = specific volume, cubic feet per pound.
W = mechanical work done by the fluid, foot pounds per pound of fluid.
q = heat transferred to the fluid, Btu per pound of fluid flowing.
z = elevation above some arbitrary datum, feet.

Subscript 1 refers to the entrance, subscript 2 to the exit.

Introducing the enthalpy h, which by definition is $u + \frac{pv}{J}$, expressed in Btu per pound of fluid, Equation 1 becomes

$$\frac{V_1^2}{2g_c} + Jh_1 + Jq + \frac{g}{g_c}z_1 = \frac{V_2^2}{2g_c} + Jh_2 + W + \frac{g}{g_c}z_2 \quad (2)$$

The equivalent differential form for energy Equation 1 is

$$\frac{1}{2g_c}dV^2 + J\,du + d(pv)\frac{g}{g_c}dz - J\,dq + dW = 0 \quad (3)$$

Replacing v by its equal $g/g_c\rho$ (where ρ is density in pounds weight per cubic foot) and rearranging, Equation 3 becomes

$$\frac{1}{2g}dV^2 + \frac{1}{\rho}dp + dz + \frac{g_c}{g}\{J\,du + p\,dv - J\,dq + dW\} = 0 \quad (4)$$

In the case of flow through a pipe, no outside work is performed so that $dW = 0$. Furthermore,

$$J\,du + p\,dv = JT\,ds = J\,dq + JT\,ds' \quad (5)$$

where

ds = total change in entropy.
ds' = change in entropy due to internal irreversibility from turbulence and friction.

Accordingly, Equation 4 may be written

$$\frac{1}{2g}dV^2 + \frac{dp}{\rho} + dz + \frac{g_c}{g}JT\,ds' = 0^* \quad (6)$$

In cases where there is no internal irreversibility, $ds' = 0$, and Equation 6 may be integrated to give

$$\frac{V_1^2}{2g} + \frac{p_1}{\rho_m} + z_1 = \frac{V_2^2}{2g} + \frac{p_2}{\rho_m} + z_2 \quad (7)$$

where

ρ_m = proper mean density.

This is commonly called the Bernoulli equation, named after the Swiss mathematician and physician who first propounded

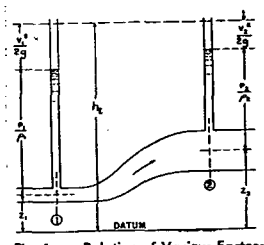

Fig. 1 .... Relation of Various Factors in Bernoulli Equation

* In the analysis of subsequent portions of this chapter the distinction between g and g_c will be omitted. Aside from the dimensional consistency the factor, g/g_c, is not in general significant in fluid flow analysis.

the theory. $\frac{V^2}{2g}$ is known as the velocity head, $\frac{p}{\rho}$ is the pressure head, and z is the elevation head, all in feet of the fluid; the total head, h_t is the sum of the other three heads. Fig. 1 shows diagrammatically the relation of the various factors. The pressure at point 2 is lower than at point 1 because of the elevation of point 2 over point 1, and the velocity at point 2 is lower than at point 1 because of the larger pipe diameter at point 2. If the pipe diameter were the same throughout, the velocity, and consequently the velocity head, would be the same at both points, but the higher elevation at point 2 would still be responsible for a loss in pressure. The utility of the equation is evident, though it should be remembered that in it the *effects of friction and turbulence are neglected,* and that Fig. 1 represents ideal conditions. It should also be noted that care must be taken in determining the proper mean density. Accordingly, the Bernoulli equation is applied most conveniently to incompressible fluids for which density is constant.

Pressure Loss in Circular Pipes

The pressure loss in circular pipes is customarily expressed by the formula:

$$h_f = \frac{flV^2}{2g\,d} \qquad (8)$$

where

h_f = the loss in head of the fluid under conditions of flow, feet.
l = the length of the pipe, feet.
V = the velocity, feet per second.
g = the acceleration due to gravity = 32.174 ft per (second) (second).
d = the internal diameter of the pipe, feet.
f = a dimensionless friction coefficient.

The formula is generally known by the name of Darcy or Fanning, though it seems to have been originated by d'Aubisson de Voisins in 1834.

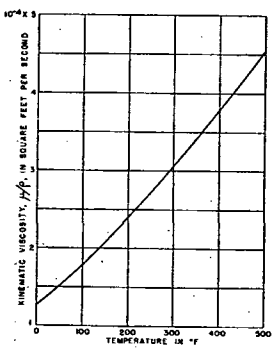

Fig. 2 .... Relation of Kinematic Viscosity to Temperature of Air

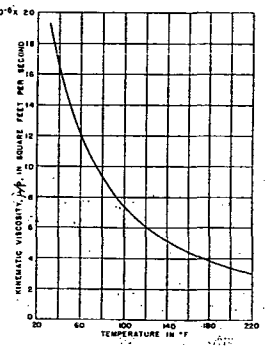

Fig. 3 .... Relation of Kinematic Viscosity to Temperature of Water

The factor f is a function of the Reynolds number,

$$N_{Re} = \frac{d\,V\rho}{\mu} \qquad (9)$$

where

N_{Re} = Reynolds number.
ρ = the density, pounds per cubic foot.
μ = the absolute viscosity, pounds per foot-second.

Both f and the Reynolds number are dimensionless. To aid in computing the Reynolds number, values of $\frac{\mu}{\rho}$, the kinematic viscosity, are shown as a function of temperature for air in Fig. 2, and for water in Fig. 3.

Fig. 4 shows the relation between f and the Reynolds number, adapted from a review by Moody.[1] The straight line sloping downward at the left of the chart supplies the values of f for laminar flow determined by the formula:

$$f = \frac{64}{N_{Re}} \qquad (10)$$

With laminar flow, the velocity profile is a parabola, having the formula:

$$V = \frac{\rho h_f}{4\mu l}(r^2 - L^2) \qquad (11)$$

where

r = the radius of the pipe, feet.
L = distance perpendicularly from the axis of the pipe, feet.

Accordingly, the maximum velocity occurs at the center of the pipe and is twice the average velocity; the average velocity is found when $L = 0.707\,r$. It is worth noting that roughness of the pipe wall has no effect on the loss in head for laminar flow.

Between values of the Reynolds number of 2000 and 4000,

[1] Superior numbers refer to the references at the end of chapter.

there is an unstable region where the flow changes from laminar to turbulent, or vice versa. The actual value is impossible of prediction for any conditions of flow, though in general it may be said that the prevailing type of flow persists into the unstable region; however, once a change starts, it proceeds very rapidly.

When the flow is turbulent, the velocity profile is essentially parabolic over four-fifths of the pipe diameter, but near the pipe walls, the effect of friction becomes evident, and in the boundary layer at the pipe wall the flow is laminar. Fig. 5 compares the velocity profiles for three different Reynolds numbers, but for the same average velocity.

The lower curve in the turbulent region in Fig. 4 represents the relation of f to the Reynolds number for smooth pipe, such as drawn brass tubing or glass tubing. The effect of roughness on f, an effect which is considerable in turbulent flow, is open to some conjecture; artificially roughened pipes, for instance, give results at variance with actual tests. The curves above the smooth pipe curve of Fig. 4 represent a summary of tests on rough pipe, each of them identified by a value of e/d, with e signifying the absolute roughness in feet. Values of e for different pipes are given in Table 1.

To find the friction loss for any pipe, follow the curve with the proper value of e/d, to the pertinent value of N_{Re}, and from this point proceed horizontally to left margin to find the value of f for use in Equation 8.

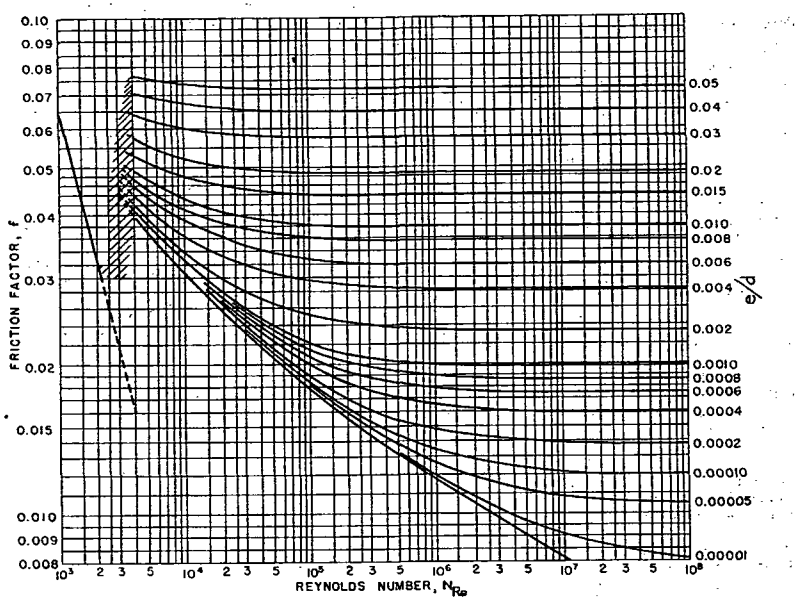

Table 1 .... Values of e for Different Kinds of Pipe

Type of Pipe	e
Smooth drawn tubing	0.000005
Commercial steel or wrought iron	0.00015
Asphalted cast-iron	0.0004
Galvanized iron	0.0005
Cast-iron	0.00085
Wood stave	0.0006 to 0.003
Concrete	0.001 to 0.01
Riveted steel	0.003 to 0.03

The curves in Fig. 4 may be approximated very closely by the empirical formula:[1]

$$f = 0.0055\left[1 + \left(20{,}000\,\frac{e}{d} + \frac{10^6}{N_{Re}}\right)^{1/3}\right] \qquad (12)$$

Equation 8 is applicable to all liquids, and to gases when

Note: The straight line at left shows values of Friction Factor for laminar flow.

Reprinted by permission from ASME Transactions.

Fig. 4 .... Relation Between Friction Factor and Reynolds Number

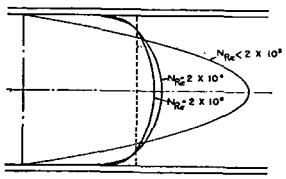

Fig. 5 .... Comparison of Velocity Profiles for 3 Different Reynolds Numbers but for Same Average Velocity

the pressure loss is less than 10 percent of the initial pressure. When the loss in head is high, the formula to be used for gases is

$$\frac{p_1^2 - p_2^2}{p_1^2} = \frac{flV_1^2}{gd\,p_1v_1} \tag{13}$$

which may be arranged to give the loss in pressure,

$$p_1 - p_2 = p_1\left[1 - \sqrt{1 - \frac{flV_1^2}{gd\,p_1v_1}}\right] \tag{14}$$

Pressure Loss in Non-Circular Pipes

The formulas for friction loss in pipes are based on the use of pipes of circular cross-section. The same formulas may be extended to noncircular sections, by suitable modification. In the basic formula, Equation 8, the internal diameter d is to be replaced by the hydraulic diameter d_H defined by the equation:

$$d_H = \frac{4 \times \text{area of cross-section}}{\text{wetted perimeter of cross-section}} \tag{15}$$

For example, in a rectangular duct, 1 ft by 2 ft, the cross-section area is 2 sq ft, and the perimeter 6 ft. Then the hydraulic diameter will be $d_H = (4 \times 2)/6 = 1\frac{1}{3}$ ft.

In the case of a round pipe,

$$d_H = \frac{4 \times \pi d^2/4}{\pi d} = d \tag{16}$$

In computing the Reynolds number, and from that the friction factor, the hydraulic diameter is not to be used. A better approximate procedure is to replace the length in the Reynolds number by the shortest dimension plus one-fourth of the hydraulic diameter. Thus, in a duct of dimension a x b where a < b, N_{Re}, for the purposes of calculating friction factors, is

$$N_{Re} = (a + 0.25d_H)V\rho/\mu \tag{17}$$

This value of N_{Re} may be used in Equation 10 for laminar flow, and in Equation 12 or Fig. 4 for turbulent flow. The error in the approximation is somewhat greater for laminar than for turbulent flow. In the former case, the relative error may be as much as 10 percent, while in the latter it almost always is less than 3 percent.

FLOW OF COMPRESSIBLE FLUIDS

In the flow of compressible fluids, the large density variations make it impracticable to use the Bernoulli equation, (Equation 7). In certain special cases, however, the exact equations for compressible flow may be stated. If flow occurs with no friction or other internal irreversibility Equation 6 becomes

$$\frac{1}{2g}dV^2 + \frac{dp}{\rho} = 0 \tag{18}$$

If, in addition, the flow is adiabatic,

$$pp^{-k} = p_1v_1^{-k} \tag{19}$$

so that Equation 18 becomes

$$\frac{1}{2g}dV^2 + \frac{p_1^{1/k}}{\rho_1}\frac{dp}{p^{1/k}} = 0 \tag{20}$$

or by integration,

$$\frac{1}{2g}(V_2^2 - V_1^2) + \frac{k}{k-1}\frac{p_1}{\rho_1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1\right] = 0 \tag{21}$$

This extension to compressible flow of Bernoulli's equation reduces to the more familiar form if the pressure change is small.

The ratio of specific heats, k, is used extensively in fluid dynamics; values of k for various gases are given in Table 2.

It is convenient in the analysis of compressible flow to introduce the velocity of propagation of pressure impulses or, more familiarly, the sonic velocity, a. For perfect gases this is given by the equation:

$$a^2 = kgp/\rho = kgRT \tag{22}$$

Accordingly, Equation 21 may be written

$$\tfrac{1}{2}(V_2^2 - V_1^2) + \frac{a_1^2}{k-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1\right] = 0 \tag{23}$$

or, by rearrangement,

$$\frac{p_2}{p_1} = \left[1 - \frac{k-1}{a_1}\left(\frac{V_2^2 - V_1^2}{2}\right)\right]^{\frac{k}{k-1}} \tag{24}$$

which permits the calculation of the ratio of pressures at entrance and exit of the steady flow device—pipe, orifice, or nozzle. From Equations 19 and 22 it follows that

$$\frac{a_2^2}{a_1^2} = \frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} \tag{25}$$

so that

$$\frac{k-1}{2}(V_2^2 - V_1^2) + a_2^2 - a_1^2 = 0 \tag{26}$$

and

$$\frac{a_2^2}{a_1^2} = \frac{1 + \frac{k-1}{2}\frac{V_1^2}{a_1^2}}{1 + \frac{k-1}{2}\frac{V_2^2}{a_2^2}} \tag{27}$$

The ratio of flow velocity to sonic velocity is known as the *Mach number*,

$$M = V/a$$

This parameter is particularly useful in compressible flow analysis. In general, if $M \leq 0.1$ the flow may be considered

to be incompressible. This is generally true in heating and ventilating air ducts.

In terms of the Mach number

$$\frac{a_2^2}{a_1^2} = \frac{T_2}{T_1} = \frac{1 + \frac{k-1}{2}M_1^2}{1 + \frac{k-1}{2}M_2^2} \tag{28}$$

and

$$\frac{p_2}{p_1} = \left(\frac{1 + \frac{k-1}{2}M_1^2}{1 + \frac{k-1}{2}M_2^2}\right)^{\frac{k}{k-1}} \tag{29}$$

The quantity,

$$p^0 = p\left(1 + \frac{k-1}{2}M_1^2\right)^{\frac{k}{k-1}} \tag{30}$$

is called the stagnation pressure, and gives a measure of pressure energy. For incompressible flow

$$p^0 = p + \frac{1}{2g}\rho V^2 = p + q \tag{31}$$

where

$$q = \frac{1}{2g}\rho V^2 \tag{32}$$

and is the dynamic pressure. A total head tube measures stagnation pressure directly.

From Equation 29 it follows that for frictionless, adiabatic flow

$$p_2^0 = p_1^0 \tag{33}$$

This represents another extension of the Bernoulli equation to compressible flow. Friction will cause a loss in pressure energy.

Ideal Flow through Nozzle or Orifice

The majority of low-head measuring systems depend upon a correlation between pressure drop, area, and quantity of flow. The basic formulas may be stated on the assumption that the flow is frictionless and adiabatic. Designating the main stream by station 1, and flow at some measuring restriction by station 2, the flow in pounds per second is

$$w = \rho_1A_1V_1 = \rho_2A_2V_2 \tag{34}$$

or, in terms of *Mach number*,

$$w = A_2M_2\sqrt{kgp_2v_2} \tag{35}$$

According to Equation 29

$$\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} = \frac{1 + \frac{k-1}{2}M_2^2}{1 + \frac{k-1}{2}M_1^2} \tag{36}$$

from which

$$M_2^2 = \frac{2}{k-1}\left(\frac{1 + \frac{k-1}{2}M_1^2}{1 - M_1^2/M_2^2}\right)\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1\right] \tag{37}$$

Table 2 .... Ratio of Specific Heat at Constant Pressure to Specific Heat at Constant Volume for Compressible Fluids

Compressible Fluid	Ratio $k = c_p/c_v$
Helium and other monatomic gases	1.66
Air and other diatomic gases	1.40
Ammonia and hydrogen sulfide	1.34
Carbon dioxide, methane, natural gas, superheated steam, moist steam down to a quality of 97 percent	1.28 to 1.32
Sulfur dioxide, ethylene, acetylene	1.24 to 1.26

so that

$$w = A_2\sqrt{\frac{1 + \frac{k-1}{2}M_1^2}{1 - M_1^2/M_2^2}}\sqrt{\frac{2kgp_2v_2}{k-1}\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1\right]} \tag{38}$$

If the initial velocity is sufficiently small, M_1^2 will be negligible so that

$$w = A_2\sqrt{\frac{2kgp_2v_2}{k-1}\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1\right]}$$

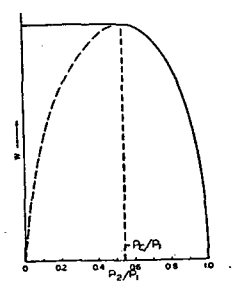
$$= A_2\sqrt{\frac{2kgp_1v_1}{k-1}\left(\frac{p_2}{p_1}\right)^{\frac{k+1}{k}}\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1\right]} \tag{39}$$

If this is computed and the figures are plotted, the curved line (partly solid and partly broken) of Fig. 6 is found. The maximum value of $\frac{p_2}{p_1}$ may be computed by differentiating w with respect to p_2 and equating the result to zero. This operation produces the equation:

$$\frac{p_2}{p_1} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} \tag{40}$$

For air, with $k = 1.40$, $\frac{p_2}{p_1} = 0.53$.

Actually, the broken part of the curve is not attained for



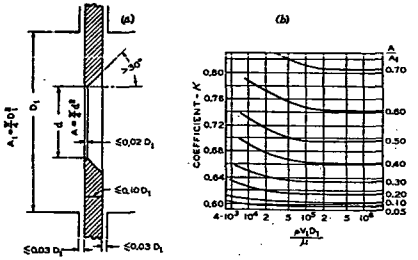


Fig. 6 .... Relation of Flow of Gas to Pressure Drop in a Converging Tube

(Coefficient shown as a function of Reynolds Number and Ratio, A/A_1.)
From Reference 4. Used by permission.

Fig. 7 .... Dimensions and Flow Coefficient for Standard Square-edged Orifice with Corner Taps or Annular Slits

the flow in the nozzle. If the ratio of p_2 to p_1 is decreased from unity, the mass rate of discharge, as well as the volume, increases from zero to a maximum, as shown by the solid section of the curve in Fig. 6; thereafter, as p_2/p_1 is decreased further, the discharge is constant, as indicated by the horizontal line. The value of p_2 at the maximum point is called the critical pressure, or p_c, and it is seen that p_c is approximately 53 percent of p_1 when air is flowing.

To find the velocity at the critical pressure, it is assumed that the upstream velocity V_1 is so small as to be negligible. Using the subscript c to indicate conditions at the critical point, from Equation 29

$$\frac{p_c}{p_1} = \frac{1}{\left(1 + \frac{k-1}{2} M_c^2\right)^{\frac{k}{k-1}}} \tag{41}$$

or

$$M_c = \sqrt{\frac{2}{k-1}\left[\left(\frac{p_1}{p_c}\right)^{\frac{k-1}{k}} - 1\right]} \tag{42}$$

Substituting the critical pressure ratio from Equation 40 it follows that

$$M_c = 1 \tag{43}$$

or that the velocity at the throat is equal to the local sonic velocity.

In developing the working equations for orifices and nozzles, it is customary to start with the incompressible form of the flow Equation 38. In this case both M_1 and M_2 are small quantities, $\rho_1 = \rho_2$, and $(p_1 - p_2)/p_2 = \Delta p/p_2$ is small. Retaining only first order terms, it follows from Equation 35 that

$$\frac{M_1}{M_2} = \frac{A_2}{A_1} \tag{44}$$

so that

$$\sqrt{\frac{1 + \frac{k-1}{2} M_1^2}{1 - (M_1^2/M_2^2)}} \cong \frac{1}{\sqrt{1 - (A_2/A_1)^2}} = \frac{1}{\sqrt{1 - \beta^4}} \tag{45}$$

where $\beta = D_2/D_1$. The quantity $1/\sqrt{1-\beta^4}$ is the velocity of approach factor as generally used, with β being the ratio of the throat or orifice diameter to the pipe diameter.

Since $\Delta p/p_2$ is small

$$\frac{2k}{k-1}\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1\right] \cong \frac{2\Delta p}{p_2} \tag{46}$$

and the mass flow is

$$w = \frac{A_2}{\sqrt{1-\beta^4}}\sqrt{2g\rho\Delta p} \tag{47}$$

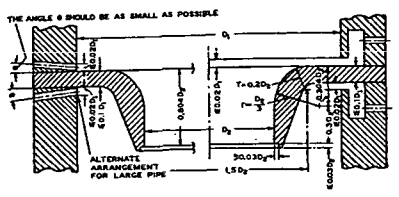
The volume flow is then

$$Q = A_2 \frac{1}{\sqrt{1-\beta^4}}\sqrt{2g\Delta p/\rho} = A_2 \frac{1}{\sqrt{1-\beta^4}}\sqrt{2gh_f} \tag{48}$$

FLOW MEASUREMENT

The measurement of quantity of flow of fluids is generally accomplished either by making observations on the change of state due to flow system configuration, such as the pressure drop across a metering orifice, or by the displacement of some device, such as a rotating vane system. The selection of the metering system will be determined by the type of fluid, the precision of measurement desired, the cost of equipment and installation, the range of flow quantity, the ease of maintenance, and the method of observation and recording.

Fluid meters may be classified as follows: (1) *Head Meters* (Pressure Sensitive), which may be of *Venturi*, *flow nozzle*, *orifice plate*, or *Pitot tube* types; (2) *Area Meters*, which may be of *gate*, *tapered tube*, or *tapered plug* types; (3) *Force Meters*, which may be of *vane*, *propellor*, or *turbine* types; (4) *Quantity Meters*, which may be of *weighing tank*, *reciprocating piston*, or *geared impeller* types.



Rate meters are generally of the first three groups, although rates are obtainable from timed observations of quantity meters. Similar quantity measurements can be obtained by suitable integration of rate meter indications.

Head Meters

The head meter is of sufficient flexibility so that almost any type of flow measurement can be handled. For this reason, standard and reference measurements are usually made in this way. With proper care, extreme precision can be obtained. Also, an inexpensive installation can be made to give moderate precision. In general, a head meter requires fairly competent installation and maintenance to give satisfactory service.

Among the types of head meters, the Venturi has the advantage of having a low pressure loss, but requires considerable length of space. The orifice plate reduces the required length to a minimum at the cost of considerable pressure drop. The flow nozzle represents a compromise, but must be calibrated individually, or made with extreme care from standard specifications, to obtain a good precision of measurement. Standard configurations, for representative orifice plates and flow nozzles, are shown in Figs. 7 and 8, respectively. Additional specifications are given in References 2, 3, and 4 at end of chapter.

The measurement of flow in head meters is dependent

From Reference 3. Used by permission of ASME.

Fig. 8 .... Dimensions for International Standards Association Flow Nozzle

upon observations of a static pressure difference between two parts of the system. Standard locations for these static pressure measurements are illustrated in Figs 8 and 16. In general, there exists a reduction in area, either by a smooth contour as in the case of a Venturi or flow nozzle, or by a vena contracta following an orifice. In either case, the flow will be given by a suitable modification of Equations 47 and 48. Adding a correction term, these become

$$w = \frac{A_2 C}{\sqrt{1-\beta^4}}\sqrt{2g\rho\Delta p} \tag{49}$$

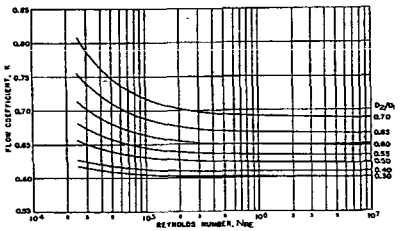
and

$$Q = \frac{A_2 C}{\sqrt{1-\beta^4}}\sqrt{2gh_f} \tag{50}$$

In all cases, A_2 refers to the minimum area of the Venturi, nozzle, or orifice. The correction factor C is introduced to account for any loss due to departure from isentropic flow, and for any deviation between the downstream measured pressure and the actual pressure at the minimum section. Since these corrections are usually dependent on configuration, as described by the ratio of upstream to minimum area A_1/A_2, it is often convenient to introduce a combined flow coefficient, K which is

$$K = \frac{C}{\sqrt{1-\beta^4}} \tag{51}$$

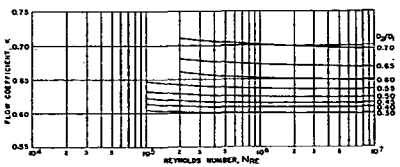
so that



$$w = KA_2\sqrt{2g\rho\Delta p} \tag{52}$$

and

$$Q = KA_2\sqrt{2gh_f} \tag{53}$$



The coefficients K and C will be determined by the area ratio A_1/A_2, or by the diameter ratio D_1/D_2 and the Reynolds number. Extensive data are available from various sources.[3, 4] Figs. 9, 10, 11, 12 show representative values of K based on N_{Re}, the Reynolds number, and the ratio of diameter of the orifice or nozzle throat to pipe diameter.

In any specific application, numerical values for areas, densities, and pressure units can be substituted in Equations 52 and 53 to obtain compact working formulas. In planning flow measurements, standard flow meter dimensions and standard pressure tap locations should preferably be used so

Fig. 12 .... Flow Coefficient for International Standards Association Flow Nozzle Shown in Fig. 8 as a Function of Area Ratio $(D_2/D_1)^2$ and the Reynolds Number N_{Re}

that published flow coefficients can be used for accurate determination of flow rates.

In measuring the flow of compressible fluids, the approximate Equations 52 and 53 must be corrected for density variations. The need for such correction is evident by comparing Equations 35 and 38 with Equation 47. Introducing a multiplicative correction factor ϕ the equation for flow with no loss becomes:

$$w = \frac{A_2\phi}{\sqrt{1-\beta^4}}\sqrt{2g\rho_1(p_1-p_2)} \tag{54}$$

By comparison with Equation 35,

$$\phi = \sqrt{\frac{k}{2}\frac{p_2}{p_1}\frac{M_2^2(1-\beta^4)}{(p_1/p_2)-1}} \tag{55}$$

From Equations 34 and 35,

$$M_1^2/M_2^2 = \beta^4(p_2/p_1)^{2/k} \tag{56}$$

Hence, by Equation 38 for a small value of M_1,

$$\phi = \sqrt{(p_2/p_1)^{1/k}\left(\frac{k}{k-1}\right)\frac{(p_1/p_2)^{(k-1)/k}-1}{(p_1/p_2)-1}\cdot\frac{1-\beta^4}{1-\beta^4(p_2/p_1)^{2/k}}} \tag{57}$$

From Equations 37 and 56, if M_2 is not too large,

$$\frac{2}{k}\frac{1}{M_2^2}\left(\frac{p_1}{p_2}-1\right) \cong 1-\beta^4+\tfrac{1}{4}[1-2(k-2)\beta^4]M_2^2 \tag{58}$$

so that, approximately,

$$\phi \cong -\frac{3}{8}\left[1+\left(1-\frac{2k}{3}\right)\beta^4\right]M_2^2 \tag{59}$$

where to the same degree of approximation from Equation 36

$$M_2^2 = 2\frac{p_1-p_2}{kp_1} \tag{60}$$

Values of ϕ are also given by Figs. 13 and 14.

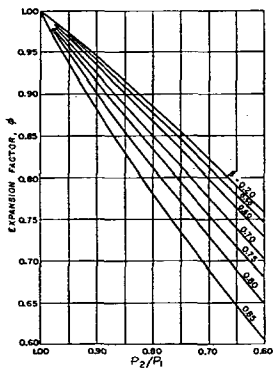

Fig. 13 .... Relation of Expansion Factor, ϕ, for Nozzles to Diameter Ratio and Pressure Loss for Air and Other Diatomic Gases

While ϕ may be used for smooth nozzles and Venturi tubes, it is necessary in the case of orifices, where the departure from ideal flow is significant, to replace ϕ by an empirical factor Y obtained by the equation

$$Y = 1-(0.41+0.35\beta^4)\left(\frac{p_1-p_2}{p_1}/k\right) \tag{61}$$

When this correction is used, the flow will be given by the equation

$$w = KA_2Y\sqrt{2g\rho_1(p_1-p_2)} \tag{62}$$

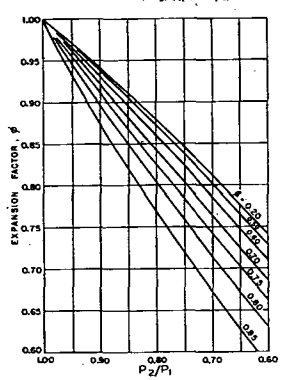

Fig. 14 .... Relation of Expansion Factor, ϕ, for Nozzles to Diameter Ratio and Pressure Loss for Steam, Carbon Dioxide and Natural Gas

Location of Head Meters and Pressure Taps

In the installation of Venturis, orifices, and nozzles, care must be taken in regard to upstream and downstream flow conditions. Recommended practice, with reference to fittings and valves, is shown by Fig. 15. If these conditions cannot be met, some flexibility is possible by introducing straightening vanes, as described more fully in References 2 and 5.

The static pressure difference across the head meter is measured by suitably located static pressure taps. For orifices, the different sets of pressure taps are called flange taps, radius taps, vena contracta taps, and pipe or full-flow taps. The relative locations of the first three of these are shown in *Fig. 16*.

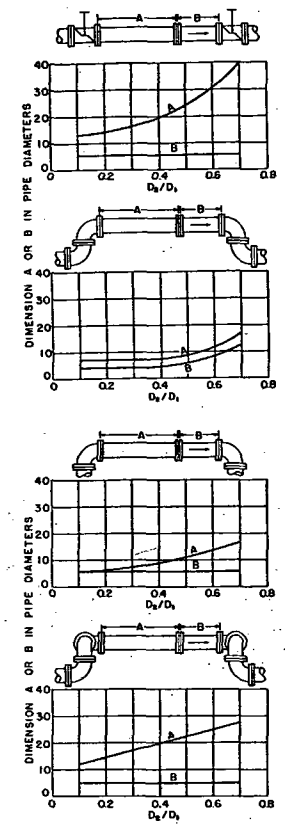

Fig. 15 .... Minimum Conditions to be Observed When Installing Orifices and Nozzles Between Fittings and Valves

The flow coefficients in Figs. 9, 10, and 11 apply only to measurements made with these pressure tap locations. The need for applying suitable coefficients to measurements obtained by means of the different taps, is indicated by the curve of change, in pressure of the flowing fluid, shown in the lower part of Fig. 16. Pipe taps are located 2½ pipe diameters upstream and 8 pipe diameters downstream (both distances being measured from the upstream face of the orifice plate) so that pressures are measured before the orifice plate has had any effect on the flow, and after the recovery in pressure has been completed. The use of pipe or full-flow taps has been limited to the metering of natural fuel gas in certain areas. As they are not suited to use in heating and ventilating work, no data for them are given in this chapter.

Still another type of pressure tap, the corner tap, is used in European practice. Pressures are taken from recesses in the flange connected to annular slits in the corners formed by the pipe wall and the orifice plate. Coefficients for these taps have been adopted by the *International Standards Association*, but are not used commercially in America.

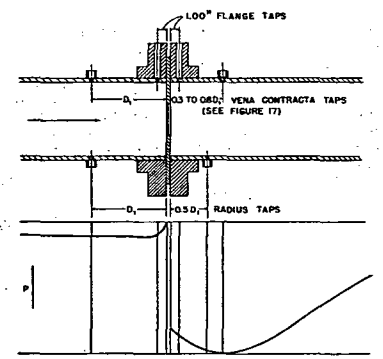

Fig. 16 .... Relative Location of Flange, Radius and Vena Contracta Taps

It will be noted that the location of the downstream pressure tap of the vena contracta arrangement is variable. Vena contracta is the term applied to the minimum cross-section of the jet from the orifice, where the static pressure is at a minimum. Its location, and the location of the downstream vena contracta tap, vary with the ratio of orifice to pipe diameter, and with rate of flow, as shown in Fig. 17; the tap is generally located in accordance with the mean curve in the figure.

Similar precautions are required when using flow nozzles and Venturi tubes. In many cases, these will be supplied

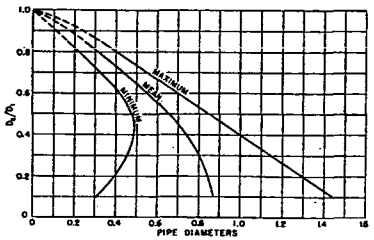

Fig. 17 . . . . Location of Vena Contracta in Relation to Ratio of Orifice to Pipe Diameter and to Rate of Flow

ready for installation. In such cases, the manufacturer's instructions should be followed with care in order to avoid serious errors. Further information on such systems is given in References 2, 3, and 5.

Pitot Tube

In certain cases, such as in rectangular ducts, it is impracticable to use standard orifices, and consequently, either a specially designed orifice must be calibrated, or an independent flow device must be used. In either case, the Pitot tube is useful. It consists essentially of an inner bent tube with its open end pointing upstream so as to measure total pressure, and an outer tube having small holes on the side for communicating static pressure to a manometer. (See Fig. 3, Chapter 44). The difference in liquid level in the manometer will be proportional to the square of the velocity, for incompressible flow, so that in general

$$V = \sqrt{2gh_f} \qquad (63)$$

For compressible flow, the differential head is to be divided by the correction F_c from Equation 64,

$$F_c = 1 + \tfrac{1}{4}M^2 + \tfrac{1}{40}M^4 \qquad (64)$$

where

$$M^2 = 2\frac{p_0 - p}{kp} \qquad (65)$$

In the use of a Pitot tube system, care is required in obtaining correct total and static pressures. The total pressure tube must be smoothly constructed, and should point directly upstream. The static pressure tap must be located so that local flow interferences will not reduce the value. In any case, it is better to obtain an independent calibration, or use a specially designed and manufactured probe. A number of such Pitot tube probes are available, and can be used without calibration.

In using Pitot tubes to obtain flow rates, it is necessary to make a traverse of the pipe and thereby to obtain one of the profiles of Fig. 5. In rectangular ducts or near valves or fittings, a disturbed flow pattern would be obtained, and therefore, in such cases, a fairly complete survey should be made. The flow in such cases will be computed from the average of the local velocities, as obtained by Equation 63.

Variable Area Flow Meters

For permanent installations where high precision, ruggedness, and ease of operation are important, the variable area flow meter has proved very satisfactory. Its most frequent use is in measurement of liquids or gases in small diameter pipes. For ducts or pipes over 6 in. in diameter, the expense of this meter may not be warranted. In large systems, however, the meter might be placed in a by-pass line and used in conjunction with an orifice.

In its most common form, the variable area meter, Fig. 18, consists essentially of a float which is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus formed between the float and inside wall of the tube. At any particular rate of flow, the float assumes a definite position in the tube, its

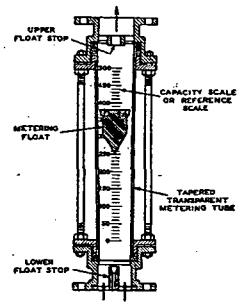

Fig. 18 . . . . Schematic Diagram of Variable Area Flow Meter

location being indicated by means of a calibrated scale on the tube.

The position of the float is established by a balance between the fluid pressure forces across the annulus and the weight of the float itself. The buoyant force which must support the float, $v_f(\rho_f - \rho)$, is balanced by the pressure difference acting on the cross-section area of the float, $A_f\Delta p$, where ρ_f, A_f, v_f, are, respectively, the float density, float cross-section area, and float volume. Accordingly, the difference in head across the annulus is given by

$$h_f = \frac{\Delta p}{\rho} = \frac{v_f(\rho_f - \rho)}{A_f\rho} \qquad (66)$$

The volume flow follows from Equation 53 as

$$Q = KA_2\sqrt{2gv_f(\rho_f - \rho)/\rho A_f} \qquad (67)$$

and the mass flow as

$$w = \rho Q = KA_2\sqrt{2gv_f(\rho_f - \rho)\cdot\rho/A_f} \qquad (68)$$

The flow for any selected fluid is, accordingly, very nearly proportional to the area, so that a convenient calibration of

the tube may be obtained. The behavior of the flow coefficient, K, has been investigated[6] and the action of the flow meter as just outlined, experimentally confirmed. The flow coefficient variation for any float must be known in order to use the meter for different fluids. Some developments have been carried on in the design of the float to reduce the variation of the flow coefficient with Reynolds number, and also with regard to float materials, to reduce the dependence of mass flow calibration on fluid density.

This type of flow meter is usually furnished in standard sizes calibrated for specific fluids by the manufacturer. The compactness, reliability, and ease of installation are particularly advantageous when many measurements of essentially the same type are to be made.

LETTER SYMBOLS USED IN CHAPTER 4

β = ratio, throat or orifice diameter to pipe diameter.
μ = absolute viscosity, pounds per foot second.
μ/ρ = kinematic viscosity, square feet per second.
ρ = density of flowing fluid, pounds per cubic foot.
ρ_m = proper mean density, pounds per cubic foot.
ρ_w = density of water at 60 F (62.37 lb per cubic foot).
ρ_f = density of float in variable area meters.
ϕ = expansion factor for nozzles.
a = velocity of sound, feet per second.
A = cross-sectional area of flow, square feet.
C = correction factor (coefficient of discharge) for flow through orifice, nozzle or Venturi.
c_p = specific heat of gas at constant pressure.
c_v = specific heat of gas at constant volume.
D = diameter of fluid stream, feet.
d = internal diameter of pipe, feet.
d_H = hydraulic diameter, feet.
e = absolute roughness of pipe surface, feet.
F_c = correction factor for differential head in compressible flow.
f = dimensionless friction coefficient.
g = gravitational acceleration, feet per (second) (second).
g_c = gravitational conversion factor = 32.174 (pounds mass per pound force) × feet per (second) (second).
h = enthalpy, Btu per pound of fluid.
h_f = loss of head, feet of fluid.
h_t = total head, feet of fluid.
J = mechanical equivalent of heat = 778 foot pounds per Btu.
K = flow coefficient (correction factor), including velocity of approach correction factor, for flow through orifice, nozzle or Venturi.
k = ratio of specific heat at constant pressure to specific heat at constant volume.
L = perpendicular distance from axis of pipe, feet.
l = length of pipe, feet.
M = Mach number.
N_{Re} = Reynolds number.
p = pressure, pounds per square foot.
p^0 = stagnation pressure, pounds per square foot.
p_c = critical pressure.
Q = discharge rate, cubic feet per second.
q = heat transferred to the fluid per pound of fluid flowing, Btu.
R = gas constant.
r = radius of pipe, feet.
s = entropy of fluid in Btu per (pound) (Fahrenheit degree).
T = temperature, absolute, Fahrenheit degrees.
u = internal energy, Btu per pound of fluid.
V = velocity, feet per second.
V_c = critical velocity, feet per second.
v = specific volume, cubic feet per pound.
W = mechanical work per pound of fluid flowing, foot pounds.
w = mass flow of gas, pounds per second.
Y = expansion factor (correcting for expansion of gas under reduced down-stream pressure).
z = elevation above some arbitrary datum, feet.

CHAPTER 5

HEAT TRANSFER

Conduction, Convection, Radiation; Equations for Conduction, Convection, Radiation, and Combined Convection and Radiation; Heat-Flow Resistance, in Series and Parallel; Practical Heat Transfer Problems; Periodic and Transient Heat Flow

HEAT is the form of energy that is transferred by virtue of an existing temperature difference. The temperature difference is the potential which causes the transfer, the latter in turn being resisted by the thermal properties of the material combined in a single term known as the resistance. Energy exchange associated with evaporation, condensation, etc., is treated elsewhere such as in the section Cooling Tower Theory in Chapter 40. The objectives of this chapter are to:

1. Describe the mechanisms and present the rate equations for the different modes of heat transfer.
2. Illustrate the application of the basic concepts to steady-state problems (temperature independent of time or a cyclic variable thereof) by means of several typical solutions of heat transfer systems.
3. Present concise summaries of available methods of analysis for transient and periodic heat transfer problems.

Further applications to specific systems will be found throughout THE GUIDE.

CONDUCTION, CONVECTION, AND RADIATION

Thermal conduction is the term applied to the mechanism of heat transfer whereby the molecules of higher kinetic energy transmit part of their energy to adjacent molecules of lower kinetic energy by direct molecular action. Since the temperature is proportional to the average kinetic energy of the molecules, thermal transfer will occur in the direction of decreasing temperature. The motion of the molecules is random; there is no net material flow associated with the conduction mechanism. In the case of flowing fluids, thermal conduction is significant in the region very close to a solid boundary or wall, where the flow is laminar and parallel with the wall surface, and where practically no cross currents exist in the direction of the heat transfer across the solid fluid boundary. In solid bodies the significant mechanism of heat transfer is always thermal conduction.

In contrast to the thermal conduction mechanism, *thermal convection* involves energy transfer by eddy mixing and diffusion[1] in addition to conduction. This is shown schematically in Fig. 1 which exhibits transfer from a pipe wall at surface temperature t_s to a colder fluid at a bulk temperature t_f. (Bulk temperature is that which would be attained if the fluid stream were drawn off at a certain section and mixed. It is therefore somewhat higher than the lowest temperature in the stream.) In the *laminar* sublayer, immediately adjacent to the wall, the heat transfer occurs by thermal conduction; in the *transition* region, which is called the buffer layer, eddy mixing as well as conduction effects are significant; in the *eddy* or *turbulent* region the major fraction of the transfer occurs by eddy mixing.

In most commercial equipment the main body of the fluid is in turbulent flow, and the laminar film exists at the solid walls only, as shown in Fig. 1. In cases of low-velocity flow in small tubes, or with viscous liquids such as heavy oil (low Reynolds numbers), the entire flow may be laminar. In these latter cases there is no transition or eddy region.

When the fluid currents are produced by sources external to the heat transfer region, as for example by a pump, the described solid to fluid heat transfer is termed *forced convection*. In contrast, if the fluid currents are generated internally, as a result of non-homogeneous densities arising from the temperature variations, the heat transfer is termed *free convection*.

In the conduction and convection mechanisms, the transfer of heat is associated with matter. For *radiant heat transfer*, however, a change in energy form takes place, from internal energy at the source to electromagnetic energy for transmission, then back to internal energy at the receiver.

The rate of heat transfer, corresponding to the three transfer mechanisms previously described, may be expressed by three rate equations. These are similar to Ohm's Law for electrical flow, the current flow through a resistance being proportional to the potential. The convection and radiation flow rate expressions may be approximated by a potential (temperature difference) and a resistance in order that heat transfer calculations may be effected more conveniently and rapidly.

Thermal Conduction Equation

Equation 1 states symbolically that the thermal conduction per unit transfer area normal to the flow, q/A, Btu per (hour) (square foot), is proportional to the temperature gradient $(dt)/(dL)$, Fahrenheit degrees per foot. The proportionality factor is termed the *thermal conductivity*, k, Btu per (hour) (square foot) (Fahrenheit degree per foot of thickness).

$$\frac{q}{A} = -k\frac{dt}{dL} \tag{1}$$

The minus sign on the right side of the equation is introduced to indicate positive transfer in the direction of decreasing temperature. Fig. 2 shows the physical significance of the indicated quantities.

It should be emphasized that the thermal conductivity used should be expressed in consistent units; either using the inch or foot throughout.

Expressions of conductivity used in the heating field are usually inconsistent in this sense, in that it is customary to refer to the conductivity *per square foot* but for one inch of thickness. This custom has been adopted for the reason that wall thicknesses are usually expressed in inches, whereas if expressed in feet, decimal or fractional thicknesses would result. When dealing with flat walls, no complication is involved in using the inconsistent expression of conductivity. However, where curved or spherical walls are concerned,

considerable complication is involved. Therefore, in this discussion the consistent units of conductivity expressed in Btu per (hour) (square foot) (Fahrenheit degrees per one foot thickness) are used throughout. *Conductivity values obtained from Chapter 9 or Table 1 in this chapter, must therefore be converted for use in the calculations of this chapter by dividing by 12.* As an example, the conductivity of brick listed as 5.0 in Table 4 of Chapter 9, becomes 0.42 when used in the calculations of this chapter. Also, it should be emphasized that in order to make the calculations and applications consistent in this chapter, *all dimensions of thickness must be expressed in feet.*

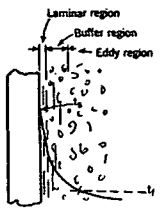

Fig. 1 .... Thermal Convection Conditions

Thermal Convection Equation

$$\frac{q}{A} = h_c(t_s - t_f) \qquad (2)$$

This rate equation states that the thermal convection per unit transfer area (q/A), Btu per (hour) (square foot) is proportional to the temperature difference ($t_s - t_f$) which is the temperature of the surface less that of the fluid. The particular fluid temperature to use for a given system will be noted under the discussion of that system. The proportionality factor is termed the *unit thermal convective conductance* (sometimes called the film coefficient for convection), h_c, Btu per (hour) (square foot) (Fahrenheit degree). Fig. 1 shows the conditions associated with convection.

The heat transmission by free or natural convection for objects surrounded by air can be conveniently expressed as in Equation 3:

$$\frac{q}{A} = C\left(\frac{1}{D}\right)^{0.2}\left(\frac{1}{T_{av}}\right)^{0.181}(t_s - t_f)^{1.27} \qquad (3)$$

where

$\frac{q}{A}$ = heat transmission by convection, Btu per (square foot) (hour).

Table 1 .... Approximate Unit Thermal Conductivities[a]

Conductivity, k = Btu per (hr) (sq ft) (F deg per in.)

Material	k	Material	k
Air	0.168	Lead	240.0
Aluminum	1416.0	Nickel	408.0
Brass (70 – 30)	720.0	Soil	2.4–12.0
Cast Iron	336.0	Steel, mild	312.0
Copper	2640.0	Water, liquid	4.08
Glass	3.6–7.32		

[a] Thermal conductivities depend to some extent on temperature. The above magnitudes are approximate only. Refer to Chapter 9, and Reference 4 for additional data.

C = a constant depending upon the shape of the surface.

D = diameter of pipe or circular duct or height of vertical wall, inches. (Effect of diameter or height becomes constant at 24 in.)

T_{av} = average of wall surface and surrounding air temperature, Fahrenheit degrees absolute.

$t_s - t_f$ = temperature excess between wall surface and surrounding air, Fahrenheit degrees.

For horizontal cylinders, the value of $C = 1.02$ has been well established by various investigations. For vertical plates, the value of $C = 1.39$ has been fairly well established. Suggested values[3] of C for horizontal plates warmer than the surrounding air are 1.79 when facing upward, and 0.89 when facing downward.

Problems in either forced convection or natural convection may be solved by the simple first-power equation if the convection coefficient is expressed as a unit conductance:

$$q = h_c A(t_1 - t_2) \qquad (4)$$

where

q = heat transmission by convection, Btu per hour.

A = surface area, square feet.

$t_1 - t_2$ = temperature difference between the surface and the fluid, Fahrenheit degrees.

h_c = unit convective conductance, from Table 2, Btu per (square foot) (hour) (Fahrenheit degree temperature difference).

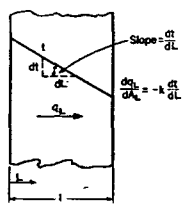

Fig. 2 .... Thermal Conduction in a Flat Slab

Thermal Radiation Equation

The relation given by Equation 5 is applicable to systems in which radiant exchange takes place between the surfaces of solids, as schematically shown in Fig. 3.

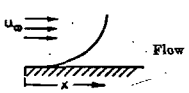
$$q_r = \sigma A_1 F_A F_E (T_1^4 - T_2^4) \qquad (5)$$

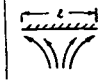
Gaseous and luminous radiation are not considered in this discussion. Equation 5 states that the net radiation per unit transfer area of surface 1, q_r/A Btu per (hour) (square foot), which *sees* surface 2 through a non-absorbing medium, is proportional to the difference of the fourth powers of the absolute surface temperatures ($T_1^4 - T_2^4$). The proportionality factor ($\sigma F_A F_E$) may be conveniently separated into three parts (excepting in some problems involving interreflections, where it is not possible to divide the product ($F_A F_E$) into separate terms):

σ = the Stefan-Boltzmann radiation constant = 1730×10^{-12} Btu per (hour) (square foot) (Fahrenheit degree absolute temperature to the fourth power).

Table 2 .... Approximate Unit Conductances for Thermal Convection for Several Flow Systems

Expressed in Convenient Empirical Form





Case	System	Heat Transfer Equation[a] and Its Limits of Application
	Forced Convection	
1 Ref. 3	 Longitudinal flow in a circular cylinder.[b]	*General Equation* $\frac{h_c D}{k} = 0.0225\left(\frac{DG}{\mu}\right)^{0.8}\left(\frac{C_p\mu}{k}\right)^{0.33}$ where $x > 4.4D$ and $\left(\frac{DG}{\mu}\right) > 2200$
2 Ref. 3	Same as Case 1.[b]	*Equation for Air* $h_c = 5.4 \times 10^{-4}(T_f)^{0.8}\frac{G^{0.8}}{D^{0.2}}$ where $x > 4.4D$ and $\left(\frac{DG}{\mu}\right) > 2200$
3 Ref. 3	Same as Case 1.[b]	*Equation for Liquid Water* (32–400 F) $h_c = 13.5(t_f)^{0.64}\frac{u_m^{0.8}}{D^{0.2}}$ where $x > 4.4D$ and $\left(\frac{DG}{\mu}\right) > 2200$
4 Ref. 4	 Flow normal to a single cylinder.	*General Equation* $\frac{h_c D}{k} = 0.26\left(\frac{DG}{\mu}\right)^{0.6}\left(\frac{c_p\mu}{k}\right)^{0.3}$ where $1000 < \frac{DG}{\mu} < 50{,}000$
5 Ref. 4	Same as Case 4.	*Equation for Air* $h_{c(average)} = 0.211(T_f)^{0.42}\frac{(u_\infty\rho)^{0.6}}{D^{0.4}}$ where $1000 < \frac{DG}{\mu} < 50{,}000$
6 Ref. 4	Same as Case 4.	*Equation for Liquid Water* (32–400 F) $h_{c(average)} = 34.0(t_f)^{0.25}\left(\frac{(u_\infty)^{0.6}}{D^{0.4}}\right)$ where $1000 > \frac{DG}{\mu} > 50{,}000$
7 Ref. 3	 Flow along a flat plate.	*General Equation* (Turbulent Flow) $\frac{h_{cx}x}{k} = 0.0296\left(\frac{xG}{\mu}\right)^{0.8}\left(\frac{c_p\mu}{k}\right)^{0.33}$ where $\left(\frac{xG}{\mu}\right) > 500{,}000$ and $h_a = 1.25h_{cx}$
8 Ref. 3	Same as Case 7.	*Equation for Air* (Turbulent Flow) $h_{cx} = 0.51(T_f)^{0.8}\frac{(u_\infty\rho)^{0.8}}{(x)^{0.2}}$ where $\left(\frac{xG}{\mu}\right) > 500{,}000$ and $h_{c(average)} = 1.25h_{cx}$
9 Ref. 3	Same as Case 7.	*General Equation* (Laminar Flow) $\frac{h_{cx}x}{k} = 0.332\left(\frac{xG}{\mu}\right)^{0.5}\left(\frac{c_p\mu}{k}\right)^{0.33}$ For $\left(\frac{xG}{\mu}\right) < 500{,}000$ and $h_{c(average)} = 2h_{cx}$
10 Ref. 3	Same as Case 7.	*Equation for Air* (Laminar Flow) $h_{cx} = 0.0562(T_f)^{0.8}\frac{(u_\infty\rho)^{0.8}}{x^{0.2}}$ For $\left(\frac{xG}{\mu}\right) < 500{,}000$

14 Ref. 5	 Free convection past a heated horizontal surface (face down).	*Equation for Air* $h_c = 0.239 \left(\frac{P}{P_a}\right)^{0.50} \left(\frac{\Delta t}{l}\right)^{0.25}$ *where* $10^3 < N_{Gr} < 10^7$

Nomenclature and Dimensions for Table 2

- c_p = heat capacity at constant pressure, Btu per (pound) (Fahrenheit degree).
- D = cylinder diameter, feet.
- f = subscript denoting film.
- g = body force per unit mass, feet per hour per hour. (For static system on earth, $g = 32.2 \times 3600^2$ feet per hour per hour.)
- $G = 3600\, u_m \rho$ = mass flow per unit cross-sectional area normal to flow, pounds per (hour) (square foot of flow cross-section).
- N_{Gr} = Grashof modulus, dimensionless ($N_{Gr} = D^3 p^2 g \beta \Delta t / \mu^2$).
- h_x = average unit thermal convective conductance from the leading edge of surface to the position x, Btu per (hour) (square foot) (Fahrenheit degree).
- h_{cx} = local unit thermal convective conductance, at the position x from the leading edge of surface, Btu per (hour) (square foot) (Fahrenheit degree).
- k = thermal conductivity, Btu per (hour) (square foot) (Fahrenheit degree per foot thickness).
- l = a dimension of the system, feet.
- m = a subscript denoting *mean*.
- P = pressure, atmospheres.
- P_a = pressure (atmospheric), atmospheres.
- t = temperature, Fahrenheit.
- T = temperature, Fahrenheit, absolute.
- u = fluid velocity, feet per second.
- V = volume, cubic feet.
- x = a dimension of the system, feet.
- β = coefficient of cubical expansion ($\beta = \frac{1}{V}\left(\frac{dV}{dT}\right)_p$); for perfect gases $\beta = 1/T$.
- Δt = difference between wall and fluid temperatures, Fahrenheit degrees.
- μ = fluid viscosity, pounds per (hour) (foot).
- ρ = density, pounds per cubic foot.
- ∞ = infinity, referring the quantity to a point not directly affected by the phenomenon in question.

[a] Fluid properties should be evaluated at the arithmetic mean fluid temperature, $t_f = (t_{surface} + t_{fluid})$ divided by 2.
[b] These expressions are suitable approximations to longitudinal flow in other than right circular cylinders, provided the hydraulic diameter is employed as the conduit dimension parameter. For non-circular cross-sections, the hydraulic diameter is equal to four times the cross-sectional area divided by the wetted perimeter.
[c] For low rates of heat transfer by free convection the exponent decreases towards zero, and for higher rates, increases towards 0.33. The above equations employing an exponent equal to 0.25 are applicable in the intermediate range indicated.

F_A = the geometrical factor which is dimensionless and ≤ 1. This factor accounts for the shape and relative position of the two surfaces. The value of $F_A = 1$ may be used in the cases of large parallel planes, long concentric cylinders or smaller bodies in large enclosures.

F_E = the emissivity factor which is also dimensionless and ≤ 1. This factor accounts for the absorption and emission characteristics of the surfaces for the radiation which exists. Emissivities or absorptivities (ϵ) for many common surfaces, are given in Table 3. The value of F_E for large parallel planes, long concentric cylinders, or large enclosed bodies is $1 \div (1/\epsilon_1 + 1/\epsilon_2 - 1)$.

The radiation under black-body conditions, or for an emissivity of 1.0, is given in Table 4[7] for cold surfaces as low as -39 F to warmer surfaces as high as 139 F. Some net radiation exchange solutions for several common radiation systems are given in Table 5.

There are several methods by which the geometrical factor F_A can be determined. One method involves the use of a mechanical geometrical integrator (Reference 8). Photographic and other methods are given in References 9 and 10.

Equivalent Conductance for Radiation

Although Equation 5 is a suitable equation for describing radiant exchange, it is not convenient for computations where other modes of energy transfer are operative. For such cases, it is convenient to define an *equivalent conductance for radiation* by the equation:

$$q_r = h_r A (t_1 - t_2) \tag{6}$$

The conductance h_r thus defined is a function of the shape-emissivity factor, as well as the temperatures of the radiator and receiver. Fig. 7 shows a plot of the equivalent conductance for two *black bodies* (i.e., with emissivities equal to unity) which exchange energy only with one another.

Combined Convection and Radiation

It should be noted that the previous equations and tables give the heat transfer by convection and by radiation computed separately. In many practical cases it is desirable to treat convection and radiation as a single combined process, using a first-power equation:

$$q_{rc} = h_{rc} A (t_1 - t_2) \tag{7}$$

where q_{rc} is the total heat flow due to radiation and convection, in Btu per hour. Values of h_{rc}, the surface or film conductance for combined radiation and convection, are given in Table 3 and Fig. 4 of Chapter 9. Complete tables for the combined heat transfer of steam and hot water radiators, pipes, coverings, etc., will be found in the appropriate chapters.

HEAT-FLOW RESISTANCE

In most of the steady-state heat transfer problems encountered in air conditioning applications, more than one of the heat transfer mechanisms are effective, and the thermal current flows through several resistances in series or in parallel. In using the resistance concept, the calculations involved are analogous to the application of Ohm's Law in electricity, viz., the heat flow or thermal current is directly proportional to the thermal potential or temperature difference, and inversely proportional to the thermal resistance:

$$q_{rc} = \frac{t_1 - t_2}{R} \tag{8}$$

Following the electrical analogy, when there is a thermal current flowing through several *resistances in series*, the resistances are additive:

$$R_T = R_1 + R_2 + R_3 + \cdots + R_n \tag{9}$$

Similarly, conductance is the reciprocal of resistance, and for heat flow through several *resistances in parallel*, the conductances are additive:

$$C_T = \frac{1}{R_T} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R_n} \tag{10}$$

Practical Heat Transfer Problems

The use of these relations for resistance and conductance makes possible the solution of many practical heat transfer problems. As discussed in Chapters 9, 23, and 32, the practical analyses of heat transfer in building walls, in fin-tube coils, and in pipe coverings, are usually computed by this method. The same resistance analysis may be applied to complicated steady-state *conduction* problems. Table 6 gives the resistances in six common cases of steady-state conduction.

A complete analysis by the resistance method is well illustrated by considering the heat transfer from the air outside to the cold water inside of an insulated pipe. The temperature gradients and the nature of the resistance analysis are indicated by the two sketches of Fig. 8.

Since air is sensibly transparent to radiation, there will be some heat transfer by both radiation and convection to the outer insulation surface. The mechanisms act in parallel on the air side. The total transfer by radiation and convection then passes through the insulating layer and the pipe wall by *thermal conduction, and thence by convection and radiation* into main cold water streams. (Radiation is not significant on the water side as liquids are sensibly opaque to radiation, although water transmits energy in the visible region.) The contact resistance between the insulation and the pipe wall is presumed to be equal to zero.

Referring to Fig. 8, the heat transferred for a given length N of pipe, q_{rc}, Btu per hour, may be thought of as flowing through the parallel resistances R_r and R_c, associated with the insulation surface radiation and convection transfer. Then the flow is through the resistance offered to thermal conduction by the insulation, R_3, through the pipe wall resistance, R_2, and into the water stream through the convection resistance, R_1. Note the analogy to the direct current electrical circuit problem. A temperature (potential) drop is required to overcome these resistances to the flow of thermal current. The total resistance to heat transfer, R_t, (hour) (Fahrenheit degrees) per Btu, is the summation of the individual resistances:

$$R_T = R_1 + R_2 + R_3 + R_4 \tag{11}$$

where the resultant parallel resistance R_4 is obtained from

$$\frac{1}{R_4} = \frac{1}{R_r} + \frac{1}{R_c} \tag{12}$$

Provided the individual resistances may be evaluated, the total resistance can be obtained from this relation. Then the heat transfer for the length of pipe (N, ft) can be established by the relation

$$q_{rc}\ (\text{Btu per hour}) = \frac{(t_s - t_f)}{R_T} \tag{13}$$

For a unit length of the pipe the heat transfer rate is

$$\frac{q_{rc}}{N}\ \text{Btu per (hour) (foot)} = \frac{(t_s - t_f)}{R_T N} \tag{14}$$

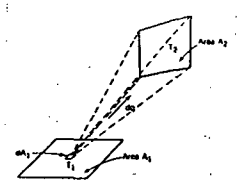

Fig. 3 .... Radiation Between Surfaces

Table 3 . . . . Radiation Factors or Emissivities, ϵ*

For the determination of factor F_E in Equation 3

Class	Surfaces	Fraction of Black-Body Radiation		Absorptivity for Solar Radiation
		At 50–100 F	At 1000 F	
1	A small hole in a large box, sphere, furnace, or enclosure	0.97 to 0.99	0.97 to 0.99	0.97 to 0.99
2	Black non-metallic surfaces such as asphalt, carbon, slate, paint, paper	0.90 to 0.98	0.90 to 0.98	0.85 to 0.98
3	Red brick and tile, concrete and stone, rusty steel and iron, dark paints (red, brown, green, etc.)	0.85 to 0.95	0.75 to 0.90	0.65 to 0.80
4	Yellow and buff brick and stone, firebrick, fire clay	0.85 to 0.95	0.70 to 0.85	0.50 to 0.70
5	White or light-cream brick, tile, paint or paper, plaster, whitewash	0.85 to 0.95	0.60 to 0.75	0.30 to 0.50
6	Window glass	0.90 to 0.95	. . . . .	Transparent*
7	Bright aluminum paint; gilt or bronze paint	0.40 to 0.60	. . . . .	0.30 to 0.50
8	Dull brass, copper, or aluminum; galvanized steel; polished iron	0.20 to 0.30	0.30 to 0.50	0.40 to 0.65
9	Polished brass, copper, monel metal	0.02 to 0.05	0.05 to 0.15	0.30 to 0.50
10	Highly polished aluminum, tin plate, nickel, chromium	0.02 to 0.04	0.05 to 0.10	0.10 to 0.40

* Emissivities of other materials may be found in Reference 4. * Reflects about 8 percent.

The temperature drop, Δt, through an individual resistance may then be calculated from the relation:

$$\Delta t = Rq_r \qquad (15)$$

where R is the resistance in question.

The problem is now reduced to one of evaluating the individual resistances of the system. This entails suitable manipulation of the rate Equations 1, 2, and 5 to produce expressions of the form:

$$q = \frac{\Delta t}{R} \qquad (16)$$

where q is the heat transfer rate, and Δt is the potential drop or temperature difference through the resistance R. Table 6 lists such solutions for six different conduction systems. Table 4 in Chapter 9 and Table 1 of this chapter indicate the magnitudes of the thermal conductivities, k, to be employed in the expressions of Table 6, after dividing k by 12.

The solution applicable to the problem depicted in Fig. 8, for the calculation of R_2 and R_3, is Case 2 in Table 6. Thus for a *1-ft length* of 2 in. nominal size pipe (I. D. = 2.067 in., O. D. = 2.375 in.) insulated with 1 in. of material having a conductivity of 0.025:

$$R_2 = \frac{\log_e \frac{1.188}{1.033}}{2\pi \times 26 \times 1} = 8.5 \times 10^{-4} \text{ (hr) (F deg) per Btu.}$$

$$R_3 = \frac{\log_e \frac{2.188}{1.188}}{2\pi \times 0.025 \times 1} = 3.9 \text{ (hr) (F deg) per Btu.}$$

The convection resistances to heat transfer from the pipe wall to the cold water, R_1, and from the air to the surface of the insulating material, R_4, are dependent on the flow conditions prevailing at these surfaces, and on the thermal properties of the fluids. These resistances are also directly dependent upon the temperature distribution, and for this reason it is necessary first to guess, on the basis of the problem statement, a temperature distribution upon which to base the initial calculations. Since the values of h_c for heat transfer between water and pipe walls are relatively high in this temperature range, it is logical to assume only a small temperature difference between the temperature of the fluid body and the temperature of the pipe wall. For the purpose of an initial guess, this temperature difference will be assumed to be 2 deg. On the other hand, h_c for heat transfer from air to a body is relatively small, and a higher temperature difference would be expected between these masses. The value initially assumed here will be 20 deg. In summary, the temperature distribution in the system is assumed as follows:

Fluid temperature = 34 F.
Inner pipe wall temperature = 36 F.
Outer insulation surface temperature = 100 F.
Ambient air temperature = 120 F.

With these assumptions and the problem statement, it is now possible to calculate values for the convective resistances. If it is found in the ultimate solution of the problem that the temperature distribution is different from that assumed, it will then be necessary to repeat the solution procedure.

If reference now be made to Table 2, it is found that Case 3 of this table is a system similar to that encountered in the

Table 4 . . . . Heat Transmission by Radiation for Black-Body Conditions*

* *Example:* Radiation from walls of room at 33 F to surface at −25 F for effective emissivity of 0.95 = (102 − 63.3) 0.95 = 37.7 Btu per (square foot) (hour).

Table 5 . . . Net Radiation Solutions

System	Solution	Remarks
$\epsilon_1 \quad \epsilon_2$ Two infinite parallel planes.	$\frac{q_r}{A} = \frac{1}{\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1} \sigma(T_1^4 - T_2^4)$	Considering interreflections. (Reference 5)
$\epsilon_1 \quad \epsilon_3 \quad \epsilon_2$ $\epsilon_1 = \epsilon_2$ One radiation shield between two infinite parallel planes.	$\frac{q_r}{A} = \left(\frac{1}{2}\right) \frac{1}{\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1} \sigma(T_1^4 - T_2^4)$	Considering interreflections. (Reference 5)
$\epsilon_1 = \epsilon_2 = \epsilon_3 = \cdots = \epsilon_n$ n radiation shields between two infinite parallel planes.	$\frac{q_r}{A} = \frac{1}{n+1} \left(\frac{q_r}{A}\right)_s$ where $\left(\frac{q_r}{A}\right)_s$ is the net radiation exchange without the shields.	Considering interreflections. (Reference 5)
Two concentric spheres or two infinitely long cylinders.	$\frac{q_r}{A_1} = \frac{1}{\frac{1}{\epsilon_1} + \frac{A_1}{A_2}\left(\frac{1}{\epsilon_2} - 1\right)} \sigma(T_1^4 - T_2^4)$	Considering interreflections and diffuse surfaces. (Reference 5)
Two areas dA_1 and dA_2	$\frac{dq_r}{dA_1} = \epsilon_1 \epsilon_2 F_A (T_1^4 - T_2^4)$	Surface diffuse, neglecting interreflection. (Reference 5)
Tube of infinite length parallel to an infinite wall.	$\frac{q_r}{2\pi RN} = \left(\frac{1}{2}\right) \epsilon_1 \epsilon_2 \sigma (T_1^4 - T_2^4)$ where N is the length of cylinder from which q_r is exchanged.	Neglecting interreflections. (Reference 5)
Surfaces are perfect radiators. Surface element dA and rectangle above and parallel to it, with one corner of rectangle contained in normal to dA.	See Fig. 4	(Reference 4)
Surfaces are perfect radiators. Adjacent rectangles in perpendicular planes.	See Fig. 5	(Reference 4)
Surfaces are perfect radiators. Opposed parallel rectangles and discs of equal size.	See Fig. 6	(Reference 4)

Table 6 . . . . Solutions for Some Steady-State Thermal Conduction Problems[a, b]

No.	System	Expressions for the Resistance R Entering into the Equation: $q = \Delta t/R$ (Btu per hour)
1.	Flat wall or curved wall if curvature is small (wall thickness less than 0.1 of inside diameter). 	$R = \frac{L}{kA}$
2.	Radial flow through a right circular cylinder. 	$R = \frac{\log_e \frac{r_o}{r_i}}{2\pi kN}$ (See footnote c).
3.	The buried cylinder. 	$R = \frac{\log_e \left(\frac{a + \sqrt{a^2 + r^2}}{r}\right)}{2\pi kN} = \frac{\cosh^{-1}\left(\frac{a}{r}\sqrt{1 + \frac{r^2}{a^2}}\right)}{2\pi kN}$ For $\frac{a}{r} \geq 3$, satisfactory approximation is: $R = \frac{\log_e \frac{2a}{r}}{2\pi kN} = \frac{\cosh^{-1}\frac{a}{r}}{2\pi kN}$
4.	Radial flow in a hollow sphere. 	$R = \frac{\frac{1}{r_i} - \frac{1}{r_o}}{4\pi k}$
5.	The straight fin or rod heated at one end. 	$R = \frac{m}{h_s p \tanh mL}$ (see footnotes d and e). For $ml > 2.3$, $\tanh mL \approx 1$ $m = \sqrt{h_s p/kA}$ A = conduction cross-section area. p = perimeter of cross-section A. h_s = unit conductance to the surroundings from the fin surface. k = thermal conductivity fin material. Δt = wall temperature—ambient temperature.
6.	Finned surface of area HB. 	$R = \frac{(s + \delta)}{h_s \left(\frac{2}{m}\tanh ml + s\right) HB}$ $m = \sqrt{\frac{h_s p}{kA}} = \sqrt{\frac{2h_s}{k\delta}}$ Δt defined as in Case 5 above.

[a] The dimensions to be employed in these solutions are: length of dimension p, L, r = feet; units of k = Btu per (hour) (square foot) (Fahrenheit degree for *one foot thickness*); units of k, Btu per (hour) (square foot) (Fahrenheit degree); units of area, A = square feet.

[b] The thermal conductivity, k, in these solutions should be taken at the average material temperature.

[c] $\log_e x = 2.303 \log_{10} x$.

[d] This expression can also be employed as an approximation for tapered fins or of annular fins by employing average magnitudes of A and p.

[e] tanh is the hyperbolic tangent.

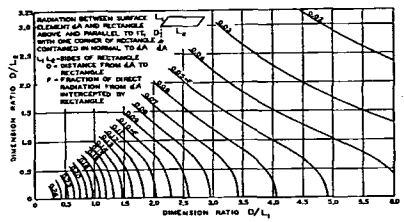

Fig. 4 . . . . Geometrical Factor F for Direct Radiation Between an Element dA and a Parallel Rectangle*

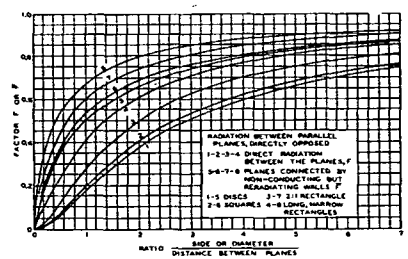

Fig. 6 . . . . Geometrical Factor F for Direct Radiation Between Opposed Parallel Rectangle and Discs of Equal Size*

* H. C. Hottel, Radiant heat transmission, (*Mechanical Engineering*, July 1930, pp. 700 to 702).

convection between the water and the pipe wall. The equation for this case is the following:

$$h_c = 13.9(t_f)^{0.545}\frac{u_m^{0.8}}{D^{0.2}} \qquad (17)$$

where

$$u_m = 5 \text{ fps}$$

$$D = \frac{2.067}{12} = 0.1725 \text{ ft}$$

$$t_f = \frac{34 + 36}{2} = 35 \text{ F}$$

$$h_c = \frac{13.9 \times 6.9 \times 3.62}{0.703} = 494 \text{ Btu per (hr) (sq ft) (F deg).}$$

This heat transfer rate is through the inner surface of the pipe and it is, therefore, this area that determines the resistance R_i.

$$A = \pi D = 0.542 \text{ sq ft per unit length of pipe,}$$

and therefore

$$R_i = \frac{1}{h_c A} = \frac{1}{494 \times 0.542}$$

$$R_i = 3.73 \times 10^{-3} \text{ (hr) (F deg) per Btu.}$$

Case 11 of Table 2 fits the conditions of the problem if only free convection heating of the pipe is assumed. The equation in this case is as follows:

$$h_c = 0.271\left(\frac{P}{P_a}\right)^{0.5}\left(\frac{\Delta t}{D}\right)^{0.25} \qquad (18)$$

where

$$\Delta t = 20 \text{ F}$$
$$D = 0.364 \text{ ft}$$
$$P = P_a = \text{one atmosphere}$$

therefore,

$$h_c = 0.271\left(\frac{20}{0.364}\right)^{0.25}$$

$$h_c = 0.737 \text{ Btu per (hr) (sq ft) (F deg)}$$

Using the surface area of the insulation, the value of the resistance per unit length is determined.

$$A = \pi\left(\frac{4.375}{12}\right) \times 1 = 1.14 \text{ sq ft}$$

$$R_c = \frac{1}{h_c A} = \frac{1}{0.737 \times 1.14}$$

$$R_c = 1.19 \text{ (hr) (F deg) per Btu.}$$

This result may not be deemed conservative inasmuch as the expression is for still air. If, however, the air is not still, but flows at approximately 5 mph or 7 fps, the heat transfer equation for forced convection would apply. This equation is Case 5 of Table 2.

$$h_{c(\text{forced})} = 0.211(T_f)^{0.43}\frac{(u\rho)^{0.8}}{D^{0.4}} \qquad (19)$$

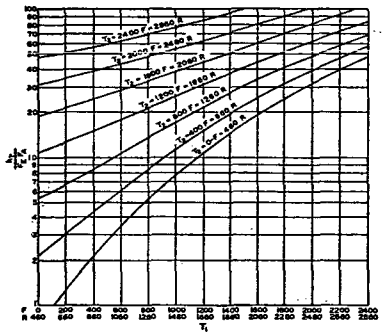

Fig. 7 .... Equivalent Conductance for Radiation Between Two Black Bodies Exchanging Energy Only with One Another

$$T_f = \frac{100 + 120}{2} + 460 = 570 \text{ Rankine (F absolute)}$$

$$u_m = 7 \text{ fps}$$

$$\rho = 0.076\left(\frac{520}{570}\right) = 0.0694 \text{ lb per cu ft}$$

$$D = 0.364 \text{ ft}$$

$$h_{c(\text{average})} = \frac{0.211(570)^{0.43}(7 \times 0.0694)^{0.8}}{(0.364)^{0.4}}$$

$$h_{c(\text{average})} = 2.73 \text{ Btu per (hr) (sq ft) (F deg)}$$

and

$$R_s \text{ (Forced Convection)} = \frac{1}{h_c A} = \frac{1}{2.73 \times 1.14}$$

$$R_s = 0.321 \text{ (hr) (F deg) per Btu.}$$

The radiation resistance, R_r, which acts in parallel with the resistance just calculated, can be computed with the aid of Fig. 7. The pipe wall, assumed at 100 F *sees* the surroundings at 120 F. If these two temperatures are used with Fig. 7, a value for $\frac{h_r}{F_A F_E}$ is determined directly.

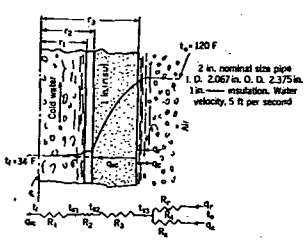

Fig. 8 .... Heat Transfer Conditions in an Insulated Cold Water Line

$$\frac{h_r}{F_A F_E} = 1.4 \text{ Btu per (hr) (F deg) (sq ft).}$$

The angle factor, F_A, is unity, and for an estimated surface emissivity of 0.95 (see Table 3), $F_E = 0.95$. Therefore,

$$h_r = 1.4\, F_A F_E = 1.4 \times 1 \times 0.95$$
$$h_r = 1.33 \text{ Btu per (hr) (F deg) (sq ft)}$$

and the radiation resistance, R_r, is then the following:

$$R_r = \frac{1}{h_r A} = \frac{1}{1.33 \times 1.14}$$

$$R_r = 0.659 \text{ (hr) (F deg) per Btu.}$$

The resultant resistance of R_s and R_r acting in parallel (see Fig. 8) can now be evaluated as:

$$\frac{1}{R_4} = \frac{1}{R_s} + \frac{1}{R_r} = \frac{1}{0.321} + \frac{1}{0.659} = 4.54 \text{ Btu per (hr) (F deg)}$$

$$R_4 = 0.216 \text{ (hr) (F deg) per Btu.}$$

The overall resistance, R_T, surroundings to cold water, is the sum of $R_1 + R_2 + R_3 + R_4 = 4.12$ (hr) (F deg) per Btu for 1-ft length of pipe. Note that the controlling resistances are R_3 and R_4, and that neglect of both R_1 and R_2 would not significantly influence the total resistance, R_T.

On the basis of this resistance calculation, the heat transfer from the surroundings to the cold water may be evaluated as:

$$\frac{q_{rc}}{N} = \frac{t_s - t_f}{R_T} = \frac{120 - 34}{4.12} = 20.8 \text{ Btu per (hr) (ft)}$$

or about 0.175 tons of refrigeration per 100 ft of pipe.

Since the calculation is based on a 1-ft pipe length,

$$q_{rc} = 20.8 \text{ Btu per hr.}$$

The temperature drops through the various resistances are now readily evaluated by Equation 16 as:

$$\Delta t = qR$$

$t_s - t_{s1}$ (air to insulation surface)
$= qR_4 = 20.8 \times 0.216 = 4.49$ F deg

$t_{s1} - t_{s2}$ (through the insulation)
$= qR_3 = 20.8 \times 3.9 = 81.2$ F deg

$t_{s2} - t_{s1}$ (through the pipe wall)
$= qR_2 = 20.8 \times 8.5 \times 10^{-4} = 0.018$ F deg

$t_{s1} - t_f$ (pipe wall to cold water)
$= qR_1 = 20.8 \times 3.73 \times 10^{-3} = 0.078$ F deg

This solution was obtained on the temperature distribution assumptions initially made. It is apparent that a better solution could be obtained if the whole problem were reiterated using the temperature distribution just calculated.

PERIODIC AND TRANSIENT HEAT FLOW

The foregoing data and examples dealt with steady-state heat transfer (not varying with time). In most practical

heat transfer problems the heat flow depends upon time. Such cases can usually be divided into two classes: periodic and transient. Periodic heat transfer repeats periodically in time. Transient heat transfer exhibits no periodicity. Graphical, analytical, and numerical methods are available for solving transient or periodic heat flow problems.[4,5,10,11,12] Graphical and numerical methods are the most versatile, and can be applied with minimum mathematical training.

A large number of analytical solutions for the case of heat conduction in variously shaped solids are available in the literature. Table 7 gives a summary of the cases reported and tabulated. Many more analytical solutions are available in the form of infinite series,[11,12,18,19] but are not tabulated. Certain complex cases may be treated by combining the simple analytical solutions as discussed in Reference 17. (See also Reference 20.)

Frequently, transient heat flow problems in one dimension have boundary conditions which make the problem difficult

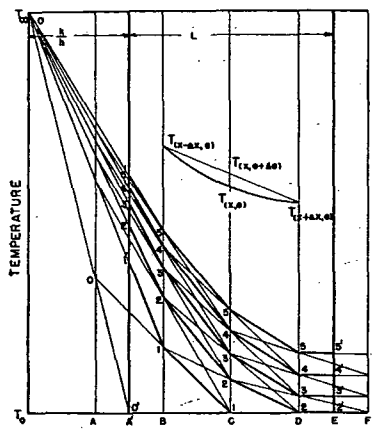

Fig. 9 .... Example of a Graphical Solution to a Problem in Transient Heat Conduction

to treat analytically. In such cases, recourse may be made to a graphical method of solution sometimes called the Schmidt method.[4,10,19,21,22] This method will be briefly outlined for the case of transient heat flow in a slab insulated on one face, and suddenly exposed on the other face through a fixed thermal resistance to a higher temperature. The technique is general, however, and methods may be devised for any boundary conditions,[5,22] and also, for one dimensional (radial) heat flow in spheres and cylinders.[22,23]

Consider the slab to be divided, as shown in Fig. 9, by n equidistant planes parallel to the slab surface and a distance Δx apart. Let the temperature of the slab at any plane and any time (θ) be denoted by $T_{x,\theta}$. Then the temperature of the slab at the two adjacent planes at the same time will be denoted as $T_{(x+\Delta x,\theta)}$ and $T_{(x-\Delta x,\theta)}$. In a similar manner the temperature of the x plane at a time $\Delta\theta$ later will be $T_{(x,\theta+\Delta\theta)}$.

In accordance with this nomenclature, the temperature at any plane x and time $\theta + \Delta\theta$ is given as

$$T_{(x,\theta+\Delta\theta)} = \frac{T_{(x+\Delta x,\theta)} + T_{(x-\Delta x,\theta)}}{2} \tag{20}$$

which may be interpreted as follows. The temperature of the slab at any plane, x, and any time, θ, is equal to the average temperature of the two adjacent planes obtained at the time $(\theta - \Delta\theta)$.

The time interval $\Delta\theta$ is determined by the equation

$$\Delta\theta = \frac{\Delta x^2}{2a} \tag{21}$$

Omitting the graphical construction at the slab boundaries, reference to Fig. 9 demonstrates the graphical method by means of which the temperature at each plane is determined at successive intervals of time in accordance with Equation 20.

For the problem stated, the boundary condition at the insulated surface is specified by the equation

$$\frac{\partial T}{\partial x} = 0$$

and at the uninsulated face by the equation

$$h(T_\infty - T) = -k\frac{\partial T}{\partial x}$$

In terms of finite differences these two equations (employing nomenclature established by Fig. 9) become

$$\frac{T_F - T_E}{\Delta x} = 0 \quad \text{or} \quad T_F = T_E \quad \text{at} \quad x = L$$

and

$$h(T_\infty - T_{A'}) = -k\frac{(T_B - T_A)}{\Delta x} \quad \text{at} \quad x = 0$$

or

$$\frac{T_\infty - T_{A'}}{k/h} = -\frac{T_A - T_B}{\Delta x}$$

The details of the graphical construction are best obtained by inspection of Fig. 9. Note that the line (0,0,0') used to initiate the graphical construction, is the only one drawn to the slab boundary A'. The numbered points indicate temperatures at the sub-slab boundaries at 1,2,3, etc., time intervals ($\Delta\theta$) after the slab is exposed to the high temperature.

For transient heat flow in two dimensions, and also, for steady-state conduction, numerical methods of solution are available in the literature.[5,10,12,19] These numerical methods are applicable to three-dimensional problems, although the calculations involved normally become too tedious for most applications of the method. An additional technique of solution for one- and two-dimensional problems in transient conduction results from the analogy of electrical resistance-capacitance networks to thermal systems.[24]

For two-dimensional problems in steady state conduction, additional techniques of solution are found in flux plotting,[5,19] and in the use of a potential tank.[5,19] These methods are of

CHAPTER 6

PHYSIOLOGICAL PRINCIPLES

Chemical Vitiation of Air, Physical Impurities in Air, Thermal Interchanges Between the Body and Its Environment, High Temperature Hazards, Acclimatization, Upper Limits of Heat for Men at Work, Application of Physiologic Principles to Air-Conditioning Problems, Effective Temperature Index and Comfort Zones

VENTILATION is defined in part as *the process of supplying air to, or removing air from, any space by natural or mechanical means.* The word in itself implies quantity, but air must be of the proper quality also. The term *air conditioning* in its broadest sense implies control of any or all of the physical or chemical qualities of the air. The ASHVE *Code of Minimum Requirements for Comfort Air Conditioning*[1] defines it "as the process by which simultaneously the temperature, moisture content, movement and quality of the air in enclosed spaces intended for human occupancy may be maintained within required limits. If an installation cannot perform all of these functions, it shall be designated by a name that describes only the function or functions performed." See definition of air conditioning in Chapter 1.

CHEMICAL VITIATION OF AIR

People living indoors bring about certain physical and chemical changes in the air about them. The oxygen content of the air diminishes and the carbon dioxide increases, but these changes are too slight to be significant except in airtight spaces as in submarines. Organic matter which is usually perceived as odors, comes from the body or clothes. Moisture and heat are given off by the body. There is no evidence of any toxic volatile material given off by man to the ambient air. Stale air may be offensive because of odors and may induce loss of appetite and loss of energy. Objectionable body odors have the same effects. These reasons, whether esthetic or physiological, usually make it desirable in the design of air-conditioning systems to provide for the elimination or control of odors arising from occupancy, cooking, or other sources. This may be accomplished by introducing odor-free air in sufficient quantities to reduce odor concentrations by dilution to a level which is not objectionable. Odor-free air may be outdoor air or air which has been cleared of odors by sorption, washing, or other appropriate means.

In the case of vitiation by a few hazardous gases such as carbon monoxide from heating, cooking, and certain industrial processes, no satisfactory chemical treatment for the elimination of the impurity has been found. The only satisfactory solution is elimination at the source by local exhaust ventilation; or, if this is impossible, reduction to a safe concentration by dilution. (See Chapter 7.) In the case of contamination by other matter, including volatile vapors and gases, chemical treatment for the removal or reduction of the impurities has been made available through air cleaning methods, which are discussed in Chapter 24.

When the only source of contamination is the human occupant, and overheating is not a problem, the minimum quantity of outdoor air needed appears to be that required to remove objectionable body odors, or tobacco smoke. The concentration of body odor in a room, in turn, depends upon a number of factors, including the dietary and hygienic habits of the occupants (frequently reflecting their socio-economic status), the outdoor air supply, air space allowed per person, odor adsorbing capacity of air-conditioning processes, and temperature and relative humidity. The intensity of odor sensation has been found to vary as the logarithm of the concentration of the odoriferous substance in the air, or inversely with the logarithmic function of the amount of outdoor air supplied and the air space per person.

The relation between air supply and occupancy has been reported by the Harvard School of Public Health[2] (Table 1) and the ASHAE Research Laboratory.[3] Outdoor air require-

Table 1 . . . . Minimum Outdoor Air Requirements to Remove Objectionable Body Odors Under Laboratory Conditions[2]

Sedentary adults	200	12
Summer season. Air cooled and dehumidified by means of a spray dehumidifier. Spray water changed daily. Total air circulation 30 cfm per person.		
Sedentary adults	200	<4

ments for removal of objectionable tobacco smoke odors are not accurately known, but available information and current practice indicate the need of 15 cfm per person or more.[4]

The total quantity of outdoor air to be circulated through an enclosure is often governed chiefly by the physical considerations for controlling temperature, air distribution, and air velocity. Other factors which must be taken into consideration, include the type and usage of the building, locality, climate, height of rooms, floor area, window area, extent of occupancy, and the operation of the system distributing the air supply. Frequently, some of these factors, particularly the need for air movement and good distribution, may be satisfied by recirculation of inside air rather than outside air.

It will be noted that, with adequate air space, the rate of air change indicated in Table 1 is from 4 to 30 cfm per person. In rooms occupied by only a few persons, such an air change will be automatically attained in cold weather by normal leakage around doors and windows, and can easily be secured in warm weather by the opening of windows. With a space allotment of 400 cu ft per person, only 1½ air changes per hour are necessary to provide a ventilation rate of 10 cfm per person.

Therefore, in the ordinary dwelling with adequate cubic space allotment, no special provision for controlling chemical purity of the air is necessary (aside from removal of fumes from heating appliances). For such conditions, the control of air temperature is the major consideration.

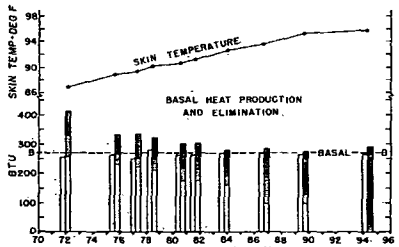
In more crowded rooms (large offices, large workrooms, auditoriums), where the cubic space per person is less and it is usually impossible to admit untempered outside air without creating drafts, mechanical ventilation is essential.

The present data regarding the effect of cubic space on outdoor air requirements are not universally accepted. *The Code of Minimum Requirements for Comfort Air Conditioning*[1] prescribes definite minimum requirements which should be familiar to the designing engineer. It should be emphasized, however, that the code fixes *minimum*, rather than *adequate* requirements. (See also Tables 1 and 3 of Chapter 13.)

Notwithstanding the rapid advance made in air conditioning, some persons still believe there is a stimulating quality in outdoor air (particularly country, mountain, and seashore air) under ideal weather conditions, which is lacking in artificially conditioned air. It is apparent, however, that modern air conditioning insures control of the phenomena of nature for the service and comfort of man independently of weather conditions. Freedom of movement, action, and thought, together with the variability of stimuli experienced by persons under ideal conditions in the country, mountains, or seashore, undoubtedly has some stimulating effect. Various experimenters have attempted to duplicate the invigorating qualities of outdoor air by the use of ozone, ionization, or ultraviolet light, but results to date have been inconclusive or negative.[5]

Ozone in amounts of 0.01 to 0.05 ppm of air is allowable in comfort air conditioning. Above this limit there is a pungent, unpleasant odor and perhaps respiratory distress, depression, and stupor.[6]

PHYSICAL IMPURITIES IN AIR



Dust particles of almost any type can produce irritation of the mucous membranes of the nose and throat, if present in high concentrations. Certain dusts may be very harmful, but coal dust is tolerated well. The effects of various industrial dusts, pollens, etc., are discussed in Chapter 7.

A certain part of the dissemination of disease in confined spaces may be due to pathogenic organisms floating in the air like dust particles. (See Chapter 8.)

While in some instances it may be possible to reduce the physical impurities of the air by dilution from a non-contaminated source, such a source is rarely available. Frequently, outdoor air contains a higher concentration of physical impurities than indoor air. Therefore, it is usually desirable to reduce the concentration of physical impurities by air cleaning methods. (See Chapter 24.)

THERMAL INTERCHANGES WITH ENVIRONMENT

Body temperature depends upon the balance between heat production and heat loss. Heat resulting from oxidation in the body (metabolism) maintains the body temperature well above that of the surrounding air in a cool or cold environment. At the same time, heat is constantly lost from the body by radiation, convection, and evaporation. Since, under ordinary conditions, the body temperature is maintained at its

** Normal control, naked, in calorimeter at temperatures from 72.8 to 94.1 F. First column in each experiment represents heat production as determined by indirect calorimetry, the second column, heat elimination. The portion marked with vertical lines represents vaporization, the dotted area convection, the unmarked area, radiation. The skin temperature represents the average reading of 18 spots on the surface.*

Fig. 1 .... Heat Loss from Human Being by Evaporation, Radiation, and Convection*

normal level of about 98.6 F, the heat production must be balanced by the heat loss. During work, the body temperature may rise; in fact, afternoon temperatures of normal persons average 1 deg above the resting value of the morning whether working or not.

The fundamental thermodynamic processes concerned in heat interchanges between the body and its environment may be described by the equation:

$$M = \pm S + E \pm R \pm C \qquad (1)$$

where

M = rate of metabolism, heat produced within the body.
S = rate of storage, change in intrinsic body heat.
E = rate of evaporative heat loss.
R = rate of radiative heat loss or gain.
C = rate of convective heat loss or gain.

The rate of metabolism, M, is always positive. The storage, S, may be either positive or negative, depending upon whether

heat is being stored or depleted owing to a rise or fall in body temperature. Under ordinary circumstances (when the dew point of the air is below the body surface temperature) the evaporation loss, E, is always positive; that is, heat from metabolism supplies this loss. R and C are positive when body surface temperature is above that of walls and air, and negative when it is below.

DuBois,[7] after careful calorimeter studies on a fasting, nude man, plotted the partition of body heat loss and heat production as a function of temperature. Fig. 1 shows some disparity between heat production and heat loss. This disparity is S in Equation 1. In the central range of the experiments S was quite low and no increase in heat loss by vaporization was apparent.

Within the range of 81–86 F air temperature, with still air, there is, for a resting nude man, a point at which his body

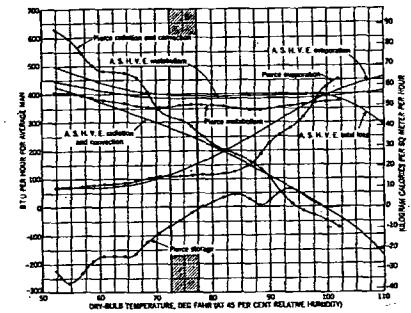


Fig. 2 .... Relation Between Metabolism, Storage, Evaporation, Radiation Plus Convection, and Temperature for the Clothed Subject

has to take no particular action to maintain its heat balance. If he is clothed, or if he is active, this point will naturally lie at a lower level. At this point, which may be termed the *neutral point for that individual*, conditions are neither too hot nor too cold. If, through a fall in air temperature, or a rise in air movement, the rate of heat loss from the skin to the environment is increased, then the body must do something to counteract this heat loss. Over a certain range, the body can achieve this by decreasing the flow of blood through the skin. This will result in some cooling of the skin and subjacent tissues, but the temperature of the deep tissues will be preserved. The range of external conditions over which this may be achieved may be termed the *zone of vaso-motor regulation against cold*. Beyond this range, the temperature of the superficial tissues will fall still further, and that of the deep tissues will fall as well, unless some other steps are taken. The body normally does react; it increases heat production by increasing muscular tension, by shivering, or by spontaneous increase in activity.[8] As long as these are adequate to meet the increased rate of heat loss to the environment, a fall in deep body temperature may be prevented. Such conditions may be said to lie in the *zone of metabolic regulation against cold*. Beyond this point, the body enters the *zone of inevitable body cooling*. Once body temperature starts to fall, man is headed for disaster.

It will be seen that, in man, deep body temperature is preserved over an important range of cold external conditions, at the expense of (1) a fall in the temperature of the peripheral tissues, and (2) an increased expenditure of energy. As regards the first of these, the farther away superficial tissue lies from the central body mass, the more readily will its temperature fall.

On the hot side of the neutral point, there exists a *zone of vaso-motor regulation against heat*, corresponding to that against cold. The blood flow through the skin is increased when the opportunities for heat loss to the environment are restricted.[9] This increase in blood flow may double the conductance of the superficial tissues over that characteristic of the neutral point, and the temperature of the skin surface may rise until it is only three degrees below that of the deep tissues. If this increase in blood flow is unable to balance the restriction in heat loss, the body has entered the next zone. Once again, the normal body takes steps to prevent a change in its deep temperature; but they are not the counterpart of the steps taken under similar circumstances on the cold side. There is, in fact, very little change in heat production, beyond that resulting from a disinclination for exertion. The second line of defense, on the hot side, is a new and powerful method of promoting heat loss—the provision of water, by the operation of the sweat glands, for evaporative cooling. As long as evaporation is adequate to restore the desired heat loss, the body is in the *zone of evaporative regulation against heat*. When this ceases to be adequate, the body is in the *zone of inevitable body heating*. The body enjoys a little more latitude in this zone than it did in the corresponding zone on the cold side, but when the deep temperature rises more than 4 deg F, it loses its efficiency. All factors which affect the evaporation of water from the skin affect heat regulation in the zone of evaporative regulation. Atmospheric vapor pressure and air motion are most important. With dry-bulb temperature above body temperature, air motion facilitates evaporative heat loss by removing hot humid air from contact with the skin and replacing it with relatively drier air.

Heat regulation in man requires an intact set of sensory nerves, a normal sympathetic nerve supply to sweat glands and blood vessels, a great many sweat glands, and a circulatory system capable of carrying heat from muscles and viscera to the skin by circulation of the blood.

Some of the phenomena of body temperature control are shown graphically in Fig. 2. The dotted curves, from a study at the John B. Pierce Laboratory of Hygiene,[10] are for subjects lightly clothed in a semi-reclining position, and give the relation between the dry-bulb temperature of the environment (with about 45 percent relative humidity) and the metabolic rate (heat production), the rate of heat dissipation by radiation and convection combined, and the latent heat loss due to evaporation from the skin and the respiratory tract. The smooth line curves from the work of the ASHAE Research Laboratory[11] give the same relationships for healthy, male subjects (18 to 24 years of age), seated at rest and dressed in customary winter indoor clothing. The Pierce Laboratory data for the semi-reclining subjects also include the rate of heat storage (either positive or negative) due to a rise or fall in body temperature. For the normally clothed subjects, a curve gives the total heat loss (that is, the sum of the radiation, convection, and evaporative losses). Here,

[a] Data by ASHAE Research Laboratory.
[b] Computed value from exposures lasting less than one hour.

storage is given by the difference between the metabolism and total heat loss.

The small difference between the metabolic rates for the two groups of subjects may be accounted for by difference in activity. Heat exchange between the body and the environment by radiation and convection is greater for the lightly clothed subject, both for cool conditions where there is excessive heat loss, and for very warm conditions where there is transfer of heat from the atmosphere to the body. The two curves for evaporative loss serve to show how physiological control uses evaporation of sweat to maintain equilibrium at high temperatures. Below 75 F, for the normally clothed subject, and below 85 F for the lightly clothed subject, evaporation loss is minimal and constant. Burch[12] has shown that this insensible perspiration reflects the permeability of the skin to the moisture of the body. Above these temperatures, control is obtained by the availability of sweat for evaporation. The difference in the curves above 75 F is probably largely determined by the difference in clothing and activity.

In the zone of evaporative heat regulation, air movement facilitates heat loss if the temperature of the air is not above that of the skin.[13] Under hot, dry conditions air movement may be of little advantage, or even of disadvantage, if it increases the addition of heat to the skin by conduction more than it promotes the loss of heat from the skin by evaporation.

HIGH TEMPERATURE HAZARDS

Studies at the ASHAE Research Laboratory[14] and elsewhere during the past two decades have made available much information dealing with the physiological effects of hot atmospheres on workers, and means of alleviating the distress and hazards associated therewith. Table 2 gives some of the physiological responses of men, at rest and at work, to hot environments. Frequent and continued exposure of workers to hot environments results in physiological derangement affecting the leucocyte count of the blood, and other factors dealing with man's mechanism of defense against infection.

Wherever S (Equation 1) becomes strongly positive and body temperature rises progressively, men will continue to work until body temperature reaches 103 F. When these body temperatures are exceeded, men work with declining efficiency and may be subject to heat stroke.

Heat exhaustion is a circulatory failure is which the venous return to the heart is reduced so that fainting results.[15] Early symptoms of heat exhaustion may include fatigue, headache, dizziness when erect, loss of appetite, nausea, abdominal distress, vomiting, shortness of breath, flushing of face and neck, pulse rate above 150, glazed eyes, and mental disturbances such as apathy, poor judgment, and irritability which usually precede fainting (syncope). Recovery is usually prompt when the man is removed to a cool place and kept lying down for a time, unless he has some other illness such as heart disease.

Heat cramps are painful muscle spasms in extremities, back, and abdomen due, at least in part, to excessive loss of salt in sweating. Formerly common in hot industries, this manifestation of illness due to heat is now greatly reduced by drinking water containing 0.1 percent salt, or by proper use of salt tablets. Heat cramps are readily alleviated by administration of salt solution intravenously.

Heat stroke is a serious effect of exposure to great heat. The body temperature climbs rapidly to excessive levels often above 105 F when for unknown reasons free sweating suddenly stops. At such high temperatures, coma appears and death may be imminent. Emergency measures are required to reduce the excessive body temperature by cooling quickly to avoid irreparable damage to the brain.[16]

The deleterious physiologic effects of high temperatures exert a powerful influence upon physical activity, accidents, sickness, and mortality. Both laboratory and field data show that physical work in warm atmospheres is a great effort, and that production falls progressively as the temperature rises.

ACCLIMATIZATION

When men move to deserts or to jungles some adaptation to the climate takes place. If work is gradually increased day by day, and if the men can get plenty of water and salt, and can sleep each night, acclimatization may be complete in 7 to 10 days. The acclimatized man works with a lower heart rate, lower skin and rectal temperature, and more stable blood pressure than when unacclimatized. The process of acclimatization requires work in the heat.[17] During the recent war, white troops lived and did hard physical work for long periods in tropical conditions when disease hazards were controlled.

Table 3 .... Upper Limits of Environmental Conditions for Acclimatized, Healthy, Young Men in Military Service

Environment	Reactions at the end of 4 hr	
	Rectal Temp F	Pulse Rate
Relatively easy	Below 101	Below 130
Difficult	101 to 102	130 to 145
Impossible	Above 102	Over 145

In recent tests made at the ASHAE Research Laboratory,[18] subjects were required to perform light work under very hot conditions for a 4-hr period each day. It was found that the ability of a new subject to endure these conditions showed daily improvement for a period of at least 2 weeks. However, after acclimatization was completed, a recess of several days had no effect on the endurance of the subject. Individuals differ widely in their capacity to acclimatize. Acclimatized men lose most of these improvements in a few weeks of temperate climate, even though they are vigorously active. In the course of acclimatization, the sweat glands come to secrete fluid less rich in salt.[18] For all except those carrying out really hard work in hot, dry atmospheres, this effects an important saving in salt loss, and makes all the difference between being exposed and not being exposed to the risk of heat cramps.

The adaptive level changes somewhat with the season. There are also marked differences between the sexes. In the cold zone the thickness of thermal insulating tissues of women is almost double that of men, although the sensory responses to cold are similar. In the hot zone, the threshold of sweating is higher for women. The thickness and insulating value of the clothing worn are also important factors in the determination of the comfort level.

UPPER LIMITS OF HEAT FOR MEN AT WORK

In very hot conditions humidity is the limiting factor, and the wet-bulb temperature assumes great importance. In 1905 Haldane recognized that 88 F wet-bulb was the limit of endurance for coal miners, and later observers have concurred.

A study was made at the Armored Medical Research Laboratory[20] to determine the upper limits of environmental conditions under which a man can perform certain work. Thirteen enlisted men, thoroughly acclimatized to the hot conditions, served as subjects. During each test, the subjects were required to march for 4 hr at the rate of 3 mph, carrying 20 lb packs under a wide range of environmental conditions which were rated as relatively easy, difficult, and impossible, on the basis of the physiological reactions of the subjects at the end of the 4-hr period as shown in Table 3 and Fig. 3.

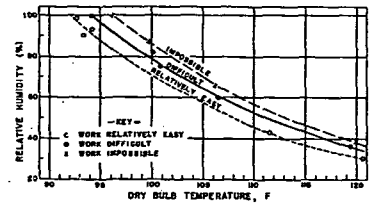

Fig. 3 .... Heat Endurance of Acclimatized Subjects Working at a Specific Rate[20]

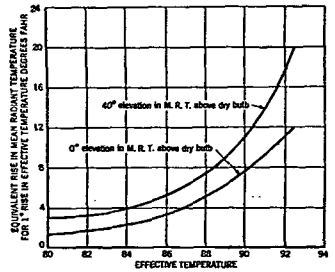
Recognition of the need of air conditioning for workers in hot industries is growing rapidly. The choice of the type of system to be used in any given instance, must be determined by the air-conditioning engineer after a study of conditions (see Chapter 51, Control of Industrial Environment). In some hot industries where few people are working in large spaces the worker himself, rather than the atmosphere, can be cooled by placing him in a small booth, and blowing cooled air over him, or by circulating cooled air through a loose-fitting suit.[21]



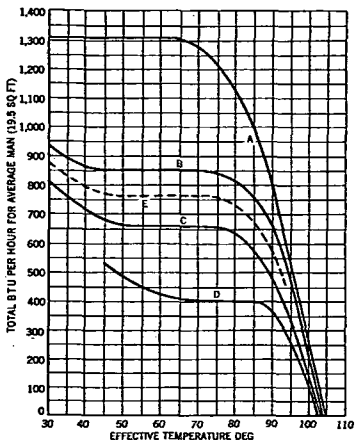


Fig. 4 .... Effect of MRT Elevation in Terms of Effective Temperature

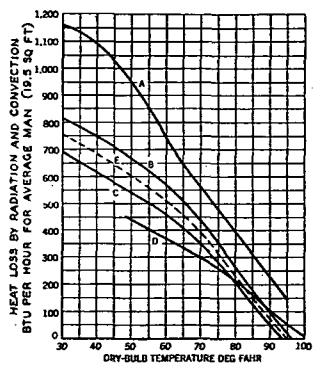
The ASHAE Laboratory has studied the effects of walls of higher temperature than the air.[22] The findings are in part shown in Fig. 4. It will be seen that the importance of mean radiant temperature, as compared with that of the effective temperature, decreases as the effective temperature rises; and also, to a certain extent, as the mean radiant temperature itself rises. The lower of the two curves relates to conditions in which the MRT was kept approximately at the level of the DBT. If this curve is followed, it will be seen that, at 80 ET, a little more than 1 deg rise in MRT produces the same effect as 1 deg rise in ET; but when the ET is 92 deg, it takes a rise of 11 F deg in the MRT to produce the same effect as 1 deg rise in ET. The upper curve relates to conditions in which the MRT was kept about 40 F deg higher that the DBT. It will be seen that under these conditions, a rise in MRT is less effective, even at low values of ET; and that it loses its relative effectiveness more rapidly as the ET rises. It should not be assumed, however, that MRT does not matter much. All that these comparisons indicate is that unit rise in MRT becomes less important *as compared with unit rise in ET*, as conditions get hotter. This may be due more to a growing importance of unit rise in ET than to a diminishing

[a] *Curve A—Persons working, metabolic rate 1310 Btu per hour. Curve B—Persons working, metabolic rate 850 Btu per hour. Curve C—Persons working, metabolic rate 660 Btu per hour. Curve D—Persons seated at rest, metabolic rate of 400 Btu per hour. Curves B and D based on test data covering a wide temperature range. Curves A and C based on test data at an Effective Temperature of 70 and extrapolation of Curves B and D. All curves are averages of values for high and low relative humidities; variation due to humidity is small.*

Fig. 5 .... Relation Between Total Heat Loss from the Human Body and Effective Temperature for Still Air[a, 14]

importance of unit rise in MRT. Under ordinary *still air* conditions the effects of air temperature and MRT appear to be interdependent. Various authorities give 0.3 to 1 deg increase of room temperature to compensate for 1 deg depression of the MRT.



APPLICATION OF PHYSIOLOGIC PRINCIPLES TO AIR-CONDITIONING PROBLEMS

In order to estimate cooling loads in occupied spaces it is necessary to know the metabolic rate (heat production) of man. This has been studied extensively, and found to remain relatively constant per unit of body surface area in a subject fasting and resting quietly after a good night's sleep. The rate is high in children, and diminishes gradually with age; it increases in certain diseases and in the presence of fever. The metabolic rate is somewhat lower in women. Heat production goes up sharply with work and varies widely in different persons doing the same work. Figs. 5, 6, and 7 and Table 27 of Chapter 13 give sufficient basic data for estimating heat production and heat loss under various conditions.

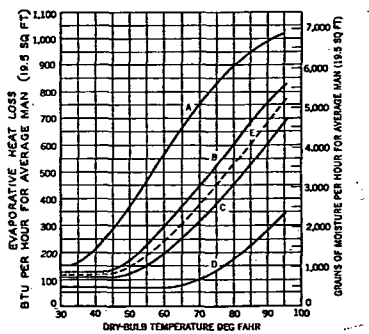
EFFECTIVE TEMPERATURE INDEX AND COMFORT ZONES

There is no precise physiologic observation by which comfort can be evaluated. Mean skin temperature offers some promise. The zone of thermal neutrality differs with clothing, season, activity, and all the other factors controlling heat production (Table 4). The comfort zone is very similar to the zone of thermal neutrality.

Sensations of warmth or cold depend not only on the temperature of the surrounding air as registered by a dry-bulb thermometer, but also upon the temperature indicated by a wet-bulb thermometer, upon air movement, and upon radiation effects. Dry air at a relatively high temperature may feel cooler than air of lower temperature with a high moisture content. Air motion makes any moderate condition feel cooler. Radiation to cold or from warm surfaces is another important factor under certain conditions affecting the comfort reaction of the individual.

[a] *See footnote a, Fig. 5.*

Fig. 6 .... Relation Between Radiation and Convection Loss from the Human Body and Dry-Bulb Temperature for Still Air[a, 14]



Combinations of temperature, humidity, and air movement which induce the same feeling of warmth are called thermo-equivalent conditions. A series of studies[22] at the ASHAE Research Laboratory established the equivalent conditions for practical use. This scale of thermo-equivalent conditions not only indicates the sensation of warmth, but also to a considerable degree determines the physiological *effects* on the body induced by heat or cold. For this reason, it is called the *effective temperature* scale or index, and it denotes sensory heat level.

Effective temperature is an empirically determined index of the degree of warmth perceived on exposure to different combinations of temperature, humidity, and air movement. It was determined by trained subjects who compared the relative warmth of various air conditions in two adjoining conditioned rooms by passing back and forth from one room to the other.

The numerical value of the index for any given air conditions is fixed by the temperature of slowly moving (15 to

25 fpm air movement) saturated air which induces a like sensation of warmth or cold. Thus, any air condition has an effective temperature of 60 deg when it induces a *sensation* of warmth like that experienced in slowly moving air at 60 F saturated with moisture. The *effective temperature index* cannot be measured directly, but is determined from dry- and wet-bulb temperatures and air motion observations by reference to an Effective Temperature Chart (see Figs. 8, 9, and 10) or tables.

Fig. 8 gives the effective temperature for any combination of dry- and wet-bulb temperatures for *still air* (15 to 25 fpm) conditions. Charts similar to Fig. 8 for air velocities of 100 and 300 fpm have been presented in earlier editions of THE GUIDE, e.g., 1939. Fig. 9 is another form of effective

[a] *See footnote a, Fig. 5.*

Fig. 7 .... Evaporative Heat and Moisture Loss from the Human Body in Relation to Dry-Bulb Temperature for Still Air Conditions[a, 14]

temperature chart embodying all three variables: dry-bulb and wet-bulb temperatures, and air velocity.

As stated previously, effective temperature is an index of the degree of warmth experienced by the body. An effective temperature line is, therefore, a line defining the various combinations of conditions which *will induce like sensations* of warmth. It does not necessarily follow that like sensations of comfort will also be experienced along the entire length of an effective temperature line. Some degree of discomfort is likely to be experienced at very high or very low relative humidities, regardless of the effective temperature. It has also been found that the optimum effective temperature varies with the season, and is lower in winter than in summer.

Tests[14] made at the ASHAE Research Laboratory in very hot conditions, with subjects doing light work, were in very close agreement with the effective temperature chart. Other work[23] under similar environmental conditions, but with subjects walking 3 mph and carrying 20 lb packs, indicated that the effective temperature lines should be more nearly horizontal. It therefore appears that the slope of the ET lines may vary, depending upon the rate of work being performed.

Table 4 .... Comparison of Comfort Ranges With Zone of Thermal Neutrality

Investigators	Effective Temperature: Optimum Line	Effective Temperature: Range	Operative Temp Range	Remarks
Comfort Zone

Keeton et al	75	74–76	...	Entire year; basal, nude. Steady state (9 hr exposure). Men and women.
Zone of Thermal Neutrality				
DuBois and Hardy	75	73.2–76.9	...	Basal; nude; men.
	71.5	64.8–76.0	...	Basal; clothed; men.
Winslow, Herrington, and Gagge	...	...	84.0–87.8	Nonbasal; at rest; nude; men.
	...	...	74 –84	Nonbasal; at rest; clothed; men.

Fig. 10 shows the ASHAE Comfort Chart[24] as published since 1950. The areas and arrows indicating the summer and winter comfort zones on the previous charts have been removed. The summer comfort zone was removed because it extended to temperatures where too large a percentage of the people would be uncomfortable. The winter comfort zone was removed for the same reason, and because of inadequate data in later studies.

The distribution curve, showing the percent of people feeling comfortable at various effective temperatures in *summer, indicates* that a maximum of 98 percent of the people were comfortable at 71 ET. The study was conducted with relative humidities between 30 and 70 percent.

The distribution curve shown on the previously used chart, showing the percent of people feeling comfortable at various effective temperatures in the *winter*, was based on research prior to 1932. This curve indicated that at 66 ET a maximum number of people were comfortable. Later studies[25] by the ASHAE Research Laboratory indicated that a maximum of 97.7 percent of the people were comfortable at 68 ET, and this finding has been confirmed by current practice.[26] However, adequate data from the later studies were available only for the ET range of 65 to 69, as presented in Fig. 10. The studies should be extended to cover a wider range. The lighter weight clothing, probably worn in the later studies, accounts for the higher desirable ET.

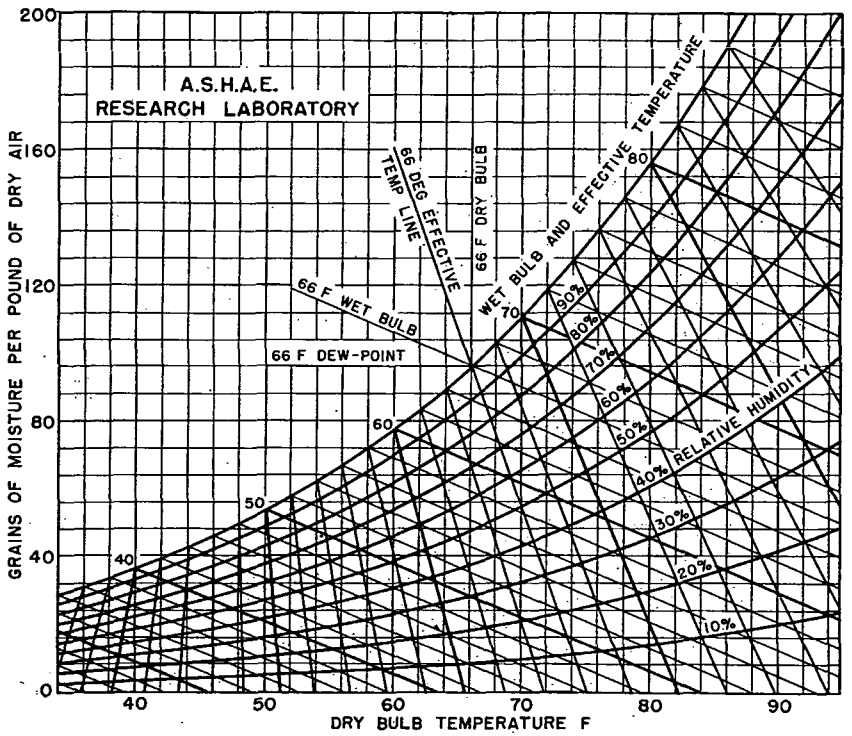

Fig. 8 .... Psychrometric Chart, Persons at Rest, Normally Clothed, in Still Air

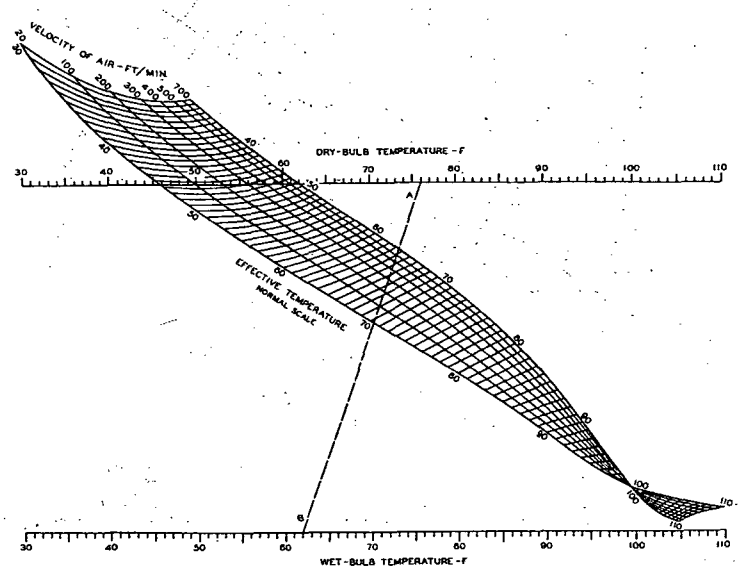
Radiation from occupants to room surfaces, and between the occupants, has an important bearing on the feeling of warmth, and may alter to some measurable degree the optimum conditions for comfort previously indicated. Since the mean radiant temperature of a space is affected by cold walls and windows, as well as by the warm surfaces of heating units placed within the room or embedded in the walls, these factors must be compensated. Likewise, in densely occupied spaces, such as classrooms, theaters, and auditoriums, temperatures somewhat lower than those indicated by the comfort line may be desirable because of counter-radiation between the bodies of occupants in close proximity to each other. Such radiation will also elevate the mean radiant temperature of the room.

Many field studies[23] have been made to determine the optimum indoor effective temperature for both winter and summer in several metropolitan districts of the United States and Canada, in cooperation with the managements of offices employing large numbers of workers (Fig. 11). On the whole, women of all age groups studied prefer an effective temperature for comfort 1.0 deg higher than men. All men and women over 40 years of age prefer a temperature 1 deg ET higher than that desired by persons below this age. The persons serving in all of these studies were representative of office workers dressed for air-conditioned spaces in the summer season, and engaged in the customary office activity.

On the basis of present knowledge, for different geographical regions and age groups, the most popular temperature varies from a low of 66 ET in winter to a high of 73 ET in summer. The spread for summer comfort is 69 to 73 ET.

A spread of 3 deg in the optimum effective temperature for summer cooling is ascribed to geographical location. However,

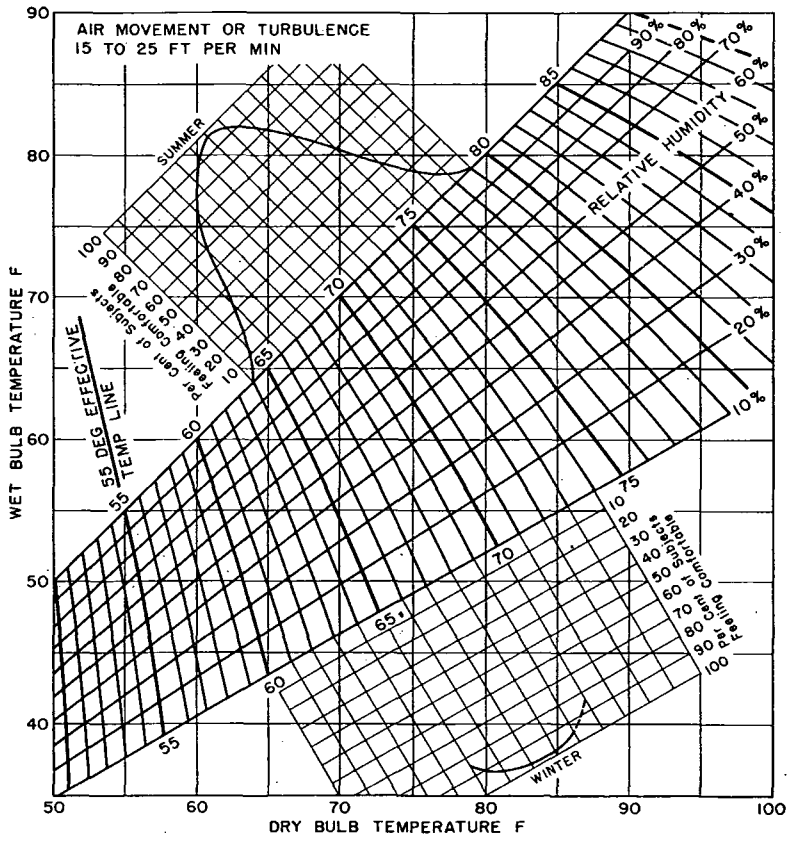
variations in sensation of comfort among individuals may be greater for any given location than variations due to a difference in geographical location. The available information indicates that changes in weather conditions over a period of a few days do not alter the optimum indoor temperature.



Laboratory studies of Keeton and others,[22] and years of practical field experience show that the adjustments in the heat regulatory mechanisms of healthy people on entering and leaving air-conditioned spaces are prompt, easy, and safe. Sudden sensation of coolness on entering a cooled room from the hot street is associated with sweat on the skin and in the clothing. Several minutes are required for the skin temperature to fall and the free moisture to disappear. Even ambulatory heart patients endure such changes with ease. The use of the word *shock* to describe any part of these adjustments is unwarranted.

Upon leaving an air-cooled space and re-entering a hot atmosphere, sudden warming occurs. Experiments at the ASHAE Research Laboratory[24] and elsewhere[25] indicated no demonstrable harm to a healthy individual. Adaptation occurred as soon as normal perspiration was established. Mild exercise shortened the adaptation time.

Most healthy, sedentary, and slightly active men and women, normally clothed and in uniform environments, with air velocities of the order of 25 fpm, are thermally comfortable the year around when the dry-bulb air temperature is in the range 73 to 77 F and the relative humidity is in the range of 25 to 60 percent.[27]



Satisfactory comfort conditions for persons at work[28] vary, depending upon the rate of work and the amount of clothing worn. In general, the greater the degree of activity, the lower the effective temperature necessary for comfort. Clothing has been evaluated for its overall insulation effects by a physical unit, the *clo* which equals 0.116 C deg per (kilogram calorie) (square meter) (hour).[29] Yaglou[30] criticizes the concept of overall insulation, and points out that different parts of the body require different amounts of insulation. The literature on effects of clothing is difficult to coordinate at the present time, as much of it is still in military service reports which are yet to be published and amplified.

For prematurely born infants, the optimum temperature varies from 100 to 75 F, depending upon the stage of development. The optimum relative humidity for these infants is placed at 65 percent.[31] No data are yet available on the op-

A. Clothing: *Customary indoor clothing.* B. Activity: *Sedentary or light muscular work.* C. Heating Methods: *Convection type, i.e., warm air, direct steam or hot water radiators, plenum systems.*

Fig. 9 .... Effective Temperature Chart Showing Normal Scale of Effective Temperature, Applicable to Inhabitants of the United States Under Following Conditions:

[a] Note—Both summer and winter comfort lines apply to inhabitants of the United States only. Application of winter comfort line is further limited to rooms heated by central systems of the convection type. The line does not apply to rooms heated by radiant methods. Application of summer comfort line is limited to homes, offices, and the like, where the occupants become fully adapted to the artificial air conditions. The line does not apply to theaters, department stores, and the like where the exposure is less than 3 hours. The summer comfort line shown pertains to Pittsburgh and to other cities in the northern portion of the United States and Southern Canada, and at elevations not in excess of 1000 ft above sea level. An increase of one deg ET should be made approximately per 5 deg reduction in north latitude.

[b] Dotted portion of winter comfort line was extrapolated beyond test data.

Fig. 10 .... ASHAE Comfort Chart for Still Air[a,b]

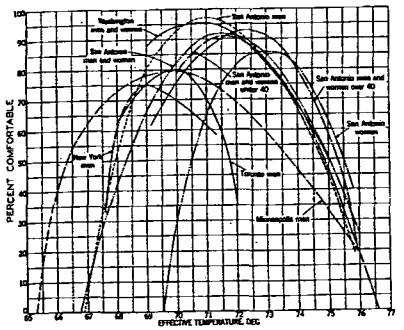


Fig. 11 .... Relation Between Effective Temperature and Percentage Observations Indicating Comfort

timum air conditions for full term infants and young children up to school age. Satisfactory air conditions for these age groups are assumed to vary from 75 to 68 F with natural indoor humidities. For children (having high metabolism) at school, in winter clothes, 70 F has been considered correct, with 55 F recommended for gymnasiums.

CHAPTER 7

AIR CONTAMINANTS

Classification of Air Contaminants; Sizes of Airborne Particles; Air Pollution by Smoke, Ash, and Cinders; Smoke Abatement and Air Pollution Control; Odor Nuisance; Industrial Air Contaminants, Flammable Gases and Vapors; Combustible Dusts; Atmospheric Pollen; Airborne Bacteria; Radioactive Air Contaminants

THE normal constituents of the earth's atmosphere are oxygen, nitrogen, carbon dioxide, water vapor, argon, small or negligible amounts of other inert gases, hydrogen, variable traces of ozone, and small quantities of microscopic and submicroscopic solid matter, sometimes called *permanent atmospheric impurities*. From the viewpoint of the air-conditioning engineer, all other airborne substances may be termed *contaminants*. This term is applied preferably, however, to undesirable or chance impurities, since the occasion may arise for adding to the air controlled amounts of solid or gaseous diluents for the prevention of explosions; germicidal vapors or mists (aerosols) for bacteria control; masking substances for odor control; or a substitute for one of the normal gases, as, for example, when helium is used to replace nitrogen in atmospheres for compressed air workers or divers.

Since control of the chemical quality of air is one of the functions of complete air conditioning, some knowledge of the composition, concentration, and properties of air contaminants under various circumstances is essential to the air conditioning engineer.

Air contaminants arise from the normal processes of wear, erosion, windstorm, sea-spray evaporation, thermal disintegration, earthquake, volcanic eruption, combustion, manufacturing, transportation, agriculture, and the biochemical or biological processes of life. They are classified at various times as organic and inorganic, visible or invisible, microscopic or macroscopic, particulate or gaseous, toxic or harmless, beneficial or destructive. The following classification is based chiefly upon the origin or method of formation of air contaminants.

CLASSIFICATION OF AIR CONTAMINANTS

Air contaminants may be classified in the following groups: (1) dust, fumes, and smokes which are solid particulate contaminants, (2) mists and fogs which are liquid particulate contaminants, and (3) vapors and gases which are nonparticulate contaminants.

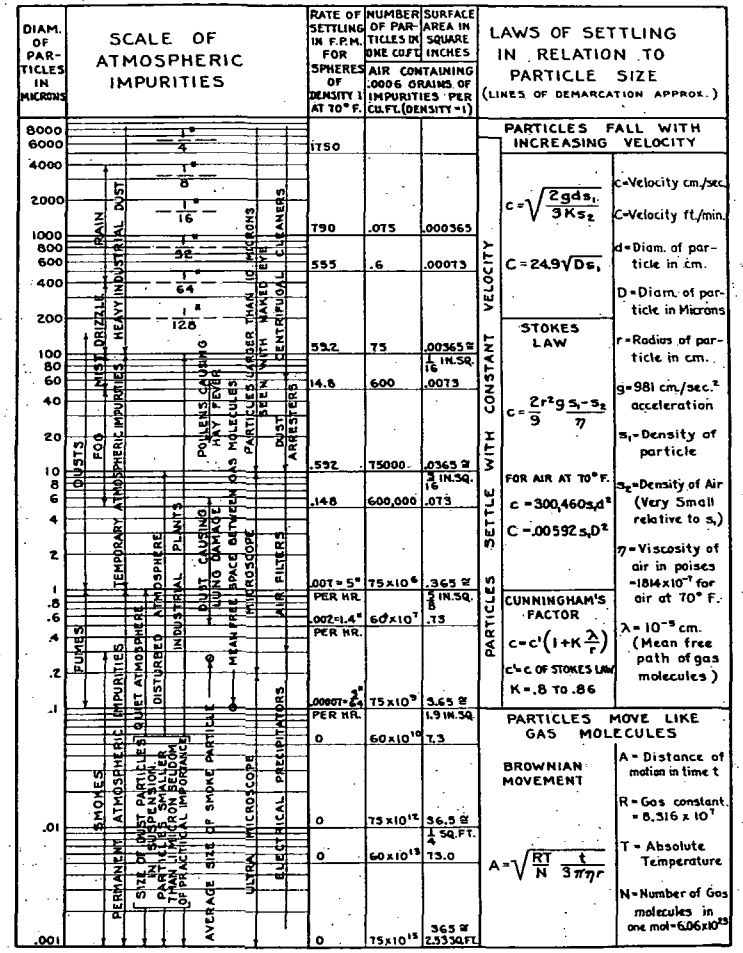
Dust, Fumes, and Smokes

Dusts are solid particles projected into the air by natural forces, such as wind, volcanic eruption, or earthquake, and by mechanical processes, such as crushing, grinding, milling, drilling, demolition, shovelling, conveying, screening, bagging, and sweeping. Some of these forces *produce* dust from larger masses, while others simply *disperse* materials that are already pulverized. Generally, particles are not called *dust* unless they are smaller than about 100 microns. Dusts may be of *mineral* type, such as rock, ore, metal, sand; *vegetable*, such as grain, flour, wood, cotton, pollen; or *animal*, such as wool, hair, silk, feathers, leather.

Fumes are solid particles commonly formed by the condensation of vapors from normally solid materials such as molten metals. Metallic fumes generally occur as the oxides in air because of the highly reactive nature of finely divided matter. Fumes may also be formed by sublimation, distillation, calcination, or chemical reaction, whenever such processes create airborne particles predominantly below the 1 micron size. Fumes permitted to *age* tend to flocculate into clumps or aggregates of larger size, thereby facilitating removal from air.

Smokes are the extremely small solid particles produced by incomplete combustion of organic substances such as tobacco, wood, coal, oil, tar, and other carbonaceous materials. The term *smoke* is commonly applied to the mixture of solid, liquid, and gaseous products of combustion, although the technical literature prefers to distinguish between such components as soot or carbon particles, fly-ash, cinders, tarry matter, unburned gases, and gaseous combustion products. The finest particulate constituents are much less than 1 micron in size, often in the range of 0.1 to 0.3 micron.

Mists and Fogs



Mists are very small airborne droplets of materials that are ordinarily liquid at normal temperatures and pressures. They may be formed by atomizing, spraying, splashing, mixing, violent chemical reaction, electrolytic evolution of gas from a liquid, or escape of a dissolved gas upon release of pressure. Very small droplets expelled or atomized into the air by sneezing constitute mists containing micro-organisms that become air contaminants.

Fogs are limited by some classifications to airborne droplets formed by condensation from the vapor state. This arbitrary distinction between mist and fog is of minor importance, as both terms are used to indicate the particulate state of airborne liquids (occasionally termed *aerosols*). *Fog nozzles* are so named because of their ability to produce extra fine droplets as compared to the mist from ordinary spray devices. The highly volatile nature of some liquids quickly reduces their airborne droplets from the mist to the fog range, and eventually to the vapor phase until the air becomes saturated with that liquid. Many droplets in fogs or clouds are microscopic and submicroscopic in size, and may be conceived as the transition state between the larger mists and the vapors.

Vapors and Gases

Vapors and Gases are nonparticulate air contaminants.

Vapors are the gaseous phase of substances that are either liquid or solid in their commonly known state, examples being gasoline, kerosine, benzene, carbon tetrachloride, mercury, iodine, camphor. Vapors may be changed to the solid or

Compiled by W. G. Frank and copyrighted, used by permission.

Fig. 1 .... Sizes and Characteristics of Airborne Particulate Matter

liquid form by increasing the pressure, decreasing the temperature, or applying both processes simultaneously. They are removed from the air by condensation with less difficulty than are the gases.

Gases are normally formless fluids which tend to occupy a space or enclosure completely and uniformly at ordinary temperatures and pressures. The following substances qualify as gases: oxygen, nitrogen, carbon dioxide, carbon monoxide, hydrogen, ammonia, sulfur dioxide. Gases, likewise, may be solidified or liquefied by the proper control of temperature and pressure.

The preceding classification is not suitable for the airborne living organisms, which range in size from the submicroscopic *viruses* to the largest pollen grains, not considering the smallest insect life. Bacteria range from about 0.2 to 5 microns in size, fungus spores from 1 to 10 microns, and pollen from 5 to 150 microns.

SIZES OF AIRBORNE PARTICLES

Fig. 1 is a graphic tabulation of the properties of airborne solids and liquids arranged according to size on the micron scale. There are 25,400 microns in 1 inch.

Particles larger than 10 microns are unlikely to remain suspended in air currents of moderate strength, but settle out by gravity at speeds dependent upon the shape, size and specific gravity of the particle, wind velocity, orientation of the collecting surface, and topography. These larger particles are of major interest to the engineer in the solution of nuisance problems, but it is usually the smaller particles, or those below 10 microns, that remain in the air long enough to be of hygienic as well as economic significance.

Industrial dust particles are predominantly of the order of 1 micron in size. Tremendous numbers are also present in the submicroscopic range below 0.5 micron, but those below 0.1 micron are not believed at present to be of practical importance, possibly due to their exceedingly small mass in comparison with the balance of airborne matter. In fact, particles this small may become the *permanent* atmospheric impurities that have little, if any, opportunity of settling because of the continual motion imparted to them by air currents and the molecular activity of gases (Brownian Movement).

The survey[1] of atmospheric pollution in 14 American cities conducted from 1931 to 1933 indicated the average size of outdoor dust particles to be 0.5 micron, as collected by the Owens jet dust counter and measured under the microscope. Inability of the *light field* microscope to reveal particles in the 0.1 micron vicinity may have influenced the determination of average particle size.

The lower limit of particle size visible to the naked eye cannot be stated definitely. It depends not only upon the individual eye, but also upon the shape and color of the particle, intensity and quality of the light, and nature of the background or opportunity for contrast. Under ideal conditions a particle of 10-micron size might be recognized, while under less favorable conditions it may be impossible to distinguish a particle smaller than 50 microns. The lower limit of visibility *probably ranges from 10 to 50 microns.*

Dusts, powders, and granular materials are frequently classified by reference to the size of screens used for separation. Particles above 40 microns are said to be the *screen sizes* and those below, the *subscreen* or microscopic sizes. Approximate or theoretical sizes of particles corresponding to the mesh scale of the U. S. Standard Sieve Series are given in Table 1.

Table 1 .... Relation of Screen Mesh to Particle Size

U. S. Standard sieve mesh	400	325	200	140	100	60	35	18
Nominal sieve opening in microns	37	44	74	105	149	250	500	1000

Microscopic examination of screened dust indicates that the average diameter of a sample of irregular particles may be substantially larger than the openings of the screen through which it has passed, if the particle shapes deviate considerably from the spherical form.[2] The smallest dimension of many such particles will correspond to the maximum permissible distance between the wires of commercial screens made to ASTM Standard Specifications. Screening does not give sharp separation into size groups, and accordingly, such a classification is statistical rather than absolute.

AIR POLLUTION BY SMOKE, ASH, AND CINDERS

Total airborne solids settling in urban areas are usually reported as *soot fall* in tons per (square mile) (month). Such data published for the cities in this country range from 20 to 200 tons per (square mile) (month). To the air-conditioning engineer this information may indicate the effectiveness of smoke abatement or fuel combustion control methods in his locality, but it does not provide a suitable index of the suspended dust that air cleaners in a ventilating system are expected to capture.[3, 4, 5] Gravimetric or weight data of the type given in Table 2 are preferable. In some cases airborne particle counts may be necessary, as for pollen, bacteria, spores, and insoluble dusts causing illness or lung disease.

Table 2 .... Dust Concentration Ranges

Location	Grains per 1000 Cu Ft[a]	Milligrams per Cubic Meter
Rural and suburban districts	0.02–0.2	0.05–0.5
Metropolitan districts	0.04–0.4	0.1–1.0
Industrial districts	0.1–2.0	0.2–5.0
Ordinary factories or workrooms	0.2–4.0	0.5–10
Excessively dusty factories or mines	4–400	10–1000
Minimum explosive concentrations	4000–200,000	10,000–500,000

[a] 1 grain per 1000 cu ft = 2.3 milligrams per cubic meter.
1 oz per cubic foot = 1 gram per liter = 1000 grams per cubic meter.

Dust concentrations by weight cannot be converted readily to concentrations by particle count because of the variability of particle size, shape, and specific gravity, and the inherent characteristics of dust counting and weighing procedures. One milligram of dust per cubic meter of air may represent dust counts from 1 million to 100 million particles per cubic foot of air (light field microscope technic) according to the size distribution of the airborne dust sample. Information of this type for a specified application is best obtained by simultaneous sampling for both counting and weighing and noting carefully at the time all factors that might affect the reproducibility of the count-weight ratio.

Smoke Abatement and Air Pollution Control

Successful abatement of atmospheric pollution caused by smoke requires the combined efforts of the combustion engi-

neer, industrial executive, public health officer, city planning commission, and the community at large. Electrification of industry and railroads, increases in the use of domestic oil and gas furnaces, and segregation of industrial districts are gradually providing effective aid in the solution of this problem. In the large cities where nuisance from smoke, fly-ash, and cinders is more serious, limited areas obtain some relief by the use of district heating. (See Chapters 33, 34, and 35 for further discussion on fuel-burning technic.)

Many present ordinances limit the number of minutes in any one hour that smoke of a specified density (determined by comparison with a Ringelmann Chart which is described in Chapter 44) may be discharged.

There is now considerable interest and activity in the control of air pollution factors in addition to smoke. Difficulty in the establishment of acceptable criteria for certain corrosive and irritant gases, such as fluorides and the oxides of sulfur and nitrogen discharged with the gases of combustion, and the frequently complicated technical and economic problems encountered in control, have delayed the drafting and enforcement of legislative measures. Recent reports of an increased incidence of diseases, such as pneumonia and lung cancer, in areas high in certain air contaminants, require further critical investigation before acceptance. The values finally adopted will undoubtedly be lower than the MAC (Maximum Allowable Concentration) limits for use in industry, because the exposure is continuous compared with the 8-hour day, 5- or 6-day week upon which MAC values are based, and because the exposed population contains individuals with greater variation in age and health status.

In foggy weather, or during an *inversion* of atmospheric conditions, accumulation of gaseous contaminants may cause irritation of eyes, nose, and respiratory passages, and possibly cause even more serious physiological effects. The Meuse Valley fog disaster (Belgium 1930) and the Donora *smog* (Pennsylvania 1948) are classic examples in the history of gaseous air pollution. In both instances it is believed that irritant gases, principally from industrial plants, accumulating during periods of exceptionally prolonged meteorological *inversion* and fog, contributed to the illness of many persons, and to the death of some who were especially susceptible.

Absorption of Solar Radiation

Absorption of solar ultra-violet light by smoke and soot is recognized as a health problem in many industrial cities. Measurements of solar radiation in Baltimore[6] by actinic methods demonstrated that ultra-violet light intensity in the country was 50 percent greater than in the city. In New York City[7] a loss as great as 50 percent in visible light was found by photoelectric measurements.

ODOR NUISANCE

A problem companionate with smoke abatement is the control of odor nuisance in the neighborhood of industrial plants discharging noxious or offensive air contaminants. Community planning and zoning will avoid much of the difficulty in the future, but meanwhile many industrial cities must resort to corrective measures by requiring installation of air cleaning devices, alteration of manufacturing processes, or termination of the offensive operation in residential or commercial districts.

Control of outdoor odor nuisance is especially troublesome because of the extremely minute quantities of contaminant that are capable of offending through a wide area. New industrial chemicals with strange or unfamiliar odors tend to receive more attention from the neighborhood than the customary odors generated by well-known processes and raw materials. Methods of odor control currently in use include charcoal adsorption, scrubbing towers and air washers, chlorination, condensation, masking, passage of the odorous air through combustion chambers, dispersion through a tall stack, and best of all, substitution of less offensive materials whenever possible.[8, 9, 10, 11]

Control of air quality within buildings ventilated for human occupancy is discussed in Chapter 6. Tobacco smoke odors, cooking odors, and body odors are air contaminants of the nuisance type which now command a decisive position in the standards of air quality for indoor comfort. However, the engineer will find, at times, that odors originating *outside* buildings in industrial or business districts may determine the kind and capacity of equipment he must provide for a high quality air-supply installation.

INDUSTRIAL AIR CONTAMINANTS

Many industrial processes are sources of contaminants. Their control is an important function of the ventilating or air-conditioning engineer, because the atmosphere within buildings is the medium whereby such finely divided matter is dispersed and transported from the source to remote locations where it may cause property damage, nuisance, fire, explosion, disease, and even death.

Tables 3, 4, and 5 give maximum allowable concentration values for many industrial air contaminants. Some of these values have been proposed by ASA Sectional Committee Z37 on Allowable Concentrations of Toxic Dusts and Gases, and others by the Committee on Threshold Limits of the American Conference of Governmental Industrial Hygienists. The values have been adopted by the American Conference of Governmental Industrial Hygienists and by many of the official industrial hygiene agencies.

It must be emphasized that these limits in the great majority of instances are only *suggested maximum working levels* since they are estimates, based in many cases upon incomplete environmental and medical studies. Where there is agreement between the *ASA Standard* Z37 and ACGIH values, reliability of the ASA Standard is increased. The values are not fixed, but are subject to revision, upward or downward, with the development of new information. There is by no means complete agreement regarding these values among responsible industrial hygienists.

In applying these guide limits, the following factors must be considered:

1. The duration of exposure is 8 hr a day for 5 or 6 days a week.

2. The measurements are indicative of the concentration in the breathing zone of the exposed person.

3. The MAC is usually accepted as the average exposure value when the upper limits do not greatly exceed the MAC value. For example, it cannot be assumed that if 100 ppm is considered *safe* for 8-hour exposure, that 800 ppm for one hour will be permissible.

4. Two substances with similar MAC values may be quite different as to physiological effects at other concentrations. In one instance the selection of a limit may be predicated upon a discomfort factor, with a wide margin of safety before systemic effects would be encountered, while in another case the value represents an appreciable fraction of the concentra-

Table 3 .... Maximum Allowable Concentration of Gases and Vapors

Substance	ASA Standards MAC ppm[b] by volume	Threshold Limit Values ACGIH[a] 1958 ppm[b]	Threshold Limit Values ACGIH[a] 1958 g/cu m or oz/1000 cu ft

tion which may be associated with severe and irreversible injury.

5. These values are *upper* limits; it is desirable to operate well below the levels if the engineering and economic factors permit. The prudent engineer will incorporate a reasonable margin of safety in his estimates of ventilation capacity.

In Table 3, Column 1 lists the ASA Sectional Committee Z37 MAC values; Column 2, those of the ACGIH Committee on Threshold Limits. Column 3 gives the value in grams per cubic meter or ounces per 1000 cu ft for the corresponding ACGIH limits.

In Table 4, Columns 2 and 3 are respectively the MAC values from the ASA and ACGIH Committees.

In Table 5, the MAC values for industrial dusts as given were obtained from data of the ACGIH Committee on Threshold Limits.

ACGIH limits for either gamma or Roentgen radiations are 0.3 roentgens per week.

Information on the properties and effects, with respect to health, of specific industrial air contaminants is available in publications listed at the end of this chapter.

FLAMMABLE GASES AND VAPORS

Adequate ventilation is a primary requirement for minimizing the hazard of fire or explosion due to gases and vapors. The need for good ventilation is not removed by the use of other precautions, such as the elimination of known ignition sources, segregation of hazardous operations, adoption of safe building construction, and installation of automatic alarms. Some safety engineers regard overventilation of an operation employing flammable liquids as a legitimate operating charge for the privilege or necessity of using a dangerous process. However, it is not possible to apply a reasonable safety factor to the ventilation estimate without consideration of the concentrations of gases or vapors that approach the danger point. Safety engineers prefer to limit the concentration to ¼ or ⅕ of the lower explosive limit, and this fact should be given full weight in determining the capacity and design of ventilating equipment. Rarely should consideration be given to *operation above the upper explosive limit* in the open areas of buildings or rooms—even though unoccupied—because the danger of temporary drop of gas concentration to a point within the explosive range is too great.

Ability of a flammable liquid to form explosive mixtures is determined largely by its vapor pressure, volatility, or rate of evaporation. *Flash point* is a convenient method of expressing this property in terms of the temperature scale. It may be defined as the temperature to which a combustible liquid must be heated to produce a flash when a small flame is passed across the surface of the liquid. The higher the flash point, the more safely can the liquid be handled. Liquids with flash points under 70 F should be regarded as highly flammable.

Upper and lower limits of flammability of gases and vapors, and the flash points of the corresponding liquids are given in Table 6.

Methods for estimating the flammable limits of mixtures of gases or vapors must be applied with caution; the reader is referred to other publications for this information.[13, 18]

Design of equipment for the control of combustible anesthetics is outlined in Chapter 8. Construction of equipment for handling air containing flammable substances, or operating in atmospheres so contaminated, is discussed in Chapter 52.

It is customary to report the concentrations of flammable

[a] Adapted from: *Fire and Explosion Hazards of Combustible Gases and Vapors*, by G. W. Jones; Chapter 13, *Industrial Hygiene and Toxicology*, edited by F. A. Patty (Interscience Publishers, 1948); *Properties of Flammable Liquids, Gases and Solids* (Associated) Factory Mutual Fire Ins. Cos., January (1940); and *National Fire Codes for Flammable Liquids, Gases, Chemicals and Explosives*—1945 (National Fire Protection Association).

[b] *Closed cup* refers to the equipment used in flash point determinations.

[c] From *Standards for Storage, Handling and Use of Flammable Liquids* (National Board of Fire Underwriters, No. 30, July 1954).

gases or vapors in percent by volume, or *volume percent*. Comparison with concentrations on the *part per million* scale used in chemical, medical, or industrial hygiene literature is readily made by the conversion: 1 percent = 10,000 ppm (parts of contaminant per million parts of air, by volume, or in other words, cubic feet of contaminant per million cubic feet of air). It will be noted in Table 6 that nearly all of the substances listed have lower explosive limits above 1.0 percent, while the *maximum allowable concentrations* for gases and vapors in Table 3 are below 1000 ppm or 0.1 percent in most cases. Therefore, control of toxic or injurious vapors to levels below their maximum allowable concentrations for health usually requires much more effective ventilation than for the prevention of a fire hazard.

COMBUSTIBLE DUSTS

A dust explosion is essentially a sudden pressure rise caused by the very rapid burning of airborne dust. The primary explosion often originates from a small amount of dust in suspension exposed to a source of ignition and the pressure and vibration it creates may be sufficient to dislodge large accumulations of dust on horizontal ledges or surfaces of the building and equipment, thereby creating a secondary explosion of great force. Thus the air-conditioning engineer is involved for two reasons: (1) to obtain a movement of dust-laden air into exhaust hoods or openings, and through ventilating or pneumatic conveying ducts, in a manner that will prevent accumulation of highly flammable dust at points

where it could ignite inside the equipment; and (2) to so design *process ventilation* as to prevent the escape of dust which might settle on horizontal surfaces and become a potential source of disaster at some distance from the dusty operation. (See Chapter 52.)

Intensity of a dust explosion depends upon: chemical and thermal properties of the dust; particle size and shape; concentration in air; proportion of inert dust in the air; moisture content and composition of the air; size and temperature of the ignition source; and degree of dispersion of the dust cloud. Investigations on the explosibility of dusts require determination of the maximum pressure developed during explosion of a known air concentration, as well as determination of the rate of pressure rise. Investigators frequently experience difficulty in obtaining dust suspensions of uniform dispersion, and this should be kept in mind when comparing results from several sources.[14]

Minimum explosive concentrations of airborne dusts already tested range from 0.01 to 0.5 oz per cubic foot, or 10 to 500 grams per cubic meter of air. Maximum pressures generated have been reported as high as 500 psig, although they are more likely to be of the order of 50 psig. Investigations on the flammable characteristics of dusts are currently made at 0.1 and 0.5 oz per cubic foot.[15–21]

ATMOSPHERIC POLLEN

Properties of pollen grains discharged by weeds, grasses, and trees and responsible for hay fever, are of special interest to designers of air cleaning equipment (see Allergic Disorders in Chapter 8, and Air Cleaning, Chapter 24). Whole grains and fragments transported by the air range chiefly between 10 and 50 microns in size, but some have been measured as small as 5 microns, and others over 100 microns in diameter. Ragweed pollen grains are fairly uniform in size within the range of 15 to 25 microns. Pollen grains can be removed from the air more readily than the particles of dust prevalent in outdoor air or produced by dusty processes, since the latter predominate in the range of 0.1 to 10 microns in size.

Most grains are quite hygroscopic and therefore vary in weight with the humidity. Illustrations and data on individual pollen grains are available in the botanical literature.[22, 23, 24] Geographical distribution of plants known to produce hay fever is also recorded.[25, 26]

The quantity of pollen grains in the air is generally estimated by exposing an adhesive-coated glass plate outdoors for 24 hr, and then counting calibrated areas under the microscope. Methods are available for determining the number of grains in a measured volume of air,[25, 27, 28] but their greater accuracy has not caused them to replace the more simple *gravity slide method* used for most pollen counts. Counting technics vary somewhat, but the daily pollen counts reported in local newspapers during the hay fever season usually represent the number of grains found on 1.8 sq cm of a 24-hr *gravity slide*.

Hay fever sufferers may notice the first symptoms when the pollen count is 10 to 25, and in some localities the maximum figures for the seasonal peak may approach 1000 for a 24-hr period, depending upon the sampling and reporting methods of the laboratory. Translation of gravity counts by special formulas to a volumetric basis, or the number of grains per cubic yard or per cubic foot of air, is unreliable because of the complexity of the modifying factors. When such information is important, it is best obtained directly by a volumetric instrument. The number of pollen grains per cubic yard of air evidently varies from 2 to 20 times the number found on 1 sq cm of a 24-hr gravity slide, depending on grain diameter, shape, specific gravity, wind velocity, humidity, and physical placement of the collecting plate.[25, 26, 27]

AIRBORNE BACTERIA

Study of the occurrence and significance of micro-organisms in the atmospheres of the indoor world is absorbing the energies of a substantial number of physicians, bacteriologists, aerobiologists, physicists, public health workers, engineers, and hospital personnel. Some data are available on the types and quantities of bacteria found in a variety of spaces, but it is not possible at present to use this information as a conclusive index of the potential health hazard of a given environment. The reported number of airborne organisms may vary from 1 to 1000 per cubic foot of air, influenced somewhat by the method of testing.[29] Many are attached to the dust particles present in the air.

Where it seems advisable or desirable to control the bacterial content of rooms, public conveyances, or buildings, highly effective methods are available (see Chapter 8), and their extended use may do much to assist the workers in this field in accumulating the necessary mass of evidence that will decide the practical value of air sterilization for the control of communicable disease. It is now well established that ultra-violet radiation is feasible for the protection or preservation of pharmaceuticals, cosmetics, and food products.

RADIOACTIVE AIR CONTAMINANTS[32]

Radioactive air contaminants are physically similar to ordinary industrial and chemical plant contaminants. They differ from ordinary contaminants, however, in that they may be highly toxic when ingested and may present a direct radiation hazard when accumulated in appreciable quantities. Another factor which must be considered in the filtration of these materials is the possibility of their being concentrated in plant and animal life in the area of contamination. Concentrations resulting from absorptions by plants and subsequent feeding of animals in the magnitude of several thousand times, is not unusual. Tolerances for radioactive contaminants have been established and are under continuing study and review. Guidance in regard to tolerance levels for discharge of contaminated air in different types of localities can best be had from the classified literature which is available through proper clearance procedures.

CHAPTER 8

AIR CONDITIONING IN THE PREVENTION AND TREATMENT OF DISEASE

Sanitary Ventilation, Control of Airborne Infection, Value of Air Cooling Under Tropical Conditions, Treatment of Disease, Operating Rooms, Nurseries for Premature Infants, Fever Therapy, Cold Therapy, Allergic Disorders, Oxygen Therapy, General Hospital Air Conditioning

THE Second World War caused an increase of interest in the preventive aspects of air conditioning. It re-emphasized the importance of the control of airborne infection and demonstrated the value of air cooling under tropical conditions for the prevention of heat rash, for promoting proper rest and sleep, and in the convalescence of patients.

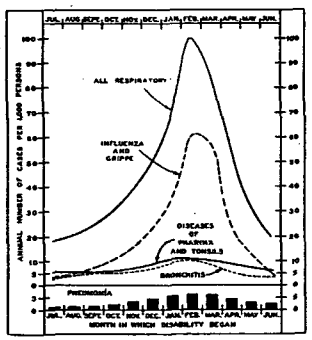
The problem of air conditioning or air purification in shelters, hospitals and other occupied buildings, to reduce the hazard from radioactive particles following an atomic explosion, merits the most careful consideration. Shelters should be without windows, underground, strong enough to resist blast and have sufficient cover to protect against initial radiation. They should be closed to outdoor air in the period immediately following a blast but may eventually have to be provided with ventilation from outdoors to limit the increase of temperature, moisture or odor, resulting from the occupancy, or in extreme cases to avoid serious oxygen deficiency and increase of carbon dioxide. When air must be drawn from outdoors and power is available, a mechanical ventilation system can be used. This will make it possible to pressurize the shelter, to utilize special filtration apparatus and to control the entry of outdoor air at will.

A surface or subsurface burst of an atomic bomb will result in a wide dispersion of airborne radioactive particles.[1] Windows of buildings within a three-mile radius from the point of detonation of a 20 KT bomb will be broken, and consequently, no appreciable protection will be afforded by the use of conventional air-conditioning systems under these conditions. Beyond the three-mile radius many structures may be found with windows undamaged and otherwise capable of providing some degree of protection from airborne radioactive particles by the utilization of an air-conditioning system. However, conventional air-conditioning systems should not be relied upon for protection in urban structures which may be utilized in the accomplishment of specific missions following an atomic detonation. There are special techniques and devices available which will provide this protection.

The smog incident in Donora, Pa., in 1948 focused the attention of health authorities and engineers on the problem of air contamination by the gaseous wastes discharged into the air above cities. The U. S. Public Health team investigating the incident[2] found that in this city several previous incidences of lesser severity had occurred during the preceding 30 years as indicated by an increase of mortality rates during certain periods. A high percentage of the population suffered to some extent during the 1948 smog. Older individuals particularly were seriously affected with cardio-respiratory symptoms.

The exact way in which the contaminants due to gaseous wastes affect the human being is unknown.[3] It is believed that the combination of contaminants rather than any single substance produces the toxic effects. The medical profession has much to learn about the effects of contaminants on human beings as a basis for determining when precise controls are needed.[3]

SANITARY VENTILATION



During the last 20 years great popular interest has been aroused in the spread of respiratory infection indoors, and in its control by ventilation or its sanitary equivalent, air disinfection. In Europe three important documents have appeared in English, Swedish, and French literature.[4, 5, 6] In the United States where the study began, the vast literature has been consolidated, and definitions, formulations, and factors of sanitary ventilation codified in a volume now being edited for publication.

The Council of Physical Medicine of the American Medical Association approved the radiant disinfection of air in 1943, and two sub-committees of the Committee on Research and Standards of the American Public Health Association have reported favorably upon the control of airborne infection by sanitary ventilation and on air sanitation respectively.[7, 8, 9, 10] The ASHAE Technical Advisory Committee on Air Sterilization from 1944 to 1949 reported progress in THE ASHAE JOURNAL, and recommended a set of definitions, formulations and factors for joint adoption by the American Public Health Association and the Society. The following section on Control of Airborne Infection gives some idea of the scope of the subject.

CONTROL OF AIRBORNE INFECTION

The majority of airborne diseases are spread indoors where people gather. Any program of air sanitation is influenced by a number of factors. In the winter months, the closing of doors, windows, and other means of access to the outdoor air to conserve warmth, as well as the crowding of persons indoors, provides conditions conducive to a high incidence of contagion. This seasonal phenomenon, illustrated in Fig. 1 which represents a study made by the U. S. Public Health Service, will concern the ventilating engineer insofar as air quality (determined by temperature, humidity, air replenishment, type of air movement, and freedom from contamination) is a major intrinsic factor. Apart from the

seasonal picture of airborne contagion, are such extrinsic factors as rate of turnover of personnel, and the marked susceptibility of the recruit as compared with permanent personnel[21] as shown (see Fig. 2) by studies of military personnel housed in barracks. These extraneous variables and the factor of contact infection (direct spray) tend to complicate any evaluation of the effectiveness of air sanitation for elimination of micro-organisms in droplet-nuclei and droplet-dust. Thus, control measures may eliminate consistently 90 percent of airborne organisms in laboratory tests, but may not effect a decrease in actual incidence of infection exceeding 30 percent. Thirty percent may be the maximal reduction in infection possible by air treatment methods. The distinction should be clearly drawn, therefore, between the effectiveness of a procedure in laboratory tests

Occurrence of diseases causing disability for 8 consecutive days or longer in a group of 100,000 wage earners (10 percent women) in different industries.

Fig. 1.... Study of Average Monthly Frequency (1921–1926 Inclusive) of Specified Respiratory Diseases

and its effectiveness and applicability in actually reducing the incidence of airborne disease. On the other hand, recent studies suggest that inhalation of dust-borne bacteria is more important than direct inhalation of infectious droplets or droplet nuclei in the spread of respiratory tract infections.[18]

The following sequence of events has been postulated as occurring in a large proportion of intra-ward infections: (*a*) ejection of relatively large protected infective particles from patients; (*b*) rapid venting or settling of these particles so that those remaining airborne are in low concentration; (*c*) survival of infective particles to permit the accumulation of high concentrations on surfaces; (*d*) repeated reintroduction of infective particles into the air under the stimulus of ward activities or by air currents of the order of 50 fpm over the floor; and (*e*) extension of infective areas by air turbulence throughout the ward or hospital. The most important link in this probable infection chain has been demonstrated to be the reintroduction of particles into the air.[23]

Intensive studies on air disinfection have indicated two distinct control measures: (*a*) suppression of dust and lint, and (*b*) disinfection of droplet-nuclei. A third measure, control of relative humidity, is important. It has been shown that the viability of certain organisms sprayed into the atmosphere from a liquid suspension is dependent on relative humidity. The mortality rate of the organisms is very high at a relative humidity of 50 percent,[24] and decreases at humidities above and below this figure. It has also been reported that the influenza virus loses much of its virulence when the relative humidity is 50 percent.[13]

Well controlled, large scale tests of the various methods of air sterilization conducted in barracks[25, 27] have confirmed the importance of dust control in minimizing the spread of airborne disease, a consideration which has guided the practices of ventilating engineers for a number of years. The importance of the dust factor has been emphasized by many engineers, and has been convincingly demonstrated by subsequent bacteriologic studies aboard ships.

Treatment of floors and bedclothes with oil emulsions has proved effective in reducing bacterial dispersion by as much as 90 percent in Army barracks and station hospitals.[17] The incidence of acute respiratory infections was from 10 to 30 percent lower in barracks with oiled floors and bedclothes than it was in control barracks which received no special treatment. More recent studies, however, have yielded inconsistent results.

An emulsifying mixture, *Fixanol C* containing cetyl pyridinium bromide, when incorporated in an oil-in-water emulsion imparted a bactericidal action. Blankets treated with this emulsion became bactericidal and retained this property for as long as three months. The possibility of hypersensitivity of an occasional individual to bromide drugs should be borne in mind when exposing large groups to treated garments or blankets.[13]

No simple method for disinfecting droplet-nuclei has yet been devised. Under favorable laboratory conditions, propylene glycol in concentrations of 0.07 to 0.14 milligrams per liter, and triethylene glycol in a concentration of 0.0045 milligrams per liter were highly germicidal for most airborne bacteria in clean air when the relative humidity was between 40 and 60 percent.[26, 29, 30] A humidity of 50 percent, without the use of glycol vapor, has been reported as destructive to some bacteria. However, maximum rates of bactericidal action of triethylene glycol vapor will be secured at humidities between 20 to 50 percent.[31]

In a recent report on the effect of triethylene glycol vapor in air disinfection, it is pointed out that the rate of ventilation, as determined by the number of air changes per hour, is important and that continuous vaporization is needed to maintain effective concentrations of glycol vapor.[31] In the absence of an apparatus to measure the concentration of vapor in the room, a slight fog is an indication of adequate concentration. Absence of such a fog indicates a non-bactericidal concentration. The report stated: "However, under experimental conditions we have observed no apparent decomposition of triethylene glycol when temperatures up to 290 F were maintained at the site of vaporization, provided the vaporizing unit was designed so that heat was applied to liquid glycol only at the point of vapor formation. On the other hand, decomposition was frequently observed when the vaporizing temperature was raised above 290 F, or when liquid glycol was kept above 120 F for long periods of time. The precise nature of the decomposition products is as yet unknown, but they may well be irritant or toxic and their formation should be avoided. For this reason, it is felt that a limit of 290 F should be applied to the temperature employed in vaporization, and furthermore, that liquid glycol should not be heated above 120 F for long periods of time.[27]

It was also recommended that vaporizers be adjustable to a wide range of output as measured by grams of liquid glycol vaporized per hour; for instance, from 0.5 g to at least 2.0 g per 1000 cu ft of volume treated, for small vaporizing units. Such high rates secure bactericidal concentration in less than an hour. Each room should be furnished with a single small vaporizer, and one vaporizer should not be expected to handle a volume greater than 4000 cu ft. Apparatus for the production of glycol vapor, and an independent duct system for carrying this vapor and diluting air for large rooms or spaces, and unit type vaporizers for small spaces, have been described.[32] There is also available a device called the glycostat for the automatic regulation of glycol vapor in the air. This instrument has been calibrated to measure the degree of saturation of the air with glycol vapor by direct reading of the variations in the intensity of

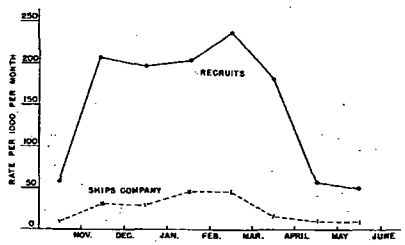


Fig. 2.... Monthly Incidence of Acute Respiratory Illness Among Naval Recruits and Ship's Company (Permanent Personnel)[21]

light reflected from the glycol condensing surface of the wheel of the instrument.[28]

Under practical conditions, particularly in the presence of dust in the air, glycol effectiveness is much reduced. The use of other chemical aerosols that have been tried is limited by their toxicity, odor, or destructiveness to fabrics and metals. A recently reported controlled experiment in the offices of the Metropolitan Life Insurance Company showed that under ordinary working conditions triethylene glycol vapor failed to reduce the number of airborne bacteria and the incidence rate of minor respiratory infections.[26]

Ultraviolet radiation of floors and upper air has been studied extensively at the Naval Training Center, Sampson, N. Y. In barracks housing naval recruits, hospital admissions for respiratory infections (mostly *catarrhal fever*) were 25 percent lower in a group of men exposed to ultraviolet radiation—2537 Angstrom Units, 1 to 7 ergs per (cm^2) (sec) at bed level—than they were in adjacent control barracks without ultraviolet radiation.[33]

A controlled study over a six-year period on the evaluation of ultraviolet radiation of sleeping quarters as a supplement to accepted methods of respiratory disease control has been reported.[34] The amount of radiation over the last two years of the period was believed to be about five times that recommended commercially. No significant effect on the incidence of disease could be detected in about 400 inmates during the six-year period. This conclusion may not be applicable to present ultraviolet equipment installed in accordance with manufacturers' recommendations. The data imply that air layers were not sufficiently mixed. However, more efficient mixing would have been obtained at the expense of increased circulation of dust and lint. Sources of ultraviolet radiation should be so situated as to protect the eyes of the occupants of the room from direct or reflected rays. A combination of ultraviolet radiation and dust control measures is believed to be more effective than either one of the two used alone, but the proof for this has yet to come.

There is no doubt that these methods will reduce the number of bacteria in the air of an enclosed space, but there is still considerable question as to whether they are practical measures for reducing the total number of respiratory infections among personnel, since exposure by contact is an important factor. Bourdillon and his group concluded that there is justification for attempting to reduce the load of airborne micro-organisms by the methods now available.[4] They have explored the properties of a number of compounds, and their conclusions are in agreement with those of American investigators.

The present status is admirably reviewed by the Committee on Sanitary Engineering of the National Research Council,[27] and by a subcommittee of the American Public Health Association.[3] Both committees believe that the problem of air disinfection is still in the experimental stage. Since knowledge of the effectiveness of glycol vapors has not kept pace with the development of vaporizing devices, there is real danger that commercial exploitation of the various devices may discredit the method and discourage careful research in this important field.[35] More experimentation is needed before a definite conclusion can be reached concerning its use in industry and public buildings.

VALUE OF AIR COOLING UNDER TROPICAL CONDITIONS

Although statistics are not at hand to indicate the deaths or retarded recoveries of patients due to lack of air cooling in ships operating in tropical waters, it is generally agreed among competent observers that high temperature and humidity are major factors in prolonging disability and increasing mortality of the sick and injured. Physiologic data obtained on healthy men, moreover, show the large loss of body fluids and the stress on the cardiovascular system in terms of increased pulse rate when these men are continuously subjected to high temperatures. Even at rest about 50 cc of fluid per hour are lost as sweat[36] through intact skin. In burn patients the difficulty, encountered in temperate climates, of maintaining fluid and electrolyte balance is tremendously augmented by the additional evaporative fluid loss in hot environments. Naval hospital ships having all wards, laboratories, and living spaces air cooled, represent a notable achievement in the control of environmental factors for the purpose of providing better treatment of patients, especially those suffering from extensive burns.

Patients who have such varied conditions as heart disease, thyrotoxicosis, shock from any cause, or severe hemorrhage, or those who have had an anesthetic, will invariably store heat when subjected to a hot humid environment. The gradient between the body surface temperature and the environmental temperature is such that loss by radiation is slight. The heat loss by evaporation in a warm humid environment is low whether the patient does or does not perspire. The

heat regulatory center may be temporarily deranged following an anesthetic, brain injury, or after an overdose of barbiturate. Loss of fluids and electrolytes is another influencing factor. In these circumstances there is great benefit from assisting the body in cooling, and this can best be done in a cool room of low relative humidity where conditions for heat loss are ideal. This measure is also valuable in controlling temperature of patients with various acute febrile diseases.[38]

Frequently from 50 to 75 percent of personnel aboard naval vessels operating in tropical waters are afflicted with heat rash to a degree that interferes with rest and sleep. In carefully controlled experiments[39] it was possible to produce a fulminating type of rash in all men living continuously at an effective temperature of 85 (90 F dry-bulb and 83 F wet-bulb). In the control group, 12 out of 24 hr were spent in a relatively cool atmosphere of 75 ET (80 F dry-bulb, and 70 F wet-bulb). These men either remained free from heat rash, or occasionally developed a mild form. Thus, intermittent cooling to a degree that prevented sweating in men at rest, eliminated a serious handicap to good performance of duty.

In both laboratory tests and aboard hospital ships a relatively cool living environment of 76 to 78 ET provided an atmosphere conducive to rest and sleep without excessive sweating. Berthing spaces tended to have extremely low odor levels. Motivation, initiative and alertness, in contrast to the usual irritability and lack of incentive incident to residence in tropical climate, were maintained.[40]

Little has been done, however, to obtain practical methods for application of air conditioning under heavy heat loads and on the enormous scale that would be needed to modify life in the tropics. Part time cooling of personnel to promote rest and sleep in tropical areas would provide a prophylactic measure of great potential importance.

TREATMENT OF DISEASE

In the past few years considerable progress has been made in using air conditioning as an adjunct in the treatment of various diseases. Among the important applications are those in operating rooms, nurseries for premature infants, maternity and delivery rooms, children's wards, clinics for arthritic patients, heat therapy, cold therapy, oxygen therapy, X-ray rooms, and the control of allergic disorders.

Normal individuals may be subjected to considerable strain in adjusting to hot humid conditions. Heat loss by radiation is reduced, as is loss by evaporation of sweat. Individuals with certain disease processes are at a still greater disadvantage since they may also have difficulty in the transport of heat from the interior to the surface of the body via the circulation.

Patients with thyrotoxicosis tolerate hot humid conditions or *heat waves* very poorly. Their metabolism is high, and therefore their heat production is excessive. They may be unable to eliminate heat from the body surface as rapidly as it is produced and transported to the skin. They develop hyperthermia or fever, and a tachycardia or rapid heart rate. The demand on the circulation for transport of heat from the interior of the body to the skin surface is increased. The increased body temperature leads to increased cell metabolism, and in turn to still greater heat production. This vicious cycle may threaten life if the cardio-vascular or transport mechanism breaks down. A cool, dry environment favors the loss of heat by radiation and evaporation from the skin, and may save the life of the patient.

Cardiac patients may be unable to maintain the circulation necessary to insure normal heat loss. Recently the importance of air conditioning hospital wards and rooms of cardiac patients, particularly those with congestive heart failure, has been stressed as a therapeutic measure.[41] It is more important in tropical or subtropical climates. Individuals with head injuries, those subjected to brain operations, and those with barbiturate poisoning may have hyperthermia, especially in a hot environment, due to a disturbance in the heat regulatory center of the brain. Obviously, one of the most important factors in recovery is an environment in which the patient can lose heat by radiation and evaporation, namely, a cool room with dehumidified air.

The patient in shock, or the patient who has had a severe hemorrhage, may have an inadequate volume of circulating blood and be unable to maintain an adequate skin circulation. This may result in heat storage or fever. Patients with extensive skin burns may be unable to lose heat adequately from the limited uninvolved skin surface, and thus develop a fever. They need adequate fluid replacement, saline solution, plasma or blood to expand the circulating blood volume and thereby improve peripheral circulation. A cool environment is valuable in aiding heat loss after adequate skin circulation is established.

A hot dry environment (89.6 F and 35 percent relative humidity) has been used over an extended period for the treatment of patients with rheumatoid arthritis, with reported improvement.[42]

OPERATING ROOMS

The widest application of air conditioning in hospitals is in operating rooms. Complete air conditioning of operating wards is important because winter humidification helps reduce the danger incident to the use of anesthetic gases; summer cooling with some dehumidification tends to eliminate excessive fatigue and to protect the patient and operating personnel; and finally, filtering aids the removal of allergens from the operating room air.

Reducing Explosion Hazard

Explosion hazards in operating rooms increase with the introduction of anesthetic gases and apparatus. Ether administered by the old drop method gives rise to an explosive mixture, but in practice this method is still regarded as comparatively safe. When ether is mixed with pure oxygen, or nitrous oxide in certain concentrations, the explosion hazard may be as great as with ethylene-oxygen, or cyclopropane-oxygen mixtures.

Of the anesthetic gases nitrous oxide alone does not explode but supports combustion. Ether, vinyl ether, ethylene, and cyclopropane are as potentially dangerous as gasoline or *illuminating gas in the home.*[43] *Chloroform does not* explode violently in contact with flame, but decomposes to liberate phosgene. All of the anesthetic gases and vapors, except ethylene, are heavier than air. Although the incidence of injury or death from explosion is negligible compared with other hazards in the operating room, the dramatic features surrounding an explosion justify continued investigation to eliminate the hazard.

During the course of ethylene anesthesia, the mixture, usually 80 percent ethylene and 20 percent oxygen, is so rich that the danger of explosion is slight in the immediate vicinity of the face mask, but leakage of ethylene into the air may result in lower concentrations, and thus introduce a serious hazard. The most dangerous period is at the end of the operation when the patient's lungs and the anesthesia apparatus are customarily *washed out* with oxygen with or without the addition of carbon dioxide. Even when this procedure is omitted, it is difficult in practice to avoid dilution of the anesthetic gas with air during the normal course of breathing following the administration. In either case the mixture would pass through the explosion range and extraordinary precaution is necessary for the safety of the patient and operating personnel.

In a study[44] of 230 anesthetic explosions and fires, 70 percent of the explosions and 60 percent of the deaths were caused by igniting agents other than static sparks. The National Fire Protection Association[45] made certain recommendations for safe practice based on available information in Pamphlet No. 56, *Recommended Safe Practice for Hospital Operating Rooms* (July 1952). These recommendations outline ways and means for eliminating or correcting hazardous conditions which experience and investigation have shown to contribute to the hazards in question. They are divided into three parts: Part I, General, deals with the nature of the hazards, Part II, Construction and Equipment, deals with physical standards for features incorporated into the construction and equipment of the surgical suite, and Part III, Administration, contains precautions to be observed by hospital personnel. The requirements and recommendations are interdependent and each will be ineffective unless coordinated with the other. To approach complete success in the prevention of anesthetic explosions, all persons—the surgical staff, the nursing staff, the maintenance staff and administrative personnel—must be educated and periodically reminded of the explosive nature of combustible anesthetic agents.

Experience has shown that neither high humidity nor intercoupling devices have eliminated the danger from static electric discharge. The removal of gas concentrations from the operating table area, by means of specially devised exhaust ventilation, should be thoroughly tested. Portable duct systems as installed aboard ship should be acceptable. Serious explosions can occur in a closed system, but proper precautions will reduce this hazard to a minimum.

A comprehensive study of the explosion problem and of the general causes and prevention of operating room hazards, by the University of Pittsburgh, the ASHAE Research Laboratory, and the U. S. Bureau of Mines has led to a fruitful attempt to eliminate the explosive range of cyclopropane, one of the best but most difficult gases to handle. The use of helium as a diluent in the total gaseous mixture controls the oxygen concentration by displacement and, because of its flame quenching properties, it is the ideal gas for this purpose. In addition, a gaseous mixture containing helium is more difficult to ignite by electric discharges, and this quality also increases the safety factor of anesthetic administration.

Operating Room Conditions

Little is known about optimum air conditions for maintaining normal body temperatures during anesthesia and the immediate post-operative period. An anesthetized patient displays dilation of blood vessels in the skin resulting in profuse sweating and (it has been believed) inability to regulate body temperature. From this it was concluded that all anesthetized patients suffered considerable heat loss, although there may be little more than 0.8 F deg variation in the rectal temperature during the course of the operation.[47] The severe physiological effects, such as excessive sweating and rapid pulse, of high operating room temperatures on attendants and patients during the hot months signify the need for proper cooling. Statements of surgeons who operate in both air-conditioned and non-air-conditioned rooms strongly indicate that the recuperative power of the patient is greater when operated upon in air-conditioned rooms.[47]

Although the comfortable air conditions for the operators are not identical with those for the patient, it is usually not difficult to compromise within a range of 55 to 60 percent relative humidity and 72 to 80 F temperature. It is generally reported that dry-bulb temperatures of 76 to 78 F with 55 percent relative humidity not only furnished comfort for the operating room workers, but apparently prevented exhaustion of patients as evidenced by rapid convalescence in the recovery ward. Additional heat may be furnished to patients locally or by suitable covering, according to body temperature in individual cases.

In the control of airborne infection in the operating room, the prevention of dispersal of infectious materials into the air, control of dust, and proper ventilation supersede attempts to remove or kill pathogenic organisms. The bacterial content of conditioned operating rooms is generally lower than that of non-conditioned rooms.

Bacterial counts aboard an air-conditioned submarine were found to be exceptionally low and not cumulative with time, although all of the air was recirculated for more than 12 hours[48] without replenishment. The removal of bacteria by the process of air cooling and condensation of moisture out of air, merits further study.[49]

The degree of air contamination can be reduced by proper ventilation if velocity of air over the floor does not exceed 50 fpm. Research is in progress on the use of filtered air flowing through a system of mechanical cleaners which protect the patient against infection from attendants, and from bacteria-containing air in the corridor or ward.[46]

Operations are frequently postponed on allergic patients during asthmatic manifestations through fear of complications. The removal of airborne allergens, therefore, is in some cases an important function of the air-conditioning system in preparing patients for operation.

The best practice in air conditioning hospital operating rooms is the use of all outdoor air with arrangements for preheat, reheat, and the control of humidity, coupled with a mechanical exhaust system that removes the air from both the high and low levels of the operating room. However, there is some evidence of lack of any cumulative effect on bacteria count due to recirculation of air through an air conditioning unit in operating rooms. This consideration and the fact that relief cooling frequently provides improved, if not ideal conditions, has led to the use of central systems employing 50 percent recirculated air. Also, perhaps as a recognition of practice, the NBFU Pamphlet No. 56 outlines the conditions under which room air conditioners may be used in operating rooms. These conditions are so written in the pamphlet that the recommendation of separate mechanical ventilation of such rooms is clearly inferred.

Stated in the reverse order, room air conditioners for relief cooling of mechanically ventilated rooms are now considered permissible when used with the necessary precautions. These precautions are not generally assured by the use of standard room air conditioners as produced by the manufacturers, and are frequently costly of accomplishment in the field. The use of larger systems employing 50 percent

recirculated air is a recognized practice. It is certain that such a system must have the necessary precautions (regarding the electrical and air moving equipment) against the hazard of gross spillage of the anesthetics. Systems using 100 percent outdoor air and adequate air removal means are regarded as following the best practice. The choice between the systems is usually made on the basis of first costs. As compared with the other daily usage costs of an operating room, the differences between the operating costs of the various air conditioning systems is not a significant item.

Good thermal construction of the operating rooms is a recommended practice. Much can be gained by thermal insulation of sterilizing equipment, and by exhaust ventilation of sterilizing rooms adjoining the operating rooms. The amount of glass surface should be kept to a minimum, particularly in walls exposed to the sun. Double windows are desirable and often necessary to prevent condensation on the glass in cold weather. The equipment capacity and control methods must be properly selected for the type of system employed, and for the loads encountered. The resulting air flow rates are usually in the range of 8 to 12 changes per hour. The method of air introduction should be selected to keep air movement in the operating area under 50 fpm. Where all outdoor air or a large percentage of outdoor air is used, the air introduction and exhaust arrangements should be designed to provide a thorough air change in all parts of the room. This may be accomplished by introducing the air at one side and exhausting it from the other side of a small room or by introducing the air at the center and exhausting from the sides of a large room. The supply and exhaust arrangements can be exchanged in the case of large rooms. An air-conditioned recovery ward in connection with the air-conditioned operating room, is of great value in stabilizing peripheral circulation, and in reducing excessive loss of fluids on hot humid days.

NURSERIES FOR PREMATURE INFANTS

One of the most important requirements in the care of premature infants is the stabilization of body temperature. This is necessary because the infant's heat regulatory system is not fully developed, with the resultant tendency for environmental temperature to influence body temperature. The younger the premature infant, the greater is the tendency. As the infant's metabolism is low, heat production is not adequate to maintain a normal body temperature in a cool environment. The resistance to infection is low, and the mortality rate is high. In general, the younger the age of the premature infant, the higher the mortality rate.

Nurseries constructed for metabolic research should be air-conditioned so that conditions are reproducible. Results of such studies may be invalid if environmental conditions are not identical, since fluid and electrolyte loss may vary greatly with change in environmental conditions.

Air-Conditioning Requirements

The optimum air conditions for growth and development of premature infants were determined by extensive research[1] at the Children's Hospital, Boston, Mass., using four valid criteria, namely, stability of body temperature, gain in weight, incidence of digestive syndromes, and mortality. Individual temperature requirements varied widely (from 72 to 100 F) according to the constitutional state of the infants and body weights. The optimum relative humidity was about 65 percent, and the air movement less than 20 fpm.

A single nursery conditioned to 77 F and 65 percent relative humidity was found to fulfill satisfactorily the requirements of the majority of premature infants. Additional heat for weak (or debilitated) infants may be furnished in the cribs or by means of electric incubators placed inside the conditioned nursery, with temperature adjusted according to individual requirements. In this way a multiplicity of chambers and of air-conditioning apparatus is obviated; the infants in the heated beds derive the benefit of breathing cool humid air, and the nurses and doctors need not expose themselves to extreme conditions.

Importance of Humidity: Although external heat is an important factor in the maintenance of normal body temperature, humidity appears to be of equal or greater importance. When the premature nurseries at the Children's Hospital were kept at relative humidity between 25 and 50 percent for two weeks or longer, the body temperature became unstable, gain in weight diminished, the incidence of gastro-intestinal disturbances increased, and the mortality rose. On the other hand, continuous exposure to air conditions with 55 to 65 percent relative humidity gave satisfactory results over a period of years. The initial physiologic loss of body weight (loss occurring within first four days of life) was found to vary inversely with the humidity. In the old nurseries with natural humidity it averaged 12.4 percent of the birth weight; in the conditioned nurseries it was 8.9 percent with 25 to 49 percent relative humidity, and 6.0 percent with 50 to 75 percent relative humidity. The number of days required to regain the birth weight was correspondingly maximum in the old nursery, and minimum in the conditioned nurseries under high humidity.

Maximum gains in body weight occurred in the conditioned nurseries under high humidity (55 to 65 percent) in infants weighing less than 5 lb. The gains were less under low humidity (25 to 50 percent) in the same nurseries, and in the old nurseries prior to use of air-conditioning apparatus.

The incidence and severity of digestive syndromes, with diarrhea, persistent vomiting, diminishing gain or loss of body weight, and other symptoms, were generally from two to three times as high under low as under high humidity.

Summarizing, the best chances for life in premature infants are created by maintaining a relative humidity of 65 percent in the nursery, and by providing a uniform environmental temperature just sufficiently high to keep the body temperature within normal limits. Medical and nursing care are, of course, factors of equal and sometimes of greater importance.

Air-Conditioning Equipment

Many of the installations now in use are of the central system type providing for filtration, for humidification and heating in cold weather, and for cooling and dehumidification in hot weather. A ventilation rate between 8 and 12 air changes per hour is desirable to remove odors and maintain uniformity of temperatures in extremes of weather. Recirculation should not be used in these wards owing to odors and the possibility of infection. There should be a frequent change in spray water.

Control of Airborne Infection

The protection of the premature and older infant against infection is of the utmost importance. It was found in one installation equipped with air conditioning, germicidal lights and mechanical barriers that air conditioning alone did not prevent respiratory cross-infections.[2] Bacterial ultraviolet barriers, air conditioning and mechanical barriers are efficient. However, infections are brought in by, and often spread by, ward personnel in spite of these measures.

FEVER THERAPY

Artificial production of high fever in man can be considered an imitation of nature's way of overcoming invading pathogenic organisms. The action may be direct and specific by destruction of the invading organism within the safe limit of human temperatures, or indirect in the case of heat resistant organisms, by general mobilization of the defensive mechanisms of the body.

Although the action may be direct and specific by destruction of the invading organisms within the safe human limits, fever therapy exerts much of its benefit through the improvement of the mechanism of bodily defense. A serious challenge to the theory on which fever therapy is based comes from the demonstration that high fever causes a reduction in the concentration of circulating antibodies in experimental animals.

Patients for fever therapy should be carefully selected. The most serious complications which may arise are heat stroke, heat exhaustion and circulatory collapse. The chief minor complications are heat cramps, fever blisters and mild dehydration.

The limits of induced systemic fever are usually between 104 and 107 F (rectal), and the duration from 3 to 8 hours at a time. The total period of fever treatment varies with the type of the organism involved.

The diseases which respond favorably to artificial fever therapy are gonorrhea and its complications (which include arthritis, pelvic infections in women, and involvement of the eye), syphilis and chorea.

The most striking results are seen in gonorrhea and syphilis, since the causative organisms can be destroyed at temperatures compatible with human life. However, the use of fever therapy has decreased since penicillin has been found so effective in the treatment of gonorrhea and syphilis. Mild fever, up to 101 F for one hour, has reventy been used in the treatment of rheumatoid arthritis. This degree of fever is not bactericidal, but is believed to stimulate the body defense mechanism.

Equipment for Production of Fever

Artificial fever can be induced by injections of various crystalloid or colloid substances, bacterial products of typhoid and malarial organisms, or by physical methods using hot baths, radiant heat cabinets, hot humidified air cabinets, or by short wave diathermy in combination with a cabinet.

The relative advantages of various methods have been evaluated clinically.[3] Among the devices for the production of fever by physical means, the one most widely used is the hot humid air or *air-conditioned* cabinet. This apparatus was developed at the Kettering Institute for Medical Research at Miami Valley Hospital in Dayton, Ohio.

In the earlier studies of the Society, temperatures were elevated more easily using saturated atmospheres. A fever therapy apparatus[4] using these same principles has proved efficient as a means of inducing and maintaining fever in a body, with small likelihood of burns because of the comparatively low dry-bulb temperatures.

When heat is necessary in treating legs or arms, such media as short- or long-wave diathermy, micro-waves, infrared, water baths, etc., have been used extensively. A recent development, a saturated atmosphere heating unit, similar to one previously described has proven satisfactory, because heat may be administered over longer periods which render deep heating possible without fear of burns or shocks. Local heating has been somewhat satisfactory in relieving the painful symptoms of peripheral vascular disease. This procedure, however, is not without danger. Elevation of tissue temperature increases cell metabolism and the need for oxygen. The inadequate blood supply and oxygen deficiency may lead to tissue death or gangrene. Application of heat to the trunk or abdomen, with consequent reflex dilatation of the vessels of the extremities, eliminates this danger of local heat application.

Short-wave diathermy within the cabinet during the induction phase has been used. When the desired body temperature has been reached by electrical induction, the atmosphere of the enclosure is kept at saturation to prevent heat loss, thus maintaining the patient's temperature at the desired point. The two underlying principles in the production of fever by the hot humid air cabinet are: (1) the transfer of heat by conduction from the circulating hot air to the body, and (2) prevention of heat loss. The latter is more important. In an atmosphere of high humidity, the heat loss by evaporation is markedly decreased.

COLD THERAPY

Cold as an anesthetic agent was advocated by Allen several years ago.[5] Freezing of the tissue must be avoided. For certain patients, in whom amputation of an extremity is indicated, the application of a tourniquet with cooling of the affected extremity down to near freezing (5 C or 40 F) is of value. The patient, following this procedure can be prepared for surgery without the handicap of absorption of septic products and severe pain. This procedure has proven especially valuable in the neglected diabetic patient with an infected gangrenous extremity. Time for treatment of coma and hydration of the patient is gained. However, if amputation of an extremity is not indicated, the application of a tourniquet and packing in ice are dangerous procedures, since loss of the limb usually results. An extremity with inadequate blood supply can be readily cooled without the use of a tourniquet, but such an extremity is also usually eventually lost. Cooling is said to reduce the metabolism of the tissue with suspension of the vital processes. It also reduces the blood flow to practically zero, and few extremities with inadequate blood supply remain viable or recover.

Packing in ice, or use of low temperatures, is contraindicated in the treatment of patients with frostbite, immersion foot or trench foot. The affected extremities should be exposed to the air in a cool room and not rubbed with snow or packed in ice. The lowering of temperature by packing the body in ice for treatment of cancer has not proven successful.

The methods used for refrigeration, depending upon available facilities, are as follows:[6]

(1) Cracked or shaved ice which is simple and has the advantage of not freezing tissues. However, it is cumbersome and sloppy to handle and is unsuited to prolonged treatments.

(2) Use of ice in a pail for immersion of local parts.

(3) Special boxes for holding ice with padded or curtained openings for the limb.

(4) Bare ice bags and cloth bags for iced wet dressings for prolonged treatments and convenience.

(5) A double-chambered cabinet using dry ice has been constructed.

(6) Electrical refrigerating apparatus, consisting of a compact noiseless unit that pumps fluid to various types of applications, is available. The applicators may be in the form of blankets containing rubber tubes suitable for covering the entire body, or all or part of a limb. Special applicators are available for insertion into various body cavities, and for inducing dental anesthesia.

(7) An air chamber at regulated temperature for treatments of frostbite and immersion foot, and amputation stumps.

The electrical apparatus is costly, but has the advantages of thermostatic regulation, light weight, freedom of movement, and permits prolonged treatments with heat, as well as cold over the range of temperatures therapeutically desirable.

ALLERGIC DISORDERS

Hay fever, asthma, eczema and contact dermatitis are classified as allergic disorders. The allergic individual responds to contact with a variety of substances, which are innocuous to a non-allergic person, with severe manifestations of hypersensitivity.

These substances are known as allergens and consist of airborne irritants such as dusts, molds, feathers, pollens, animal dander and others; of food protein such as milk, wheat, eggs, etc., or of simple chemicals brought in contact with the skin. They may enter the body by various routes of which inhalation is the most common type. Ingestion of offending food substances is not infrequent.

The offending substance reacts with the sensitized cells of the mucous membranes or skin. During this reaction, histamine or a histamine-like substance is released and causes (a) increased capillary permeability, (b) secretion of mucus and (c) muscular contraction. In the eyes and nose this produces itching, redness and lacrimation or rhinorrhea, in short, the symptoms of hay fever. In the lungs it causes, in addition to the secretory response, a contraction of the smooth muscles of the bronchi resulting in a bronchial asthma.

It is commonly known that non-specific environmental factors such as dust, irritating gases, change of temperature and humidity may precipitate asthmatic attacks in allergic subjects, even in the absence of exposure to specific allergens. It is assumed that the presence of frequent allergic bronchial constriction renders the smooth muscles of the bronchi so sensitive to various non-specific stimuli that the threshold of their response to such irritation is considerably lower than that of a non-allergic individual.

Air-Conditioning Apparatus

Of all the measures to relieve a specifically sensitive individual, elimination of exposure to the responsible allergen is the most efficient, though not always a practical, form of treatment. In recent years considerable effort has been made to accomplish such elimination by removal of respiratory allergens from enclosures by filtration or other air-conditioning processes.

Paper or cloth filters, mounted in inexpensive window or floor units, prove quite satisfactory in many cases, but since dust and smoke frequently cause asthmatic attacks, it is desirable that an air filter, to be of full value in the treatment of asthma, should remove all possible dusts and pollens regardless of size or amount. Electrostatic air cleaners are more efficient than most commonly used types for capturing very fine dust.

Although the chief remedial factor in the treatment by conditioned air is the filtration of pollen, a certain amount of cooling and dehumidification appears to be desirable. A comfortable temperature between 70 and 75 F, and a relative humidity well below 50 percent has proved satisfactory.[6] Direct drafts, overcooling or overheating are apt to initiate or aggravate the symptoms.

Limitations of Air-Conditioning Methods

The results obtained with air filtration, or other air conditioning processes, in the control of allergic conditions, are fairly comparable to those obtained by desensitization treatment, so long as the patients remain in the pollen-free atmosphere. For all practical purposes filtration gives only temporary relief. In mild cases sleeping in an air-conditioned space may make it possible for the individual to pass more comfortable nights. With rare exceptions, the symptoms recur on exposure to pollen-laden air. Moreover, the usefulness of air-conditioning methods is limited, because all cases are not caused by airborne substances. Cases of bacterial asthma do not respond to treatment with filtered air.

Despite these limitations, air-conditioning methods possess definite advantages in the simplicity of treatment, convenience, and under certain conditions, almost immediate relief.[7] Pollen cases are usually relieved of most of their symptoms within 1 to 3 hr after exposure to properly filtered air. A pollen-free atmosphere is especially valuable when desensitization has given little or no relief, and when desensitization is not advisable owing to intercurrent illness.

OXYGEN THERAPY

Oxygen therapy is used to prevent or relieve anoxia. Some of the more important clinical conditions in which oxygen treatment is beneficial include pneumonia, severe anemia, cardiac decompensation, pulmonary atelectasis, asphyxia and asthma. The effectiveness of oxygen therapy is dependent on the concentration of the oxygen in the inspired air, or the partial pressure of oxygen in the pulmonary alveoli.

Oxygen is usually administered by nasal catheter, face mask or tent.[8] The necessity of air conditioning in oxygen therapy arises from the fact that oxygen is too expensive a gas to waste in the ventilation of oxygen tents and oxygen chambers. Air conditioning is applied to the oxygen tent or chamber through reconditioning of the atmosphere in a closed circuit. Excessive heat, moisture and carbon dioxide are removed.

Oxygen Tents

In oxygen tents, the air enriched with oxygen is usually circulated by means of a small motor blower which sends the air over soda lime to remove carbon dioxide, and then over ice to remove excess heat and moisture. The concentration of oxygen in the tent is regulated by means of a pressure reducing valve and flow meter. In an inadequately cooled tent, high temperatures and humidities are inevitable, increasing the discomfort of the patient and imposing an added strain on an already overburdened heart. Oxygen therapy under such conditions may do more harm than good. An ice melting rate of approximately 10 lb per hr gives satisfactory results in patients with fever in a medium size oxygen tent.

Oxygen tents are confining to the patient. They may terrify the restless and delirious patient. Medical and nursing care is complicated, as the tent must be opened or removed with attendant loss of oxygen. Oxygen concentrations of 50 percent or more are difficult to maintain, and it is a problem to keep the temperature and humidity low enough in hot weather. However, with attention to details, the patient can be made quite comfortable. In fact, during hot humid weather an oxygen tent may be very valuable in controlling a patient's temperature, since the upper part of the body within the cooled tent loses heat rapidly.

Oxygen Chambers

The conventional oxygen chamber is an air-tight sheet-metal enclosure of fire-proof construction, large enough to accommodate one or two patients. Trap doors or curtains are provided for the personnel, food and service, to avoid loss of oxygen. Glass windows in the ceiling and walls admit light from outside the chamber. The air conditioning system may be of the gravity type, or of the fan type using mechanical refrigeration or air drying agents.

The temperature and humidity requirement in oxygen therapy depends primarily upon the physical condition of the patient, and secondarily upon the type of disease. In pneumonias[9] prescribed conditions should be a temperature of 60 to 75 F, humidity 50 to 55 percent, moderate air movement, oxygen concentration of 50 percent, and carbon dioxide of less than one percent.

Oxygen in Aviation

An important application of the principle of oxygen therapy is in aviation. High altitude military airplanes in this country are normally provided with gaseous oxygen equipment, and military personnel are required to utilize oxygen at all times while in flight above 15,000 ft, or between 12,000 to 15,000 ft for longer than two hours, or between 10,000 to 12,000 ft for longer than six hours.

Today all large passenger aircraft are pressurized to provide passenger comfort in flight at altitudes of 20,000 feet or more. Smaller civilian aircraft are usually not pressurized and must carry gaseous oxygen equipment where appreciable altitudes must be attained.

GENERAL HOSPITAL AIR CONDITIONING

Complete conditioning of a large hospital involves a capital investment and running expenses which may not be justified. In clean and quiet districts, the requirements of almost all general and private wards during the cool season of the year can be satisfactorily fulfilled by the use of conventional heating equipment, in conjunction with window air supply and gravity or mechanical exhaust. Insulation against heat and sound is much more important than humidification in winter; thermal insulation will also help in keeping the building cool in warm weather. Excessive outside noise and dust may require the use of silencers and air filters in the openings.

Cooling and dehumidification in warm weather are important. In new hospitals particularly, the desirability of cooling certain sections of the building should be given serious consideration. Financial reasons may preclude the cooling of the entire building, but the needs of the average hospital can be met by the use of built-in room coolers and a few portable units which can be wheeled from ward to ward when needed.

In the North, and certain sections of the Pacific Coast, cooling is needed but a few days during summer, while in the South, it can be used to advantage from May to October, and in tropical climates almost continuously throughout the year.

F. L. Grocott of the Anglo-Iranian Oil Co. states that in Iran, the medical staff after 10 years' experience with air conditioning, demand a uniform environment of 75 F and 50 percent relative humidity under all summer outdoor conditions for general wards and treatment rooms, and 70 F with 30 to 50 percent relative humidity for winter conditions. In the operating rooms, 70 F with 50 percent relative humidity is demanded all the year 'round, although the annual external range is 40 F to 120 F. No ill effects have been noted in the medical personnel, though they are exposed to changes from external to internal conditions many times daily. Temperature shock in either direction seems to create discomfort for a short interval, but if the individual is in good health, no injury results.[10]

Aside from comfort and recuperative power of the patients, cooling is of great assistance in the treatment of fevers in the new-born and in post-operative cases, in enteric disorders, fevers, heat stroke, heart failure, thyroid crisis, and in a variety of other ailments which often accompany summer heat waves.

Problem of Odors

Experiences in the evacuation of battle casualties in aircraft and their subsequent hospitalization have stimulated efforts to find ways of minimizing odors arising from draining wounds, old odorous casts, and gangrenous wounds. For aircraft, chemical sprays and vapors, perfumes, oxidizing gases and simple exhaust methods are unsatisfactory. An ideal deodorant would purify the air by means of odor adsorption so that subsequently the air could be recirculated. Based upon the effectiveness of activated carbon commercially and industrially to adsorb odors, individual adsorption units have been used successfully. In hospital wards the feasibility of adsorption methods over other methods for elimination of odors remains to be answered.[11]

CHAPTER 9

HEAT TRANSMISSION COEFFICIENTS OF BUILDING MATERIALS

Heat Transfer Symbols; Calculating Overall Coefficients; Conductivity of Homogeneous Materials; Soil Conductivity and Specific Heat; Surface and Air Space Conductance; Overall Coefficients and Their Practical Use; Computed Coefficients of Walls, Roofs, Ceilings, and Floors; Effect of Insulation; Combined Ceiling, Roof, and Floor Coefficients; Glass Coefficients; Calculating Surface Temperatures

THE design of air-conditioning or heating systems for buildings requires a knowledge of the thermal properties of the walls enclosing the space. (The term *walls* in this case, includes windows, doors, ceilings, floors, roofs, and skylights.) The rate of heat flow through the walls under steady-state conditions at design temperatures is usually the basis for calculating the heat required. For a given wall under standard conditions the rate is a specific value designated as U, the *overall coefficient of heat transmission* or thermal transmittance. It may be determined by test in a guarded hot box apparatus, or it may be computed from known values of the thermal conductance of the various components. Because it is impracticable to test all combinations of building materials, the procedure and necessary data for calculation of the value of U are given in this chapter, together with convenient tables of computed values for a large number of the more common constructions.

HEAT TRANSFER SYMBOLS

U = overall coefficient of heat transmission or thermal transmittance (air-to-air); the time rate of heat flow expressed in Btu per (hour) (square foot) (Fahrenheit degree temperature difference between air on the inside and air on the outside of a wall, floor, roof, or ceiling). The term is applied to the usual combinations of materials, and also to single materials, such as window glass, and includes the surface conductance on both sides. This term is frequently called the U value.

k = thermal conductivity; the time rate of heat flow through a homogeneous material under steady conditions per unit temperature gradient through unit area perpendicular to the temperature gradient. Its value is expressed in Btu per (hour) (square foot) (Fahrenheit degree per inch of thickness). Materials are considered homogeneous when the value of k is not affected by variation in thickness or size of sample within the range normally used in construction.

C = thermal conductance; the time rate of heat flow through a unit area of a material from one of its surfaces to the other per unit temperature difference *between the two surfaces*. Its value is expressed in Btu per (hour) (square foot) (Fahrenheit degree). The term is applied to specific materials as used, either homogeneous or heterogeneous, for the thickness or construction stated, not per inch of thickness.

f = film or surface conductance; the time rate of heat flow between a unit area of a surface and the surrounding air. Its value is expressed in Btu per (hour) (square foot of surface) (Fahrenheit degree temperature difference). Subscripts i and o are used to differentiate between inside and outside surface conductances, respectively.

a = thermal conductance of an air space; the time rate of heat flow through a unit area of an air space per unit temperature difference *between the boundary surfaces*. Its value is expressed in Btu per (hour) (square foot of area) (Fahrenheit degree). The conductance of an air space is dependent on the temperature difference, the height, the depth, the position, character, and temperature of the boundary surfaces. Since the relationships are not linear, accurate values must be obtained by test and not by computation.

e = emissivity; the ratio of the total radiant flux emitted by a surface to that emitted by an ideal black body at the same temperature.

E = effective emissivity; the combined effect of the surface emissivities e of the boundary surfaces of an air space; the boundaries assumed to be parallel and of large dimensions as compared to the distance between them.

r = surface reflectivity; the ratio of the radiant flux reflected by an opaque surface to that falling upon it.

R = thermal resistance. Its value is obtained from the reciprocal of heat transfer as expressed by U, k, C, f, or a. It may be expressed in (Fahrenheit degrees per Btu)/(hour) (square foot). For example, a wall with a U value of 0.25 would have a resistance value of $R = 1/0.25 = 4.0$ *ru*. The word *ru* has been suggested as an abbreviation for resistance unit.

CALCULATING OVERALL COEFFICIENTS

From Chapter 5, Equation 7, the total resistance to heat flow through a wall is equal numerically to the sum of the resistances in series.

$$R_T = R_1 + R_2 + R_3 + R_4 + \cdots + R_n \qquad (1)$$

where R_1, R_2, etc., are the individual resistances of the wall components, and R_T is total resistance.

For a wall of a single homogeneous material of conductivity k and thickness x with surface coefficients f_i and f_o,

$$R_T = \frac{1}{f_i} + \frac{x}{k} + \frac{1}{f_o} \qquad (2)$$

Then by definition, $U = 1/R_T$

For a wall with air space construction and consisting of two homogeneous materials of conductivities k_1 and k_2, thicknesses x_1 and x_2, respectively, and separated by an air space of conductance a,

$$R_T = \frac{1}{f_i} + \frac{x_1}{k_1} + \frac{1}{a} + \frac{x_2}{k_2} + \frac{1}{f_o} \qquad (3)$$

and $U = 1/R_T$

For types of building materials having non-uniform or irregular sections such as hollow clay tile or concrete blocks, it is necessary to use the conductance C of the section unit as manufactured instead of a conductivity k. The resistance of the section $1/C$ is therefore substituted for x/k in Equations 2 and 3.

It will be noted that in order to compute the U value of a construction it is first necessary to know the conductivity

and thickness of the homogeneous material, the conductance of non-homogeneous materials (such as concrete blocks), the surface conductances of both sides of the construction, and the conductances of any contained air spaces. These items are discussed in the pages that follow.

Conductivities and Conductances

The method of calculating the overall coefficient of heat transmission for a given construction is comparatively simple, but accurate values of conductivities and conductances must be used to obtain satisfactory results. In addition, there are sometimes parallel heat-flow paths of different resistances in the same wall, and these may necessitate modification of the formula. In such cases calculated results should be checked by test.

The determination of the fundamental conductivities and conductances requires considerable skill and experience to obtain accurate results. It is recommended that thermal conductivities of homogeneous materials be determined by means of the Guarded Hot Plate.[1] For determination of conductances, a Guarded Hot Box method[2] is generally used.

Conductivity of Homogeneous Materials

Thermal conductivity is a property of a homogeneous material and of types of building materials such as lumber, brick, and stone, which may be considered homogeneous. Most insulating materials, except reflective types, are of a porous nature and consist of combinations of solid matter with small voids. Such materials including fibrous, cellular, or granular matter are generally known as mass or bulk insulations. The thermal conductivity of these materials will vary with density; mean temperature; size of voids, fibers, or particles; degree and extent of bond between particles; moisture present; and the arrangement of fibers or particles within the material.

The effect of density upon conductivity (at constant mean temperature) is illustrated for two fibrous materials in Fig. 1. Typical variation of conductivity with mean temperature is shown in Fig. 2.

Thermal Conductivity of Soil

The following statements are based largely on results of a study[3] made in the Engineering Experiment Station, University of Minnesota, and published in *Bulletin* No. 28. Tests were made on nineteen different soils which represented a wide textural variety, including gravel, sand, sandy loam, silt loam, and clay, as well as some crushed rocks and a fibrous peat. Moisture contents in tests varied from air-dried values

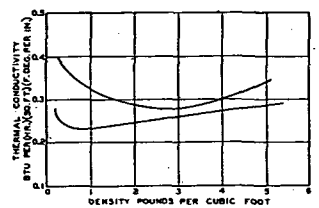

Fig. 1 . . . . Typical Variation of Thermal Conductivity with Density—for Fibrous Material

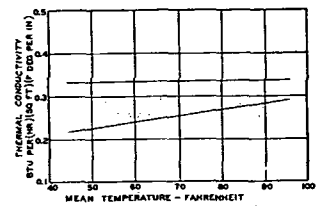

Fig. 2 . . . . Typical Variation of Thermal Conductivity with Mean Temperature

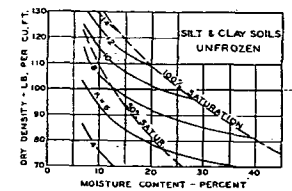
to those greater than the optimum moisture content; densities varied from a loosely-poured condition to the maximum density obtainable by heavy ramming. The general findings of the investigation are as follows:

Effect of Temperature. Soils were tested at several mean temperatures. The degree of influence of temperature depends upon whether it is above or below freezing. For increases of moisture content exceeding about 6 to 12 percent, the conductivity of frozen soil becomes progressively greater than that of the unfrozen soil.

Effect of Density. Density affects the thermal conductivity of a soil in about the same manner for all soils, at any moisture content, and for either the frozen or unfrozen condition. On the average, each one pound per cubic foot increase in dry density increases the thermal conductivity by about 3 percent.

Effect of Moisture. An increase in moisture content, up to the point of saturation, causes an increase in thermal conductivity. The rate of increase in typical soils was as follows: average conductivities, in Btu per (square foot) (hour) (Fahrenheit degree per inch), of four sands at a density of 110 lb per cu ft were: 6.8 at 2.5 percent moisture, 8.9 at 5 percent moisture, 11.2 at 10 percent moisture. Five soils of a fine texture at a density of 100 lb per cu ft, gave average conductivities of 6.7 at 10 percent moisture, and 9.5 at 20 percent. Thus, the doubling of moisture content within the ranges cited increases the conductivity by approximately 30 or 40 percent. At higher moisture contents the percentage increase would be less.



Effect of Soil Characteristics. The thermal conductivity of the soil, at a given density and moisture content, varies in general with the texture of a soil, being relatively high for coarse-textured soils and relatively low for fine-textured soils. The mineral composition of the soils also affects the conductivity. Quarts tends to give high values, whereas minerals such as plagioclase-feldspar and pyroxene, which are constituents of basic rocks tend to give low values of thermal conductivity. These points are illustrated by the values in Table 1 which lists seventeen soils in approximate order of their magnitude of thermal conductivity from greatest to least for seven different density-moisture content conditions. Some of the values in this table have been determined by extrapolation and are consequently approximate. Blank spaces in the table indicate that the density or moisture content, or both, are such that no tests were possible for that condition or that no tests were sufficiently close to permit a reasonable extrapolation of the data. Granular soils, particularly those with high quartz contents, head the tabulation or have the greatest conductivity

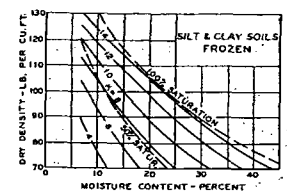


Table 1 . . . . Thermal Conductivity (*k*) Values of Soils in Approximate Order of Decreasing Values[a]

Mean Temperature—40 F

Soil Designation	Mechanical Analysis % by Weight				Moisture Content—%						
	Gravel	Sand	Silt	Clay	4			10		20

[a] *k* = Btu per (square foot) (hour) (Fahrenheit degree per inch).

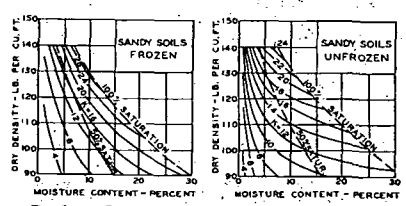

Fig. 3 . . . . Determining Thermal Conductivity of Soils from Density and Moisture Content

at a given condition. Sandy loam soils are midway in the table and fine grained soils such as clay and silt loam are last.

Estimating Thermal Conductivity. The four diagrams of Fig. 3 are presented to aid in the estimate of the thermal conductivity of any soil. Two of the charts are for sands or sandy soils, and two for silt and clay soils. One of the diagrams for each type of soils is for the frozen, and the other for the unfrozen condition. It is expected that these charts will give conductivity values with a precision of 25 percent. The effect of such factors as density, moisture content, freezing, or texture may be easily approximated by use of these graphs.

Specific Heat of Soils

Tests to determine specific heat were run on twelve soils. On five of the soils, tests were made at three or four mean temperatures varying from about 10 to 140 F. The specific heat values of all twelve soils varied by only a small amount (about 0.01), and averaged 0.19 at 140 F. The specific heat values of the soils decreased with a decrease in temperature. The average value at zero F would be about 0.16. Values at temperatures between zero and 140 F can be estimated by considering a straight-line relationship between the two values given.

Surface Conductance

The surface conductance of a wall is the combined heat transfer to or from the wall by radiation, convection, and conduction. Each of the three portions making up the total may vary, independently of the others, thus affecting the total conductance. The heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emissivity), the temperature difference between them, and the solid angle through which they *see* each other. The heat transfer by convection and conduction is controlled by the roughness of the surface, by air movement, and temperature difference between the air and the surface.

The importance of the effect of temperature of *surrounding surfaces* on the surface conductance, due to the effect on radia-

Table 2 . . . . Variation in Surface Conductance Coefficient for Vertical Surfaces with Different Temperatures of Surrounding Surface

Surrounding Surface Temperature	75 F	70 F	69 F	60 F	50 F
Convection—Btu per (hr) (sq ft)	6.6	6.6	6.6	6.6	6.6
Radiation—Btu per (hr) (sq ft)	4.4	8.6	9.6	17.0	24.9
Total—Btu per (hr) (sq ft)	11.0	15.2	16.2	23.6	31.5

tion, is illustrated in Table 2, which applies to a vertical surface at 80 F, with ambient air at 70 F and with radiation exchange corresponding to an effective emissivity of 0.83.[4]

In many cases, because the heat resistance of the internal parts of the wall is high compared with the surface resistance, the surface factors are of minor importance. In other cases, e.g., single glass windows, the surface resistances constitute almost the entire resistance and are therefore very important. An analysis of various factors affecting surface conductance and the difference between surface and air temperatures will be found in Reference 5. (See also Chapter 30.)

The convection part of the surface conductance is affected markedly by air movement. This is illustrated by Fig. 4, which shows the results of tests[6] made on 12-in. square samples of different materials at a mean temperature of 20 F, and for wind velocities up to 40 mph. These conductances include the radiation portion of the coefficient which, for the conditions of the tests, was about 0.7 Btu per (hr) (sq ft) (F deg). More recent tests[7] on smooth surfaces show that surface length also affects significantly the convection part of conductance; the average value decreases as the surface length increases. Moreover, observations[8] of the magnitude of low temperature radiant energy received from outdoor surroundings show that only under certain conditions may the out-of-doors be treated as a black body radiating at air temperature.

Because of these factors, the selection of surface conductance coefficients for a practical building becomes a matter of judgment. Surface conductances are shown in Tables 3 and 4. *In calculating the overall heat transmission coefficients for the walls, etc., of Tables 5 through 16, the appropriate indoor and outdoor surface coefficients given in Table 4 for Air Surfaces have been used.* Both values combine the effects of convection and radiation, and are applicable to ordinary building materials. They should not be used for low emissivity surfaces such as bright metal. For exposed reflective surfaces refer to Table 3, Section A, and to footnotes under Table 16.

In special cases, where surface conductances become important factors in the overall rates of heat transfer, more selective coefficients may be required. Principles and data given in Chapter 5, Heat Transfer, may be applied in such cases.

Air Space Conductance

The transfer of heat across an air space involves the boundary surfaces as well as the intervening air, and depends markedly on the orientation of the air space and the direction of heat flow. The coefficients given for air space conductance represent the total conductance from one surface bounding the air space to the other. The total conductance is the sum of a component due to radiation and a component due to convection and conduction combined. These components may vary independently of each other.

The radiation portion of the coefficient is affected by the temperature of the two boundary surfaces, and by their respective surface emissivities ϵ, the combined effect of which is expressed by means of the *effective emissivity* E of the air space. The radiation component is not affected by the thickness of the space or by its orientation or direction of heat flow. The heat transfer by convection and conduction combined, however, is markedly affected by the orientation of the air space and the direction of heat flow, is significantly affected by the temperature difference across the space and in some cases by the thickness of the space, and is affected to only a small extent by the mean temperature of its surfaces. For air spaces usually employed in building construction, the radiation and convection-conduction components may vary independently of each other.

Table 3, Section C, gives the thermal conductances and resistances of air spaces of uniform thickness and moderately

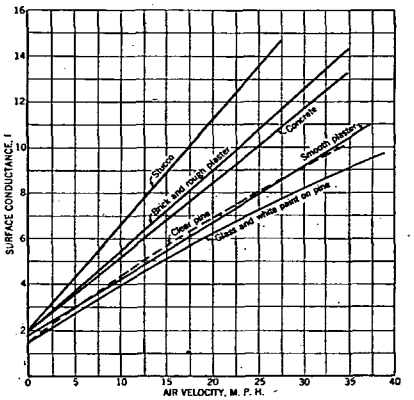

Fig. 4 . . . . Curves Showing Relation Between Surface Conductance for Different Surfaces at 20 F Mean Temperature

smooth surfaces, based on experimental measurements conducted at the National Bureau of Standards.[9] Although the conductances of air spaces vary to some extent with thickness in the range over ¾ in., average values are tabulated for the range from ¾ in. to 4 in., for all except horizontal spaces with heat flow downward. The error involved by averaging is less than 10 percent in the extreme case and less than 5 percent in most. For more exact values Reference 9 may be consulted.

For narrow air spaces, which may be defined as those for which the product of the cube of the thickness of the space in inches times the temperature difference (Fahrenheit degrees) across the space is less than 3 for heat flow horizontally or downward, or less than 1 for heat flow upward, the conductance is the sum of the radiative heat transfer coefficient and that for conduction alone through air, since convection is practically suppressed. The radiation component can be computed by means of Equation 4 and Table 4 of Chapter 5; the conduction component can be computed using the conductivity of air at the appropriate mean tempearture (see Table 1, Chapter 5).

The effects of different mean temperatures, temperature differences, and effective emissivities are indicated in Table 3 of this chapter, Section C. As indicated, use may be made of interpolation and moderate extrapolation of conductance values in the table to obtain conductances for conditions moderately different from those given. Interpolation of resistance values is not recommended, especially in relation to emissivity values.

Table 3, Section B, gives values for the surface reflectivities and emissivities of materials used as boundaries of air spaces in building construction, for total radiation at ordinary building temperatures. Effective emissivities for various combinations of these materials, for use in conjunction with Section C of Table 3, are given in the last two columns of Section B.

When considering heat transfer across air spaces in building construction, the emissivities of the boundary surfaces must be known. The possibility of change in emissivity of highly reflective surfaces due to exposure to conditions promoting chemical action, deposition of dust, soiling of the surface, or the application of coatings, even though transparent to the eye, must be considered in selecting a material for use.[10] Surface emissivity values should be obtained by tests.

OVERALL COEFFICIENTS AND THEIR PRACTICAL USE

The values in Tables 3 and 4 for component elements and materials were selected by the ASHAE Technical Advisory Committee on Insulation as representative for dry materials at 75 F mean temperature. They are based on available published data obtained by the guarded hot plate method (*ASTM* C177-45) or by the guarded hot box method (*ASTM* C236-54T). Because there are variations in commercially available materials of the same type, not all of these selected representative values will be in exact agreement with data for individual products. The exact value for a certain manufacturer's material can be secured from unbiased tests or from guaranteed data of the manufacturer.

The most exact method of determining the heat transmission coefficient for a given combination of building materials assembled as a building section is to test a representative section in a guarded hot box. However, it is not practicable to test all the combinations which may be of interest in building construction. Experience has indicated that *U* values for many constructions, when calculated by the methods given in this chapter, using accurate values for the component materials, are in good agreement with values determined by guarded hot box measurements.

Caution

Although the validity of calculating *U* values for all of the types of constructions in Tables 5 through 16 has not been fully demonstrated, calculated values are given because measured values are not available. It is emphasized that the calculated values in Tables 5 through 16 are given for the convenience of the user.

In calculating *U* values, exemplary conditions of components and installations are assumed, i.e., that insulating materials are uniformly of the nominal thickness and conductivity, that air spaces are of uniform thickness and surface temperatures, that effects due to moisture are not involved, and that installation details are in accordance with design. Some evidence of departures of measured values from calculated values for certain insulated constructions is given in *Building Materials and Structures Report* BMS 151, National Bureau of Standards. In order to provide a reasonable factor of safety to account for departures of constructions from exemplary conditions, in part due to field construction requirements and practices, some may wish, before making corrections for framing (as indicated in Fig. 6), to increase moderately the calculated *U* values of the insulated walls, floors and ceiling sections obtained from Table 16. Where reflective air spaces are involved, increases of *U* values up to 10 percent for applications where heat flow is horizontal or upward, and up to 20 percent where heat flow is downward, appear reasonable on the basis of present information.

Computed Heat Transmission Coefficients

In the analysis of any wall construction for the purpose of calculating the overall coefficient of heat transmission *U*, it is first necessary to determine the paths of heat flow, that is,

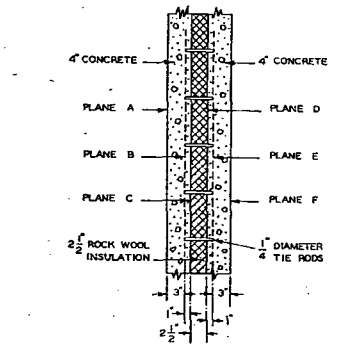

Fig. 5 . . . . Section of Concrete Wall Having Steel Tie Rods and Insulation

whether they are parallel or series, or a combination of both. This is in accordance with the basic laws of heat transfer which state that *in parallel flow the conductances are additive*, while *in series flow the resistances are additive*. Likewise, in order to determine the total resistance for the wall, the conductance must be known.

The importance of this analysis cannot be overemphasized. This is especially true in wall constructions in which there are parallel paths of heat flow, and one path has a high heat transfer while others have a low heat transfer. The method of making this calculation can best be shown by *Example 1* and Fig. 5. As this wall was tested by the hot box method at the University of Minnesota, a direct comparison can be made between calculated and tested values.

Example 1: Calculate the coefficient of heat transmission *U* for a wall shown in Fig. 5. Wall construction consists of two 4-in. concrete walls separated by a 2½-in. space filled with insulation; ¼-in. diameter metal tie rods are embedded a distance of 1 in. in each 4-in. concrete wall, and spaced 9 in. vertically and 12 in. horizontally. Values of *k* are: insulation 0.30, concrete 12.00, tie rods 400.00.

(Continued on p. 103.)

Table 3 .... Surface Conductances and Resistances for Still Air

All conductance values expressed in Btu per (hr) (sq ft) (F deg temp diff)

SECTION A. Surface Conductances for Still Air[a, b]

Notes: [d] Spaces of uniform thickness, bounded by moderately smooth surfaces.

[e] Where a range of thickness is given, the given conductance is the average over the range; extreme values within the range differ therefrom by less than 10 percent.

[f] Interpolation, and moderate extrapolation, of conductance values are permissible for other values of mean temperature, temperature difference and effective emissivity E.

[g] Effective emissivity of space, E, is given by $\frac{1}{E} = \frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1$ where ϵ_1 and ϵ_2 are the emissivities of the surfaces of the air space. (See Section B, above.)

[h] The conductances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

[e] Based on National Bureau of Standards data presented in *Housing Research Paper* No. 32, Housing and Home Finance Agency, 1954 (U. S. Government Printing Office, Washington, D. C.).

Table 4 .... Conductivities (k), Conductances (C), and Resistances (R) of Building and Insulating Materials (Design Values)[a]

These constants are expressed in Btu per (hour) (square foot) (Fahrenheit degree temperature difference). Conductivities (k) are per inch thickness and, conductances (C) are for thickness or construction stated, not per inch thickness

Material	Description	Density (lb per Cu Ft)	Conductivity or Conductance (k)	Conductivity or Conductance (C)	Resistance (R): Per inch thickness (1/k)	Resistance (R): For thickness listed (1/C)

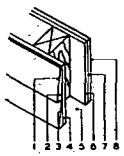
[a] Representative values for dry materials at 75 F mean temperature, selected by the ASHAE Technical Advisory Committee on Insulation. They are intended as design (not specification) values for materials of building construction in normal use. For conductivity of a particular product, the user may obtain the value supplied by the manufacturer or secure the results of unbiased tests.

[b] Air space resistance values shown here are for spaces faced both sides with ordinary *nonreflective* materials ($\epsilon = 0.90$ and $E = 0.82$) and are based on following conditions: Winter—60 F mean temperature and 20 deg temperature difference, Summer—90 F mean temperature and 10 deg temperature difference except for horizontal air space with heat flow downward which is based on 20 deg temperature difference.

[c] Surface resistance values shown here are for ordinary *nonreflective* materials ($\epsilon = 0.90$).

[d] See also Insulating Materials, Board.



[e] Includes paper backing and facing if any. In cases where the insulation forms a boundary (highly reflective or otherwise) of an air space, refer to Table 3, Sections B and C, to obtain the insulating value of the air space for the appropriate effective emissivity and temperature conditions of the space.

[f] Insulating values of acoustical tile vary depending on density of the board and on the type, size, and depth of the perforations. An average conductivity *k* value is 0.42.

[g] The U. S. Department of Commerce, *Simplified Practice Recommendation for Thermal Conductance Factors for Preformed Above-Deck Roof Insulation*, No. R 257-55, recognizes the specification of roof insulation on the basis of the *C* values shown. Roof insulation is made in thicknesses to meet these values. Therefore, thickness supplied by different manufacturers may vary depending on the conductivity *k* value of the particular material.

Table 5 .... Coefficients of Transmission (U) of Frame Walls[a]

These coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph

Example—Wall D 4

Resistances used are given below in this table or in Table 3 or 4

Construction	Resistance (*R*)
1. Outside surface (15 mph wind)	0.17
2. Siding, wood, ½ in. x 8 in. lapped (av. *R*)	0.85
3. Building paper	0.06
4. Wood sheathing ($^{25}/_{32}$ in.)	0.93
5. Air space[b]	0.97
6. Gypsum lath (⅜ in.)	0.32
7. Plaster (sand agg.) (½ in)	0.09
8. Inside surface (still air)	0.68
Total resistance	4.12
$U = 1/R = 1/4.12 =$	0.24

See value 0.24 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace items 3 and 4 with insul. bd. sheathing ($^{25}/_{32}$ in.) and items 6 and 7 with gypsum wall board (⅜ in.)		
Total resistance		4.12
Deduct 3. Building Paper	0.06	
4. Wood sheathing ($^{25}/_{32}$ in.)	0.93	
6. Gypsum lath (⅜ in.)	0.32	
7. Plaster (sand agg.) (½ in)	0.09	1.40
Difference		2.67
Add 4. Insul. bd. sheathing ($^{25}/_{32}$ in.)	2.06	
6. 7. Gypsum bd. (⅜ in.)	0.45	2.51
Total resistance		5.18
$U = 1/R = 1/5.18 =$		0.19

To Adjust U Values for Construction with Added Insulation between Framing Members, See Table 16.

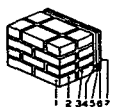
[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
[c] Note that although several types of exterior finish may be grouped because they have approximately the same thermal resistance value, it is not implied that all types may be suitable for application over all types of sheathing listed.
[d] Average resistance of items listed. This average was used in computation of *U* values shown.
[e] Building paper is not included except where noted.
[f] Small air space between building paper and brick veneer neglected.
[g] Where stucco is applied over insulating board or gypsum sheathing, building paper is generally required, but the change in *U* value is negligible.

Solution: In Fig. 5 the following paths of heat flow from plane *A* to plane *F* will be noted:

1. From *A* to *B*: One path through 3 in. of concrete.
2. From *B* to *C*: Two paths, (*a*) through 1 in. of tie rod, and (*b*) through 1 in. of concrete.
3. From *C* to *D*: Two paths, (*a*) through 2½ in. of tie rod, and (*b*) through 2½ in. of insulation.
4. From *D* to *E*: Two paths, (*a*) through 1 in. of tie rod, and (*b*) through 1 in. of concrete.
5. From *E* to *F*: One path through 3 in. of concrete.



It will be noted that items 2 and 4 are paths of similar flow, and could be treated as one. If equilibrium or steady-state heat transfer is assumed, there will exist a temperature difference between the metal tie rod and the concrete, and also between the metal tie rod and the insulating material. The rate of heat transfer between these materials is dependent upon their conductivity values and the temperature difference. As the conductivity of the metal tie rods is considerably higher than that of the concrete or insulating material, it cannot be assumed that the same rate of heat transfer takes place for all parallel paths. Likewise, an appreciable error would be made by assuming that no heat transfer takes place between the metal tie rod and the surrounding materials. Although the pattern of the isotherms is unknown, the following method of calculation does partially take into account the heat flow between the metal tie rods and its bounding materials.

Parallel Flow. The conductances through the areas of parallel heat flow may be determined as follows:

1. The area of each ¼-in. diameter tie rod is 0.00034 sq ft, and as the tie rods are spaced 9 in. vertically, and 12 in. hori-

Table 6 .... Coefficients of Transmission (*U*) of Solid Masonry Walls[a]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph

Example—Wall G 2

Resistances used are given below in this table or in Table 3 or 4

Construction	Resistance (*R*)
1. Outside surface (15 mph wind)	*0.17*
2. Face brick (4 in.)	*0.44*
3. Common brick (4 in.)	*0.80*
4. Air space[b]	*0.97*
5. Gypsum lath (⅜ in.)	*0.32*
6. Plas. (sand agg.) (½ in.)	*0.09*
7. Inside surface (still air)	*0.68*
Total resistance	*3.47*
$U = 1/R = 1/3.47 =$	0.29

See value 0.29 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Assume plain wall—no furring or plaster.		
Total resistance		*3.47*
Deduct 4. Air space	*0.97*	
5. Gypsum lath (⅜ in.)	*0.32*	
6. Plas. (sand agg.) (½ in.)	*0.09*	*1.38*
Total resistance		*2.09*
$U = 1/R = 1/2.09 =$		0.48

To Adjust U Values for Construction with Added Insulation between Furring Strips, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.

[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.

[c] If stucco or structural glass is applied to the exterior, the additional resistance value of 0.10 would have a negligible effect on the *U* value.

[d] Brick, 8 in. (7⅝ in. actual) is assumed to have no backing. Walls 8, 12 and 16 in. have 4 in. of face brick and balance of common brick.

zontally, there will be $0.00034 \times \frac{1}{3} = 0.00045$ sq ft of tie rod to each square foot of wall area. Then from plane B to plane C, the conductance C_1 is

$$C_1 = \frac{0.00045}{1.0} \times \frac{400}{1.0} + \frac{0.99955}{1.0} \times \frac{12}{1.0}$$

$$= 0.180 + 11.994 = 12.174$$

2. For tie rod and insulation from plane C to plane D the conductance C_2 is

$$C_2 = \frac{0.00045}{1.0} \times \frac{400}{2.5} + \frac{0.99955}{1.0} \times \frac{0.30}{2.5}$$

$$= 0.072 + 0.120 = 0.192$$

3. For tie rod and concrete from plane D to plane E the conductance C_3 is

$$C_3 = \frac{0.00045}{1.0} \times \frac{400}{1.0} + \frac{0.99955}{1.0} \times \frac{12}{1.0}$$

$$= 0.180 + 11.994 = 12.174$$

Series Flow. After the conductance values have been determined, the total resistance and U value can be determined as follows;

$$R_T = \frac{1}{f_i} + \frac{z_1}{k_1} + \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \frac{z_2}{k_2} + \frac{1}{f_o}$$

$$R_T = \frac{1}{1.65} + \frac{3.0}{12.0} + \frac{1}{12.174} + \frac{1}{0.192} + \frac{1}{12.174} + \frac{3.0}{12.0} + \frac{1}{6.0}$$

$$R_T = 0.606 + 0.250 + 0.0822 + 5.208$$

$$+ 0.0822 + 0.250 + 0.167 = 6.727$$

$$U = \frac{1}{R_T} = \frac{1}{6.727} = 0.149 \text{ Btu per (hr) (sq ft) (F deg).}$$

The hot box test value, from University of Minnesota, for this wall, corrected for a 15 mph wind velocity, was $U = 0.150$ Btu per (hr) (sq ft) (F deg). The error between the calculated and test values would be

$$\frac{0.150 - 0.149}{0.150} \times 100 = 0.67 \text{ percent.}$$

If the effect of the tie rods were omitted from the calculations, the overall U value would be 0.103. Although the percentage of area occupied by the tie rods per square foot of wall area is $0.00045/1.0 \times 100 = 0.045$ percent, the error between the calculated and test values would be

$$\frac{0.150 - 0.103}{0.150} \times 100 = 31 \text{ percent.}$$

Values Used in Calculation of *U* Value Tables

Tables 5 through 15 are based on values given in Table 4. The following conditions have been used:

Equilibrium or steady-state heat transfer, eliminating effects of heat capacity.

Surrounding surfaces at ambient air temperatures.

Exterior wind velocity of 15 mph for winter and 7.5 mph for summer.

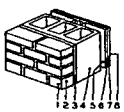
Surface emissivity of ordinary building materials $\epsilon = 0.90$.

Stud space in frame construction not insulated. (See Table 16 for method of correcting for added insulation.)

In construction involving air spaces the U values shown are calculated for areas between framing. See Fig. 6 in section Correction for Framing if an allowance is to be made for this effect.

Air space resistance values used are those shown in Table 4 under Air Spaces.

Air spaces are ¾ in. or more in width.



Variations of conductivity with mean temperature is neglected.

Corrections for framing to be made on basis of parallel heat

(*Continued on p. 108.*)

Table 7 .... Coefficients of Transmission (U) of Masonry Walls[a]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph

Example—Wall G 1

Resistances used are given below in this table or in Table 3 or 4

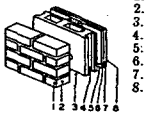
Construction	Resistance (R)
1. Outside surface (15 mph wind)	0.17
2. Face brick (4 in.) (av. R.)	0.39
3. Cement mortar (½ in)	0.10
4. Concrete block (cinder agg.) (4 in.)	1.11
5. Air space[b]	0.97
6. Gypsum lath (⅜ in.)	0.32
7. Plas. (sand agg.) (½ in)	0.09
8. Inside surface (still air)	0.68
Total resistance	3.85
$U = 1/R = 1/3.85 =$	0.26

See value 0.26 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace items 6 and 7 with wood panels (¾ in.) and vapor barrier applied over furring strips		
Total resistance		3.85
Deduct 6. Gypsum lath (⅜ in.)	0.32	
7. Plas. (sand agg.) (½ in)	0.09	0.41
Difference		3.44
Add 6. Vapor barrier	0.06	
7. Wood panel (¾ in.)	0.94	1.00
Total resistance		4.44
$U = 1/R = 1/4.44 =$		0.23



To Adjust U Values for Construction with Added Insulation between Furring Strips, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust U values for the effect of added insulation between framing members, see Table 16.

Table 8 .... Coefficients of Transmission (U) of Masonry Cavity Walls[a]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph

Example—Wall H 6

Resistances used are given below in this table or in Table 3 or 4

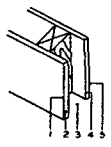
Construction	Resistance (R)
1. Outside surface (15 mph wind)	0.17
2. Common brick (4 in.) (av. R.)	0.76
3. Air space[b]	0.97
4. Concrete block (gravel agg.) (4 in.)	0.71
5. Air space[b]	0.97
6. Gypsum lath (⅜ in.)	0.32
7. Plas. (lt. wt. agg.) (½ in.)	0.52
8. Inside surface (still air)	0.68
Total resistance	4.90
$U = 1/R = 1/4.90 =$	0.20

See value 0.20 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace item 4 with 8 in. concrete block and items 6 and 7 with ⅝ in. plas. (sand agg.) applied directly to concrete block.		
Total resistance		4.90
Deduct 4. Concrete block (gravel agg.) 4 in.	0.71	
5. Air space	0.97	
6. Gypsum lath (⅜ in.)	0.32	
7. Plas. (lt. wt. agg.) (½ in.)	0.32	2.32
Difference		2.58
Add 4. Concrete block (gravel agg.) 8 in.	1.11	
7. Plas. (sand agg.) (⅝ in.)	0.11	1.22
Total resistance =		3.80
$U = 1/R = 1/3.80$		0.26



To Adjust U Values for Construction with Added Insulation[c] between Inner and Outer Tiers or between Furring Strips, See Table 16

Plywood: (¼ in.)	*0.31*	0.60	0.34	8
(⅜ in.)	*0.47*	0.55	0.31	9
(½ in.)	*0.63*	0.50	0.28	10
Wood panels (¾ in.)	*0.94*	0.43	0.24	11
Wood-lath and ½ in. plas. (sand agg.)	*0.40*	0.57	0.32	12
Sheet-metal panels	*0*	0.74	0.43	13
Glass and glass blocks		See Table 21		

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.

flow through 2 x 4 in. (nominal) studs, 16 in. on centers, the framing covering 15 percent of wall area, as shown in Fig. 6.

Thermal resistance for gypsum board and insulating board apply equally to plain material and to those which may be decorated at the factory or on the job.

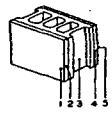
In order to condense the tables an average resistance value (Av.*R*) has been used in some tables for types of materials having approximately the same thermal resistance values. The difference between the average value and the exact value for any given material usually causes no significant change in the resulting *U* value.

Actual thicknesses of lumber assumed to be as follows:

Nominal	*Actual*	*Nominal*	*Actual*
1 in. (S-2-S)	²⅝₃₂ in.	3 in. (S-2-S)	2⅝ in.
1½ in. (S-2-S)	1⁵⁄₁₆ in.	4 in. (S-2-S)	3⅝ in.
2 in. (S-2-S)	1⅝ in.	Finish flooring,	
2½ in. (S-2-S)	2⅛ in.	(maple or oak)	¾ in.

It should be noted that the effects of poor workmanship in construction and installation have an increasingly greater percentage effect on heat transmission as the coefficient becomes numerically smaller. Failure to meet design estimates may be caused by lack of proper attention to exact compliance with specifications. A factor of safety may be employed as a precaution when it is judged desirable.

Insulating Materials



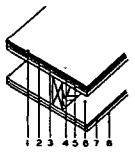
In order to determine the benefit derived from the addition of insulating materials to a given construction, the overall coefficient of heat transmission U_i of the insulated construction may be compared with the corresponding coefficient *U* without insulation. Table 16 (Part A to Part E) and Fig. 6 may be used for determining the coefficients of transmission of constructions with any combination of fibrous, bulk, or mass insulation and air spaces of various effective emissivities.

Example 2: Find the coefficient of transmission of a frame wall consisting of ½ x 8-in. bevel lap wood siding, building pa-

(Continued on p. 111.)

Table 10 .... Coefficients of Transmission (*U*) of Masonry Partitions[a]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on still air (no wind) conditions on both sides



Example—Wall C 2		*Example of Substitution*

[b] Metal core and supports disregarded. Plaster troweled smooth both sides.

Table 11 .... Coefficients of Transmission (*U*) of Frame Construction Ceilings and Floors[a]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference between the air on the two sides) and are based on still air (no wind) conditions on both sides

Example—Floor K 5

Resistances used are given below in this table or in Table 3 or 4

Heated room above unheated space

Construction (Heat flow down)	Resistance (*R*)
1. Top surface (still air)	0.92
2. Linoleum or tile (av. *R*)	0.05
3. Felt	0.06
4. Plywood (⅜ in.)	0.78
5. Wood subfloor ($^{25}/_{32}$ in.)	0.98
6. Air space[b] (7½ in.)	1.25
7. Metal lath and ¾ in. plas. (lt. wt. agg.)	0.47
8. Bottom surface (still air)	0.92
Total resistance	5.45
$U = 1/R = 1/5.45 =$	0.18

See value 0.18 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Assume heated room is below unheated space so heat flow is up		
Total resistance		5.45
Deduct 1. Top surface (heat flow down)	0.92	
6. Air space (heat flow down)	1.25	
8. Bottom surface (heat flow down)	0.92	3.09
Difference		2.36
Add 1. Top surface (heat flow up)	0.61	
6. Air space (heat flow up)	0.85	
8. Bottom surface (heat flow up)	0.61	2.07
Total resistance		4.43
$U = 1/R = 1/4.43 =$		0.23

To Adjust U Values for Construction with Added Insulation between Framing Members, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
[c] Includes asphalt, rubber, and plastic tile (⅛ in.), ceramic tile, or terrazzo (1 in.).
[d] Includes thermal resistance of ⅜ in. gypsum wall board.

per, $^{25}/_{32}$-in. wood sheathing, studs, gypsum lath, and sand aggregate plaster, with 2-in. fibrous insulation between studs.

Solution: According to the example calculation in Table 5 a wall of this construction with no insulation between studs has a coefficient *U* of 0.24. Referring to Table 16, Part A, it will be found that a wall of this value with 2-in. fibrous insulation between the studs has a coefficient *U* of 0.087.

Attention is called to the necessity of applying the insulating material in accordance with the manufacturer's specification. The engineer must evaluate carefully the economic considerations involved in the selection of an insulating material as adapted to various building constructions. Lack of proper evaluation, or improper installation may lead to unsatisfactory results. Special attention must be given to vapor barriers as outlined in Chapter 10. Moisture from condensation or other sources materially reduces the heat-flow resistance of insulation.

INSULATED CONSTRUCTIONS—HOW TO USE TABLE 16

In Tables 5 through 15, *U* values are given for many common types of building wall, floor, and ceiling constructions. For such of these constructions as contain an air space, the tabulated *U* value is based on the assumption that the air space is empty, and that its surfaces are of ordinary building materials of low thermal reflectivity, such as wood, masonry, plaster, or paper. Considerable benefit in reducing the heat transmission coefficient of a construction can be effected by the application of thermal insulating materials in the air space.

Table 16 provides a means of determining, without calculation, the *U* value of the between-framing area of such constructions with the added insulation installed in the air space. Column 1 of Table 16 refers to the *U* values of uninsulated constructions as taken from Tables 5 through 15. Columns 2 to 14 of the table give corresponding coefficients U_i for the constructions with various insulating applications in the between-framing air space, as indicated by the column headings. Table 16 is in 5 parts, (A, B, C, D, and E) corresponding to the type of building element and the direction of heat flow. Each part is based on temperature conditions considered generally appropriate for the case.

Any and all *U* values are based on a series of assumptions as to nominal characteristics. Common variations in conditions, materials, workmanship, etc., can introduce much greater variations in *U* values than the variations resulting from the assumed mean temperatures and temperature differences described. From this it is also clear that the use of more than two significant figures in stating a *U* value is assuming more precision than can possibly exist. Three significant figures are used in Table 16 merely as a means of reducing cumulative errors when the table is used several times to obtain a single result. It should ont be assumed that the figures are accurate, overall, to three significant figures. Also, a result taken from Table 16 should always be rounded off to two significant figures.

To use Table 16:

1. Find in Column 1 of the appropriate table the value for *U* obtained from Tables 5 through 15 for the construction without added insulation.

2. If there is a column which exactly corresponds to the condition for which you desire the *U* value, read the answer in this column, opposite the Column 1 value. Interpolate if necessary.

3. If there is no column which fully corresponds to the condition for which you desire the *U* value, then obtain the answer by means of two or more steps—each time using the value obtained in one step to reenter the same table through Column 1. In this way *U* values may be obtained for combinations of insulation in the framing space.

For combinations of fibrous insulations and air spaces, take account of the fibrous component first and the air space second as illustrated in Example 6. This is necessary to assure the approximately correct temperature difference across the air space.

Examples of the Use of Table 16

Example 3: Find the coefficient of transmission U_i of the frame wall shown as an example at the top of Table 5 when (*a*) a 2-inch blanket fibrous insulation is added between the studs and in contact with the gypsum lath and when (*b*) aluminum-foil-backed gypsum lath is added.

Solution: According to Table 5, the *U* value for this construction with no insulation in the air space is 0.24. Referring to Table 16, Part A, for walls, it is found that corresponding to the value 0.24 in Column 1, the coefficient for conditions (*a*) and (*b*) are:

(*a*) In Column 4, find U_i = 0.087. Use 0.09.

(*b*) From Table 3, Section C, the effective emissivity E of aluminum foil is 0.05.

In Column 8 find U_i = 0.173. Use 0.17.

Example 4: Consider the floor-ceiling construction shown in the example at the top of Table 11, insulated with a sheet of aluminum foil, or paper faced on both sides with foil, (effective emissivity E of air space = 0.05) placed between the joists and dividing the air space into two equal spaces. From Table 11, the *U* value for the uninsulated construction is 0.18 for heat flow down for summer, and 0.22 for heat flow up for winter. Determine the coefficient U_i for:

(*a*) Heat flowing downward from uncooled room above to cooled space below (a summer condition) and,

(*b*) Heat flowing upward from heated room below to unheated space above (a winter condition).

Solution:

(*a*) Use Table 16, Part D, and corresponding to *U* = 0.18 in Column 1 find, in Column 11, U_i = 0.049. Use 0.05.

(*b*) Use Table 16, Part C, and corresponding to *U* = 0.22 in Column 1 find, in Column 11, U_i = 0.12.

Special Uses of Table 16

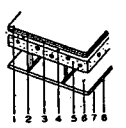
Values of U_i for insulating applications or combinations other than those indicated by the headings of Columns 2 to 14 of Table 16 can be ascertained if the table is used appropriately. For instance, going horizontally in the table from Column 2 to Column 3 is equivalent to adding ¼ in. of fibrous insulation to the construction. Similarly, going from Column 2 to Column 4 adds 1½ in. of fibrous insulation to the construction. In the same way, going horizontally from Column 8 to Column 11 is equivalent to adding to a construction the insulating value of one additional highly reflective (E = 0.05) air space, and going from Column 6 to Column 12 in effect adds two non-reflective (E = 0.82) air spaces to the construction, etc.

Examples 5 and 6 show the combinational use of Table 16

Example 5: Determine the coefficient U_i for the wall of *Example 3*, with 1½ in. of fibrous insulation added on one side of the air space.

Solution: U_i can be determined in several ways, by using Table 16, Part A, for example;

(*a*) By going from Column 1 to Column 2 three times, for a total of 1½ inches of insulation, as follows; enter Column 1 at 0.24 and find U_i = 0.166 in Column 2; enter Column 1 at 0.166 and find U_i = 0.126 in Column 2; enter Column 1 at 0.126 and find U_i = 0.102 in Column 2. Therefore, for a total of 1½ in. of insulation, use 0.10.



(*b*) More simply, by going from 0.24 in Column 2 to 0.103 in Column 4. Use 0.10.

Example 6: Considering again the wall of *Example 3*, assume that one-inch blanket insulation is to be installed in mid-space,

(*Continued on p. 113.*)

Table 12A .... Coefficients of Transmission (*U*) of Concrete Floor-Ceiling Constructions[a] (Winter Conditions, Upward Flow)

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on still air (no wind) conditions on both sides

Example—Floor 3 4

Resistances used are given below in this table or in Table 3 or 4

Heated room below unheated space Construction (heat flow up)	Resistance (*R*)
1. Top surface (still air)	0.61
2. Asphalt tile and felt	0.11
3. Plywood (⅜ in.)	0.78
4. Air space[a]	0.85
5. Concrete slab 4 in. (av. *R*)	0.40
6. Air space[b] (8 in.)	0.85
7. Metal lath and ½ plas. (sand agg.)	0.13
8. Bottom surface (still air)	0.61
Total resistance	4.54
$U = 1/R = 1/4.54 =$	0.23

See value 0.23 in bold face type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace items 2, 3, and 4 with hard wood block (1 13/16 in.) on slab		
Total resistance		4.54
Deduct 2. Asphalt tile and felt	0.11	
3. Plywood (⅜ in.)	0.78	
4. Air space	0.85	1.74
Difference		2.80
Add 2. Wood block (1 13/16 in.)		0.74
Total resistance		3.54
$U = 1/R = 1/3.54 =$		0.30

To Adjust U Values for Construction with Added Insulation in Air Space above Suspended Ceiling, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
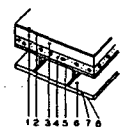
[c] Table 16 can be used only if sleeper space is nonreflective. The sleeper air space is not to be counted in using Table 16.
[d] Concrete is assumed to have a thermal conductivity *k* of 12.0 as given in Table 4.
[e] Includes asphalt, rubber, and plastic tile (⅛ in.), ceramic tile on terrazzo (1 in.).

leaving equal air spaces on the two sides. The coefficient U_i is desired for two cases in which

(*a*) the blanket has non-reflective surfaces on both sides, so that both air spaces are non-reflective (E = 0.82) and,

(*b*) the blanket has one highly reflective surface, so that one of the air spaces is highly reflective (E = 0.05).

Solution:



(*a*) In Table 16, Part A, when *U* without added insulation is 0.24, U_i for one inch of fibrous insulation and one non-reflective air space, is 0.127 in Column 3. To add the second non-reflective air space, enter Column 6 at 0.127, and by interpolating find U_i = 0.112 in Column 9. Use 0.11.

(*b*) U_i for one inch of fibrous insulation and one non-reflective air space is 0.127 as in (*a*). To add one E = 0.05 air space, enter Column 8 at 0.127 and by interpolating find U_i = 0.092 in Column 11. Use 0.09.

(*Continued on p. 121.*)

Table 13A .... Coefficients of Transmission (*U*) of Flat Masonry Roofs with Built-up Roofing, with and without Suspended Ceilings[a] (Winter Conditions, Upward Flow)

These Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph

Example—K 4

Resistances used are given below in this table or in Table 3 or 4

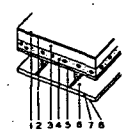
Construction (heat flow up)	Resistance (*R*)
1. Outside surface (15 mph wind)	*0.17*
2. Built-up roofing—⅜ in.	*0.33*
3. Roof insulation (none)	—
4. Concrete slab (lt. wt. agg.) (2 in.)	*2.22*
5. Corrugated metal	*0*
6. Air space[b]	*0.85*
7. Metal lath and ¾ in. plas. (lt. wt. agg.)	*0.47*
8. Inside surface (still air)	*0.61*
Total resistance	*4.65*
$U = 1/R = 1/4.65 =$	0.22

See value 0.22 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace item 4 with 4 in. concrete slab (gravel agg.) and roof insulation (*C* = 0.36) on top of slab.	
Total resistance	*4.65*
Deduct	
4. Concrete slab (lt. wt. agg.) (2 in.)	*2.22*
Difference	*2.43*
Add 3. Roof insulation (*C* = 0.36)	*2.78*
4. Concrete slab (gravel agg.) 4 in.	*0.44*
Total resistance	*5.65*
$U = 1/R = 1/5.65 =$	0.18



To Adjust U Values for Construction with Added Insulation in Air Space, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
[c] *U* values would also apply if slab were poured on metal lath, paper-backed wire, fabric, or asbestos-cement board (¼ in.).
[d] Concrete assumed to have a thermal conductivity *k* of 12.0 and a density of 140 lb per cu ft.
[e] Concrete assumed to have a thermal conductivity *k* of 0.90 and a density of 30 lb per cu ft.
[f] Gypsum slab ¾ in. thick since this is recommended practice.
[g] Gypsum fiber concrete with 12½ percent wood chips (thermal conductivity $k = 1.66$).
[h] See Table 16 E for *U* value of roof and ceiling construction with roof insulation added to roof deck.

Table 13B .... Coefficients of Transmission (*U*) of Flat Masonry Roofs with Built-up Roofing with and without Suspended Ceiling[a] (Summer Conditions, Downward Flow)

These coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 7.5 mph

Example—Roof 1' 2

Resistances used are given below in this table or in Table 3 or 4

Construction (heat flow down)	Resistance (*R*)
1. Outside surface (7.5 mph wind)	*0.25*
2. Built-up roofing (⅜ in.)	*0.33*
3. Roof insulation (none)	*0.00*
4. Concrete slab (gravel agg.) (6 in.)	*0.48*
5. Temporary form bd.	*0.00*
6. Air space[b] (8 in.)	*1.25*
7. Gypsum lath (⅜ in.) and ½ in. plas. (lt. wt. agg.)	*0.64*
8. Inside surface (still air)	*0.92*
Total resistance	*3.87*
$U = 1/R = 1/3.87 =$	0.26

See value 0.26 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace item 3 with roof insulation (*C* = 0.36) and remove suspended ceiling	
Total resistance	*3.87*
Deduct 6. Air space	*1.25*
7. Gypsum lath (⅜ in.) and ½ in. plas. (lt. wt. agg.)	*0.64*
Difference	*1.98*
Add 3. Roof insulation (*C* = 0.36)	*2.78*
Total resistance =	*4.76*
$U = 1/R = 1/4.76 =$	0.21

To adjust U Values for Construction with Added Insulation in Air Space, See Table 16

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
[c] *U* values would also apply if slab were poured on metal lath, paper-backed wire fabric, or asbestos-cement board (¼ in.).
[d] Concrete assumed to have a thermal conductivity *k* of 12.0 and a density of 140 lb per cu ft.
[e] Concrete assumed to have a thermal conductivity *k* of 0.90 and a density of 30 lb per cu ft.
[f] Gypsum slab ¾ in. thick since this is recommended practice.
[g] Gypsum fiber concrete with 12½ percent wood chips (thermal conductivity $k = 1.66$).
[h] See Table 16 E for *U* value of roof and ceiling construction with roof insulation added to roof deck.

Table 14A .... Coefficients of Transmission (U) of Wood or Metal Construction Flat Roofs and Ceilings[a] (Winter Conditions, Upward Flow)

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based upon an outside wind velocity of 15 mph

Example—Roof J.2

Resistances used are given below in this table or in Table 3 or 4

Construction (Heat flow up)	Resistance (R)
1. Outside surface (15 mph wind)	0.17
2. Built-up roofing, 3/8 in.	0.33
3. Roof insulation (C = 0.72)	1.39
4. Wood deck (1 in.)	0.98
5. Air space[b]	0.85
6. Gypsum wall board (3/8 in.)	0.32
7. Acoustical tile (1/2 in.)—glued	1.19
8. Inside surface (still air)	0.61
Total resistance	5.84
U = 1/R = 1/5.84	0.17

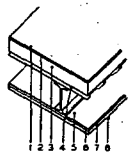
See value 0.17 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Table 3 or 4

Replace item 4 with 2 in. wood deck (exposed to inside) and omit items 5, 6, and 7.	
Total resistance	5.84
Deduct 4. Wood deck (1 in.)	0.98
5. Air space	0.85
6. Gypsum wall board (3/8 in.)	0.32
7. Acoustical tile (1/2 in.) glued	1.19 3.34
Difference	2.50
Add 4. Wood deck (2 in.)	2.03
Total resistance	4.53
U = 1/R = 1/4.53 =	0.22

To Adjust U Values for Construction with Added Insulation in Air Space, See Table 16



Type of Deck (Built-up Roof in All Cases)		Insulation Added on Top of Deck[d]		TYPE OF CEILING												
				None	Gypsum Bd. (3/8 in. and Plas.)			Metal Lath and Plas.		Insul. Bd. (1/2 in.)	Acoustical Tile					Number

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust U values for the effect of added insulation between framing members, see Table 16.
[c] Wood deck 1, 2, and 3 in. is assumed to be 25/32, 1 9/16, and 2 5/16 in. thick, respectively. The thermal conductivity k is assumed to be 0.80.
[d] If a vapor barrier is used beneath roof insulation it will have a negligible effect on the U value. For information on vapor barrier requirements see Chapter 10, Moisture in Building Construction.

Table 14B .... Coefficients of Transmission (U) of Wood or Metal Construction Flat Roofs and Ceilings[a] (Summer Conditions, Downward Flow)

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based upon an outside wind velocity of 7.5 mph

Example—Roof F' 27

Resistances used are given below in this table or in Tables 3 or 4

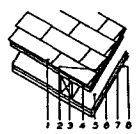
Construction	Resistance (R)
1. Outside surface (7.5 mph wind)	0.25
2. Built-up roofing (3/8 in.)	0.33
3. Roof insulation (C = 0.24)[d]	4.17
4. Metal deck	0.00
5. Air space[b]	1.85
6. Metal lath and 7. 3/4 in. plas. (sand agg.)	0.15
8. Inside surface (still air)	0.68
Total resistance	7.03
U = 1/R = 1/7.03 =	0.14

See value 0.14 in boldface type in table below.

Example of Substitution

Resistances used are given below in this table or in Tables 3 or 4

Replace item 3 with roof insulation (C = 0.36) and items 6 and 7 with metal lath and 3/4 in. plas. (lt. wt. agg.)	
Total resistance	7.03
Deduct 3. Roof insulation (C = 0.24)	4.17
6. Metal lath and 7. 3/4 in. plas. (sand agg.)	0.15 4.30
Difference	2.73
Add 3. Roof insulation (C = 0.36)	2.78
6. Metal lath and 7. 3/4 in. plas. (lt. wt. agg.)	0.47 3.25
Total resistance	5.98
U = 1/R = 1/5.98 =	0.17



To Adjust U Values for Construction with Added Insulation in Air Space See Table 16

Type of Deck (Built-up Roof in All Cases)		Insulation Added on Top of Deck[d]		Type of Ceiling

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] To adjust U values for the effect of added insulation between framing members, see Table 16.
[c] Wood deck 1, 2, and 3 in. is assumed to be 25/32, 1 9/16, and 2 5/16 in. thick, respectively. The thermal conductivity k is assumed to be 0.80.
[d] If a vapor barrier is used beneath roof insulation it will have a negligible effect on the U value. For information on vapor barrier requirements see Chapter 10, Moisture in Building Construction.

Table 15 .... Coefficients of Transmission (U) of Pitched Roofs[a, b]

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph for heat flow upward and 7.5 mph for heat flow downward

Example—Roof C 4		Example of Substitution	
Resistances used are given below in this table or in Table 3 or 4		*Resistances used are given below in this table or in Table 3 or 4*	
Construction (Heat flow up)	Resistance (*R*)	Find *U* value for same construction with heat flow down (summer conditions)	
1. Outside surface (15 mph wind)	*0.17*	Total resistance	*3.19*
2. Slate shingles (½ in.)	*0.05*	Deduct 1. Outside surface (15 mph wind)	*0.17*
3. Building paper	*0.06*	5. Air space	*0.90*
4. Wood sheathing ($^{25}/_{32}$ in.)	*0.98*	8. Inside surface (still air)	*0.62* 1.69

[a] See text section Calculating Overall Coefficients for basis of calculations.
[b] Pitch of roof—45 deg.
[c] To adjust *U* values for the effect of added insulation between framing members, see Table 16.
[d] When insulation is installed between rafters, the space above should be ventilated and in this case the roof construction is disregarded in calculation of *U* values. To adjust *U* values for pitched roof construction with added insulation between framing members, use the average of values for horizontal and vertical heat flow in Table 16A and either 16C or 16D depending on direction of heat flow.

Table 16 .... Determination of U Value Resulting from Addition of Insulation or Air Spaces to Uninsulated Building Sections*

[a] For constructions with air spaces as insulation, coefficients are based on National Bureau of Standards data in *Housing Research Paper* No. 32 (U. S. Government Printing Office, Washington, D. C.).
[b] Based on an indoor-outdoor temperature difference of 70 F deg, and a mean temperature of 50 F. Values are applicable conservatively to winter and summer conditions.
[c] *U* value taken from Tables 5 to 15, based on one nonreflective 3¾-in. air space between framing members.
[d] Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).
[e] For values of effective emissivity E of air space, see Table 3, Section B.
[f] Certain *U* values in Column 6 differ from Column 1 because they are adjusted to the specific temperature drop across the air space in question as affected by the *U* value of the construction.

[a] For construction with air spaces as insulation, coefficients are based on National Bureau of Standards data in *Housing Research Paper* No. 32 (U. S. Government Printing Office, Washington, D. C.).
[b] Based on a temperature difference of 50 F deg from air to air, and a mean temperature of 50 F.
[c] *U* value taken from Tables 11 and 12, in which it is assumed that the air space between joists or above the suspended ceiling is nonreflective (E = 0.82), and is 8 in. thick.
[d] Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).
[e] For values of effective emissivity E of air space, see Table 3, Section B.

* For construction with air spaces as insulation, coefficients are based on National Bureau of Standards data in *Housing Research Paper* No. 32 (U. S. Government Printing Office, Washington, D. C.).

[j] Based on a temperature difference of 75 deg F from air to air, and a mean temperature of 40 F.

[k] *U* value taken from Tables 11, 12, 13-A, 14-A, and 15, in which it is assumed that the air space between joists or above the suspended ceiling is nonreflective (E = 0.82), and is 8 in. thick.

[l] Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).

[m] For values of effective emissivity E of air space, see Table 3, Section B.

[n] Certain *U* values in Column 6 differ from Column 1 because they are adjusted to the specific temperature drop across the air space in question as affected by the *U* value of the construction.

* Interpolation or mild extrapolation may be used.

CORRECTION FOR FRAMING

Correction for parallel heat flow through framing and insulated areas may be made by use of Fig. 6. Correction for the effect of framing should be applied after final U_i and U_o values have been obtained for a given construction. In many cases this correction may be omitted.

Example 7: Consider a frame wall with 2-in. blanket insulation which has a U_i value of 0.08. By calculation it is found that heat loss from the area backed by framing members (U_s) is 0.13. U_s/U_i is 1.63. From Fig. 6 if 15 percent of wall area is backed by framing, the value $U_{ai}/U_i = 1.1$. U_{ai} is therefore $1.1 \times 0.08 = 0.088$.

U_{av} = average *U* value for building section.
U_i = *U* value for area between framing members.
U_s = *U* value for area backed by framing members.
S = percentage of area backed by framing members.

Fig. 6 . . . . Correction for Effect of Framing in Insulated Building Sections

VENTILATED ATTICS—HOW TO USE TABLE 17

Table 17 is intended to be used with Table 11, Part D of Table 16, and Fig. 6, or when ceiling resistance is known. Its purpose is to determine the resistance to heat flow of the attic space under various conditions of ventilating air temperatures and rates, ceiling resistance, roof or sol-air temperatures, and surface emissivities.[11] Ventilating air temperature is the outdoor design temperature.

The total resistance, $1/U$, obtained by adding the ceiling and attic resistances can be converted to a U value so that the heat gain may be calculated. The applicable temperature difference is that difference between room air and sol-air temperature or between room air and roof temperatures. (See footnote d, Table 17.)

Table 17 may be used for both pitched and flat residential roofs over attic spaces. When there is an attic floor, the ceiling resistance should be that which applies to the complete ceiling-floor construction.

All values in Table 16, Part D, include the resistance of a non-reflective surface facing the attic space. Therefore, if separate calculations are made, include only the value of a non-reflective surface and not the value of a reflective surface in determining ceiling resistance. The use of Table 17, Part B, will account for this reflection surface.

Example 8: Determine the heat gain for a 1000 sq ft ceiling of ⅜-in. gypsum board and ½-in. light weight aggregate plaster, with no flooring above, when insulated with a 2-in. foil-enclosed fibrous blanket. The blanket is installed so as to form a reflective air space between the ceiling and the blanket. The attic has a gable roof which meets the ventilation requirements in Table 3, Chapter 10. (Use ventilation rate of 0.1 cfm per sq ft.)

Design temperatures are: indoor air = 75 F, outdoor air = 95 F, and sol-air = 160 F.

Solution: From Table 11, for heat flow down, the U value for this ceiling G3 without insulation is 0.40. Referring to Table 16, Part D, with the value 0.40 in Column 1, find U_i = 0.101 in Column 4; enter Column 1 at 0.101 and find U_i = 0.056 in Column 8. Correct for framing (8 in. joists on 16 in. centers) from Fig. 6 and find corrected ceiling coefficient U_c = 0.059; R_c = 17.0.

By interpolation in Table 17, Part B, using 95 F ventilation air and 160 F sol-air temperatures, the effective attic resistance R_a is 8.2.

The overall coefficient for the combined ceiling and attic is:

$$U_o = \frac{1}{R_c + R_a} = \frac{1}{17.0 + 8.2} = 0.04$$

Heat gain = $U_o A (t_o - t_i) = 0.04 \times 1000 \times (160-75) = 3400$ Btuh

COMBINED CEILING AND ROOF COEFFICIENTS

If the attic space between the ceiling and roof is unheated and *not ventilated*, the combined coefficient from room air below the ceiling to exterior air can be calculated from the following formula:

$$R_T = \frac{1}{U_{ce}} + \frac{1}{nU_r} \qquad (4)$$

The combined coefficient U is the reciprocal of R_T, or

$$U = 1/R_T \qquad (5)$$

where

U = combined coefficient to be used with ceiling area.
R_T = total resistance of ceiling and roof.
U_{ce} = coefficient of transmission of ceiling.
U_r = coefficient of transmission of roof.
n = ratio of roof area to ceiling area.

It should be noted that the overall coefficient U should be multiplied by the ceiling area to determine heat loss, and not

[a] The term *effective resistance* is used when there is attic ventilation. A value for no ventilation is also included. The effective resistance of the attic may be added to the resistance (1/*U*) of the ceiling (Table 16, Part D) to obtain the effective resistance of the combination based on sol-air (Chapter 13) and room temperature. These values apply to wood frame construction with a roof deck and roofing having a conductance of 1.0 Btu/(sq ft) (hr) (F deg).

[b] When attic ventilation meets the requirements of Table 3 in Chapter 10, 0.1 cfm/sq ft may be assumed as the natural summer ventilation rate for design purposes.

[c] *Resistance Unit*, abbreviated *ru* is one (hr) (sq ft) (F deg) per Btu. Determine ceiling resistance from Tables 11 and 16, and correct for framing by Figure 6. Do not add the effect of a reflective surface facing the attic to the ceiling resistance from Table 16, Part D, as it is accounted for in Table 17, Part B.

[d] Roof surface temperature rather than sol-air temperature (see Chapter 13) may be used if 0.25 is subtracted from the attic resistance shown.

[e] Based on air discharging outward from attic.

[f] Surfaces with effective emissivity E of 0.05 between ceiling joists facing the attic space.

by the roof area. Values of U_r and U_{ce} should be calculated using a value of 2.5 (the reciprocal of one-half the air space resistance, 0.80) rather than the conductances of surfaces facing the attic, since the attic is assumed to be equivalent to an air space.

If the attic contains windows, dormers, and vertical wall spaces, and if their area is small compared to that of the roof, they may be considered part of the roof area. For accuracy, the sum of the coefficients of each individual section, multiplied by its percentage of the total area, should be used as U_r. Where attic wall areas are large or where louvers or vents are used, it is preferable to estimate the attic temperature as illustrated in Chapter 12, and calculate the heat loss through the ceiling by multiplying the value of U_{ce} for the ceiling by the difference in temperature above and below the ceiling.

BASEMENT FLOOR, BASEMENT WALL, AND CONCRETE SLAB FLOOR COEFFICIENTS

The heat transfer through basement walls and floors to the ground is dependent on the temperature difference between the air within and that of the ground, on the material constituting the wall or floor, and on the conductivity of the surrounding earth. The conductivity of the earth will vary with local conditions, and is usually unknown. Tests[12] at the ASHAE Research Laboratory indicate a heat flow of approximately 2.0 Btu per (hr) (sq ft) through an uninsulated concrete basement floor, with a temperature difference of 20 deg between ground temperature and the air temperature 6 in. above the floor (see Table 18).

For basement walls below grade only, the temperature difference for winter design conditions will be greater than for the floor. The test results indicate a unit area heat loss, at mid-height of the basement wall portion below grade approximately twice that of the same floor area.

For concrete slab floors laid in contact with the ground at grade level, tests[13] indicate that for *small floor areas* (equal to

Table 18 .... Coefficients of Transmission (*U*) of Concrete Basement Floors on Ground with Various Types of Finish Flooring

$U = 0.10^a$ Btu per (hr) (sq ft) (Fahrenheit degree temperature difference between the ground and the air over the floor).

[a] Since authentic data are not available, this coefficient is sometimes used for concrete floors on ground. For more recent procedures[13] refer to *National Bureau of Standards Report* BMS-103.

that of a house 25 feet square) the heat loss may be calculated as proportional to the length of exposed edge rather than total area. This amounts to 0.81 Btu per (hr) (linear foot of exposed edge) (Fahrenheit degree difference between the indoor air temperature and the average outdoor air temperature). It should be noted that this may be appreciably reduced by insulating under the ground slab, and also along the edges between the floor and the abutting walls. See also sections on Basement Temperatures and Heat Loss, and on Floor Heat Loss in Basementless Houses, in Chapter 12. In most calculations if the perimeter loss is calculated accurately, no other floor loss need be considered.

GLASS AND DOOR COEFFICIENTS

The *U* values for glass sheets and hollow glass block, given in Sections A, B, and C of Table 19, have been computed by methods ind data given in an ASHVE Research Paper.[8] It is assumed that the surface conductance for convection loss to the air is 4.0 Btu per (hr) (sq ft) (F deg). It is also assumed that the glass loses heat by radiation to the ground and to the clear sky, which together have an effective radiating temperature *below* the air temperature. It is therefore necessary to determine, by trial and error, the temperature of the outdoor glass surface such that the sum of the radiation and convection losses equals the heat conducted through the glass section, and equals the heat delivered to the glass from the heated space. This heat flow, divided by the air-to-air temperature difference, results in a *U* value that is used in the usual manner. The equivalent surface conductance for radiation and convection combined, based on *air-to-surface* temperature difference, therefore varies from about 5.5 for single glass to about 6.6 for double glass for exactly the same environmental design conditions. Curtains, draperies, Venetian blinds, etc., will result in lower glass surface temperatures than when the windows are not covered.

It is assumed that the room air temperature equals the average temperature of the room surfaces *seen* by the glass. Special consideration should be given to those cases where the glass *sees* interior surfaces at temperatures differing greatly from the room air temperature, i.e., such cases as in sun rooms, greenhouses, and some panel heated rooms, or where there is an unusual amount of air motion in the vicinity of the glass. Although based on zero outdoor air, the values change only slightly with different design temperatures, being about 5 percent greater for a 30 F outdoor design temperature.

In computing the Table 19 values, consideration of the dependence of the indoor surface conductances upon temperature and direction of heat flow leads to surface conductances averaging about 1.50 for block and vertical glass, and about *1.80* for horizontal glass, as compared to the value of 1.46 used in computing *U* values given in other tables in this chapter. *These values should therefore be used in estimating the temperature at which condensation on glass surfaces will occur.*

The application factors given in Section D of Table 19 are based upon hot box tests summarized in a research bulletin,[14] and are approximate only. In practice, some variation in heat flow through windows having the same ratio of glass to sash area, may be expected because of difference in construction details and in air-space edge effects. The high conductance of aluminum and steel sash must be taken into consideration where excessive amounts of metal sash and frames are involved. This is particularly important when they are in close proximity to radiation heat sources and are consequently subjected to high differential temperatures.

Table 19 .... Coefficients of Transmission (*U*) of Windows, Skylights and Glass Block Walls

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides). Those for outdoor exposures are based upon the following outdoor conditions: 0 F air temperature, clear skies, no solar radiation, and 15 mph outdoor wind velocity

SECTION A—VERTICAL GLASS SHEETS

Aluminum	80	1.10	80	1.30	80	1.10

[a] For 1 in. or greater.

[b] See Chapter 13, Tables 14 and 15, for summer load.

[c] See Chapter 13, Tables 14, 15, and 16, for summer load.

[d] From unpublished data recommended by ASHAE Tech. Adv. Comm. on Heat Flow Through Fenestration.

[e] Unit type double glazing (two lights or panes in same opening).

[f] Use with *U* values for two sheets with 1 in. air space.

[g] Based on area of exposed portion of sash; does not include frame or portions of sash concealed by frame.

[h] For metal storm sash or metal sash with attached storm pane.

Heat transmission coefficients for wood doors, with and without glass storm doors are given in Table 20.

WIND VELOCITY EFFECT ON *U* VALUES

Tables 5 through 8, 13-A, 14-A, 15, parts of Table 19, and Table 20 show values of U for winter calculations, for an outdoor wind velocity of 15 mph. Tables 13-B and 14-B show values of U for summer calculations and an outdoor wind velocity of 7.5 mph. Tables 11, 12, and 15 show values of U for both winter and summer. Tables 9 through 12 are for indoor U values and are based upon still air. All roof coefficient tables also take into account the direction of heat flow. Care must be exercised in selecting the table which applies to the design conditions. Table 21 shows comparative values of U for other wind velocities. When this table is used for summer

Table 20 .... Coefficients of Transmission (*U*) of Solid Wood Doors

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based upon an outside wind velocity of 15 mph.

Nominal Thickness Inches	*Actual Thickness Inches*	*U*[a,b] *Exposed Door*	*U*[a,b] *With Glass Storm Door*[c]
1	$^{25}/_{32}$	0.64	0.37
1¼	1¼6	0.55	0.34
1⅜	1⅜6	0.49	0.32
1¾	1⅜	0.48	0.31
2	1⅝	0.43	0.28
2¼	2⅛	0.36	0.26
3	2⅝	0.31	0.23

[a] Computed using k = 1.10 for wood, f_i = 1.46, f_o = 6.0, and 1.03 for air space.
[b] A U value of 0.85 may be used for single exposed doors containing thin wood panels or single panes of glass, and 0.39 for the same with glass storm doors.
[c] 50 percent glass and thin wood panels.

U values, it is necessary to enter the table at 7.5 mph which can be interpolated between 5 and 10 mph. Any value taken from this table should be rounded to two significant figures.

Example 8: Find the coefficient of transmission U of a frame wall consisting of stucco, $^{25}/_{32}$-in. insulation board sheathing, 2 x 4-in. studs, gypsum lath and plaster, and with 2-in. blanket insulation between studs, for 25 mph wind velocity.

Solution: From Table 5, this wall, F37, with no insulation between studs has a value of U = 0.22. From Table 16, Part A, Col. 4, this wall with 2-in. insulation added has a value of U = 0.084. Entering Table 21 in the 15 mph column, interpolate between 0.080 and 0.090 in 15 mph column and proceed horizontally to the 25 mph column where the U value is found by interpolation to be 0.085.

CALCULATING SURFACE TEMPERATURES

In many heating and cooling load calculations it is necessary to determine the inside surface temperature or the temperature of the surfaces within the structure. As the resistance of any path of heat flow is expressed in Fahrenheit degrees per (Btu)/(hour) (square foot), the resistances through any two paths of heat flow would be proportional to the temperature drop through these paths, and can be expressed as follows:

$$\frac{R_1}{R_2} = \frac{(t_i - t_x)}{(t_i - t_o)} \qquad (6)$$

Table 21 .... Conversion Table for Wall Coefficient *U* for Various Wind Velocities

U for 15 mph[a]	*U* for 0 to 30 mph Wind Velocities					
	0	5	10	20	25	30

[a] U in first column is from previous tables or as calculated for 15 mph wind velocity.

where

R_1 = the resistance from the indoor air to any point in the structure at which the temperature is to be determined.
R_2 = the overall resistance of the wall from indoor air to outdoor air.
t_i = indoor air temperature.
t_x = temperature to be determined.
t_o = outdoor air temperature.

Example 9: Determine the inside surface temperature for a wall having an overall coefficient of heat transmission U = 0.25, indoor air temperature 70 F, and outdoor air temperature −20 F.

Solution:

$$R = 1/f_i = 1/1.46 = 0.684$$

$$R_2 = 1/U = 1/0.25 = 4.00$$

Then, by Equation 6

$$\frac{0.684}{4.00} = \frac{70 - t_x}{70 - (-20)}$$

$$t_x = 54.6 \text{ F}$$

Example 10: Determine the temperature of the bottom of a 4-in. insulated concrete roof slab to which has been glued ½-in. acoustical tile (C = 0.84) as the interior finish. The roof-ceiling overall coefficient of heat transmission U is 0.14 for heat flow up. The indoor air temperature is assumed to be 70 F and the outdoor air temperature −20 F.

Solution:

$$R_1 = \frac{1}{f_i} + \frac{1}{C} = \frac{1}{1.63} + \frac{1}{0.84} = 1.80$$

$$R_2 = \frac{1}{U} = \frac{1}{0.14} = 7.14$$

Then, by Equation 6

$$\frac{1.80}{7.14} = \frac{70 - t_x}{70 - (-20)}$$

$$t_x = 47.3 \text{ F}$$

The concrete surface temperature is of interest since reference to a psychrometric chart or table will show that moisture condensation could occur on this surface under the above conditions (47.3 F) if the relative humidity in the room exceeds 44 percent. Additional roof insulation should be considered above the slab to avoid condensation at this point if higher relative humidities in the room are anticipated.

The same procedure can be used for determining the temperature it any point within the structure.

A chart for determining inside wall surface temperature is given in Fig. 13 of Chapter 30, Panel Heating.

CHAPTER 10

MOISTURE IN BUILDING CONSTRUCTION

Properties of Water in Air; Water in Building Materials; Vapor Transmission; Permeance and Testing; Visible Condensation; Concealed Condensation in Heated Buildings; Control of Concealed Condensation; Condensation in Cooled Structures.

THE behavior of moisture is too often overlooked or given scant attention in the design and construction of buildings. It is present as a vapor in all air and as adsorbed moisture in most building materials. It may be present also at times in the free liquid state or as ice, in the solid state, within the range of temperatures encountered in many buildings. Problems involving moisture may arise from changes in moisture content, from the presence of excessive moisture, or from effects associated with its changes in state.

Of particular interest is the change from the vapor to the liquid or solid state, known as condensation. This may be associated with a reduction of temperature with time, or may occur as a result of migration of water vapor to regions of lower temperature. Moisture problems involving condensation are therefore most likely to occur in buildings in any climate in which there is a source of water vapor at temperatures above normal, or in cooled structures, and in buildings in cold climates.

Moisture problems in residences occur in winter and become increasingly important as homes are built smaller and tighter. Water vapor originates from such necessary living requirements as cooking, laundering, bathing, and the breathing and perspiration of people. In a typical family of four, the average daily production of water vapor from these sources may be as much as 25 lb, and may be much greater where such appliances as humidifiers, automatic washers, and dryers are used.[1] Another large source of water vapor is sometimes the bare earth in a crawl space or basement. All this water vapor must escape from the dwelling.

PROPERTIES OF WATER VAPOR IN AIR

Water vapor in air is a gas which occupies all the space, along with the air present. In many ways, the water vapor can act independently of the air, since in general its properties do not depend on the presence of the air. It exerts its own vapor pressure, and can move about through air in a space, or move through materials under differences in its own vapor pressure, independently of the air. However, when the air is moved suddenly or is heated or cooled, the water vapor present is similarly affected, so that it is usually necessary to consider it as a part of an air-vapor mixture.

The properties of mixtures of air and water vapor are relatively well known and are discussed in Chapter 3, Thermodynamics. Changes in these properties with heating and cooling can be followed readily with the aid of a psychrometric chart, shown in outline in Fig. 1. The saturation line represents the limiting concentrations of water vapor which can exist as vapor at various temperatures.

A common condition inside buildings, 70 F and 40 percent relative humidity, is represented by point A. This is a condition of partial saturation; i.e., less than 100 percent relative humidity. The vapor pressure of the water present in the air, although not shown on the chart, can be calculated readily from the vapor pressure at saturation and the relative humidity, since relative humidity is very nearly equal to the ratio of the actual vapor pressure to the saturation pressure at the existing temperature.

The increasing relative humidity accompanying cooling from the condition represented by A on the chart to point B can readily be followed. At B, however, at 44.6 F, the relative humidity becomes 100 percent, and the air-vapor mixture is said to be saturated. The temperature at which this particular air-vapor mixture, upon cooling, becomes saturated is its dew-point temperature. Upon further cooling, to 35 F, the original amount of water vapor can no longer be retained and is reduced, in this case, to the condition represented by C, from 0.0633 lb per lb dry air to 0.0427 lb per lb dry air. The process ABC is typical of that which an air-vapor mixture experiences when it comes in contact with a cool window surface. Cooling from B to C results in visible condensation on the glass surface. If the point C were below 32 F, the condensation would be in the form of frost.

Once the temperature drops below the dew point, or frost point if below 32 F, the vapor pressure at the condensing surface is also reduced, thereby establishing a gradient of vapor pressure from the room air to the window surface. This gradient will operate, in conjunction with the convective action within the room, to move water vapor continuously to the window surface to be condensed, so long as the concentration of water vapor in the room is maintained.

A common winter process is that shown by DE, showing air at 20 F, saturated, being heated to 70 F with a resulting large decrease in relative humidity. This explains, in part,

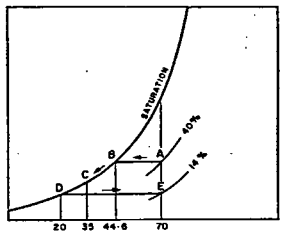

Fig. 1 . . . . Two Typical Heating and Cooling Processes in Air within Buildings Shown on ASHAE Psychrometric Chart

the greatly reduced relative humidities experienced in houses in extreme cold weather, when cold outdoor air enters the house and is heated.

WATER IN BUILDING MATERIALS

The surfaces of most common materials have an affinity for water molecules. Molecular forces of attraction will hold water molecules to the surface, but decrease very rapidly with increase in distance of molecular proportions. The film thickness and therefore the amount of water held in equilibrium with the surrounding atmosphere is roughly proportional to relative humidity. Surface films of water molecules, at low humidities, may be only one molecule thick; at moderate humidities poly-molecular films may be established, while at humidities very close to 100 percent, the films become so thick, relatively, that small pores may become filled and larger capillaries may be partially filled. At saturation conditions all voids in the material may be completely filled.

Some materials such as silica gel, alumina and most natural fibrous materials present very large effective surfaces to the water molecules, so that the amount of water held on the effective surface in these materials may be relatively large, even at moderate humidities. These are said to be hygroscopic. Other materials, such as most metals, not penetrated by the water molecules, present relatively small surfaces and so may take only minute quantities of water, except when wetted directly by liquid.

Substances having a great affinity for water, and their use as dehumidifying agents, are described in Chapter 42. Data on the moisture contents of various common materials in equilibrium with the atmosphere at various relative humidities are given in Table 2 of Chapter 50, and equilibrium moisture content is further discussed in Chapter 53 on Industrial Drying Systems.

Significant dimensional changes take place in many materials used in buildings, with change in moisture content. The best known are those which take place in wood, of the order of 0.1, 2, and 4 percent in the longitudinal, radial and tangential directions, respectively, on a change from air dry at 12 to 15 percent moisture content to oven dry conditions. Most wood-fiber products, including papers, will exhibit moisture expansion consistent with the basic wood properties to a degree dependent on the fiber orientation and arrangement. Data on wood are available in publications on wood technology. Almost all plant and animal fibers experience appreciable moisture changes with changing relative humidity and undergo substantial dimensional changes of the same order as those in wood. Less generally recognized are the dimensional changes that can occur in masonry materials as a result of changes in moisture content.

Water is either an essential or a contributory factor in almost all cases of breakdown of building materials resulting from chemical changes such as the rusting of steel, physical changes such as the spalling of masonry by frost action, or biological processes such as the rotting of wood. The control of water in building constructions may be necessary to ensure adequate service from the materials involved.

Condensation of water vapor, although not the only means by which wetting may be brought about, is nevertheless a most insidious one, particularly in respect to freeze-thaw breakdown, since from its nature it is most likely to occur at points of low temperature at which there may later be risk of freezing while the material remains in a saturated condition.

Moisture in building materials may have a marked effect upon the transmission of heat through them. It has been commonly assumed that moisture when present in a material will remain more or less stationary and will increase the conductivity largely by adding to the path available for heat flow. On this basis, the effect of moisture on heat flow can be accounted for quite simply by the use of suitable coefficients of conductivity in the usual heat-flow equations. The data presented in Chapter 9 on moist soils are of this type.

Evidence to date indicates, however, that in porous materials partially saturated with water there is likely to be a migration of moisture to the cold side under the influence of the temperature gradient. This can occur by a process of evaporation, vapor flow, and condensation within the material, a substantial amount of heat being transferred as latent heat of the vapor, particularly in the case of open fibrous materials. The transmission of heat through moist materials becomes complex whenever conditions are such as to produce any appreciable migration of the moisture, and, consequently, calculations by the usual heat-flow theory alone, are an approximation.

The usual approach to the calculation of moisture migration has been to consider the flow as hydraulic, under the influence of hydrostatic forces when the materials are saturated, and as a vapor flow produced by vapor pressure differences in unsaturated materials. These simple concepts might be adequate were it not for the fact that there are interactions between water molecules and the material through which they are passing, as already mentioned. Further complications may be introduced by the presence of salts and electrical potentials.

It is now recognized that the migration of moisture under conditions of partial saturation in a material having an affinity for water actually occurs as a kind of series-parallel flow of vapor and liquid, with the liquid phase having more and more influence as the moisture content, or the degree of saturation, increases. The two kinds of flow cannot be separated since they are closely coupled everywhere along the flow path by evaporation and condensation. Enough is already known to indicate that the isothermal or constant temperature case of vapor flow under a vapor-pressure gradient is much more manageable than the cases in which there are both temperature and vapor-pressure gradients. Cases of combined heat and moisture flow are now known to be extremely complicated and it is quite clear that when both are occurring, neither one can be adequately dealt with independently of the other. No adequate way of handling the general case theoretically has yet been found, despite efforts being made in many laboratories. The bibliography at the end of this chapter includes some of the more important papers on this subject.

A relatively simple equation for the calculation of water-vapor flow based upon the concept of vapor pressure alone as the driving force, has been in use for a number of years. It can be applied without great difficulty to cases where uniform temperatures or only small temperature gradients exist, and to cases of low or moderate relative humidity. It has also been shown to be useful in other cases, provided that the proper values representative of the conditions to which it is being applied can be found for the flow coefficient to be used in the calculations. The complications inherent in the combined mechanisms of heat and moisture flow are not adequately covered by the variables used in the equation, but appear in the determination of suitable values of the flow coefficient, which, however, may vary greatly for any one material, depending on the conditions of flow.

VAPOR TRANSMISSION THROUGH MATERIALS

The equation presently used in calculating water-vapor transmission through materials is based on a form of Fick's

Law, and is as follows:

$$w = -\mu \frac{dp}{dx} \tag{1}$$

where

w = weight of vapor transmitted through a unit area in unit time.

p = vapor pressure.

x = distance along the flow path.

and hence:

$\frac{dp}{dx}$ = vapor pressure gradient.

μ = permeability.

The close parallel with Fourier's equation for heat flow will be noted. The actual transmission of vapor through a material is extremely complex, so that the coefficient, μ, is not a simple one but is actually a function of relative humidity and temperature, and may vary along the flow path through the material in question.[2]

Integrating Equation 1 from $x = 0$ to $x = l$ and from p_1 to p_2, and rearranging, the following is obtained:

$$w = \frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2} \times \frac{(p_1 - p_2)}{l} \tag{2}$$

Let

$$\frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2} = \bar{\mu} \tag{3}$$

Then,

$$w = \bar{\mu} \frac{p_1 - p_2}{l} \tag{4}$$

where

l = length of flow path (or thickness of material).

If Equation 1 had been integrated, assuming the coefficient μ to be independent of vapor pressure (and temperature) along the flow path, Equation 4 would have been obtained, but with $\bar{\mu}$ replaced by μ. The coefficient $\bar{\mu}$ is therefore an average permeability coefficient applicable to the varying conditions along the flow path of length l, while the coefficient μ is the *spot* or *differential* permeability.

Equation 4 may be rewritten and units assigned:

$$W = \bar{\mu} A \theta \frac{\Delta p}{l} \tag{5}$$

where,

W = total weight of vapor transmitted, grains.

A = area of cross-section of the flow path, square feet.

θ = time during which the transmission occurred, hours.

Δp = difference of vapor pressure between ends of the flow path, inches of mercury.

l = length of flow path, (or thickness of specimen), inches.

The basic units given are those now favored by the building industry. The permeability μ or $\bar{\mu}$ is therefore expressed in a unit of grains-inches per (square foot) (hour) (inch of mercury vapor pressure difference).

Whenever it is convenient to deal with a material of a stated or implied thickness other than the unit thickness to which μ or $\bar{\mu}$ refer, use may be made of the permeance coefficient M, where $M = \bar{\mu}/l$. The designation *perm* for the unit of permeance is now widely used, and is a convenient substitute for the unit, 1 grain per (square foot) (hour) (inch of mercury vapor pressure difference).[3] The corresponding unit of permeability is *perm-inch*, since it is the permeance of unit thickness. The corresponding flow equation is:

$$W = MA\theta\Delta p \tag{6}$$

Resistance to vapor flow provided by a sheet or board is the reciprocal of the permeance, and correspondingly, the over-all vapor resistance of an assembly (like a wall) of materials in series is the sum of the resistances of its component parts. The over-all permeance of the assembly may be found from the permeances of the individual components[4, 5] in a manner paralleling that used in calculating the over-all coefficient of thermal conductivity from the individual conductances:

$$M_t = \frac{1}{\left(\frac{1}{M_1} + \frac{1}{M_2} + \frac{1}{M_3} \cdots + \frac{1}{M_n}\right)} \tag{7}$$

This simple theory for vapor flow, as in the case of the corresponding simple heat-flow theory, assumes conditions of unidirectional, steady-state flow. Useful calculations can be made for an assembly or sub-assembly for which the inflow and outflow of vapor are equal (a condition at which no condensation occurs) if a permeance applicable to actual conditions can be assigned to each component part. Over-all permeances, vapor pressures and vapor flow can be calculated, and in conjunction with thermal calculations, relative humidities can be determined, and the imminence of condensation predicted. (See *Example 1*, and Fig. 2. See also Chapter 13, Cooling Load, for use of vapor-flow calculations.)

Example 1: A wood frame wall is exposed to indoor conditions 70 F and 50 percent relative humidity (0.37 in. Hg vapor pressure) and outdoor conditions 0 F and 80 percent relative

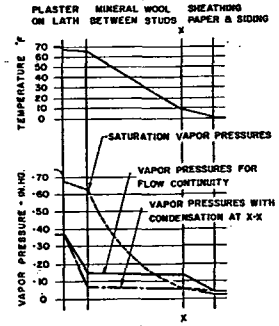

Fig. 2 .... Temperatures and Vapor Pressures under Vapor Flow Conditions in the Insulated Frame Wall of Example 1.

humidity (0.03 in. Hg vapor pressure). The wall consists of painted plaster on gypsum lath on the inside over 2 × 4 in. studs, mineral wool fill between studs, 1 in. wood exterior sheathing, paper, and pine lap siding. Check for possible condensation.

To simplify the example, consider the paint, plaster, and lath as a single element having a permeance $M = 1.0$ perms and a thermal conductance $C = 2.4$, and the exterior sheathing, paper, siding, and paint as another single element for which $M = 2.0$ perms and $C = 0.50$. From Table 1 the value for the permeability of mineral wool fill may be found as $\bar{\mu} = 116$ perm-inches. The thermal conductivity for mineral wool, $k = 0.27$.

Solution: In this particular wall, insulated, and with moderate warm-side relative humidities, condensation is unlikely to occur until the sheathing is reached. To check directly for condensation on the warm side of the exterior sheathing (designated as plane X − X in Fig. 2 for convenient reference) proceed as follows:

Calculate according to the method of Chapter 9 the temperature at plane X − X. *This is found to be 9° F. The saturation* vapor pressure at this temperature is 0.06 in Hg. If condensation is imminent or occurring at X − X, the vapor pressure there will be 0.06 in. Hg. Calculate the permeance for the portion of the wall from the warm side to X − X, and the vapor flow rate to X − X as follows:

$$\text{Permeance of wall to X} - \text{X} = \frac{1}{\frac{1}{1.0} + \frac{3.625}{116}} = 0.97 \text{ perms.}$$

Vapor pressure drop to X − X = 0.37 − 0.06 = 0.31 in. Hg.

Vapor flow to X − X = 0.97 × 0.31 = 0.30 grains per (sq ft) (hr).

Calculate the vapor flow rate from X − X to outdoors as follows:

Permeance of wall from X − X to outdoors = 2.0 perms.

Vapor pressure drop from X − X to outdoors
= 0.06 − 0.03
= 0.03 in. Hg.

Vapor flow rate to outdoors = 2.0 × 0.03 = 0.06 grains per (sq ft) (hr).

It is apparent that continuity of vapor flow is not possible, since at the highest vapor pressure at X − X permitted by the temperature, there is indicated a greater flow to plane X − X than from it to outdoors. Condensation is indicated at a rate of 0.30 − 0.06 = 0.24 grains per (sq ft) (hr).

Whether this condensation rate will be serious must still be decided, since it might readily be absorbed by the sheathing during the condensation period without excessive wetting. When the temperature at X − X is below freezing, as in this case, the condensation will be in the form of frost which may accumulate until released over a short period upon a rise in outdoor temperature.

Condensation will be reduced or avoided if the permeance of the warm side of the wall can be reduced so that the flow to X − X is limited to 0.06 grains per (sq ft) (hr). Permeance required for this is $\frac{0.06}{0.37 - 0.06} = 0.19$ *perms or less. A more* resistant paint film on the plaster, reducing the paint-plaster-lath permeance to 0.19 perms would accomplish this.

When the critical plane for condensation is unknown, or for a more informative, graphical representation of the situation throughout the wall, temperatures and vapor pressures may be calculated and plotted as in Fig. 2. The vapor pressures throughout the wall, for continuity of flow, are calculated in a manner similar to the temperatures; the external vapor pressures are given, and the vapor pressure drops across each element are taken in proportion to resistance to vapor flow.

The curve for saturation vapor pressures at the various *temperatures throughout the wall* is also shown in Fig. 2 and is seen to fall below the curve for vapor pressures with continuity of flow, toward the outer portions of the wall. This indicates that with the given temperatures and vapor pressures, continuity of flow is not possible and that condensation will occur. Condensation on the sheathing is indicated as a definite possibility, and the new vapor-pressure curve can be constructed for this condition, as shown. This new curve does not rise above the saturation-vapor-pressure curve, thereby confirming that the critical plane for condensation was correctly assumed.

With the vapor pressures thus established, the relative humidities may be found, by reference to the saturation vapor pressures. The permeances originally assigned to the various elements may then be re-examined in the light of the service conditions of temperatures and relative humidities indicated, and the analysis repeated, if necessary, using more appropriate *permeance values.*

In a more detailed analysis, individual values might be assigned to the elements forming the outer portion of the *wall which is here dealt with as a composite, homogeneous* element.

The transmission of water vapor as outlined is based on the assumption of a diffusion process. The possibility of vapor being transferred as part of a moving air stream has thus far been ignored, except in *Example 1* in which it is implied that the air circulation on either side of the wall will be sufficient to eliminate surface-film resistances to vapor flow. Differences in total pressure of the air may result in a transfer of vapor with air, augmenting and at times over-riding the effects of the flow produced by vapor-pressure gradients alone. This can be particularly important in the transfer of vapor through cracks and pinholes or through air-permeable building constructions. Similar effects can be obtained with air-permeable materials themselves.[6]

This means of vapor transfer is similar to that of transfer of heat by air leakage in and through building constructions, and requires, for purposes of calculation, information on the nature and amount of the air leakage. It will seldom be important in constructions without air spaces and having parged or plastered surfaces. It may, however, be an important means of vapor transfer through constructions lacking in air tightness, and may contribute to condensation difficulties, since the mechanism of condensation is not dependent upon the way in which the vapor is transferred.

PERMEANCE AND TESTING

The simplest method of finding the permeance of a specimen is to seal it over the top of a cup containing desiccant or water, placing it in a controlled atmosphere, and weighing it periodically. The steady rate of weight gain or loss is normally the water vapor transfer. When the cup contains a desiccant the procedure is called the *dry-cup method* and when the cup contains water, the *wet-cup method.* Usually the surrounding atmosphere is held at 50 percent relative humidity, thus providing, in either method, substantially the same difference of vapor pressure, but the results obtained by the two methods for the same specimens are likely to be much different, the wet-cup method producing the higher values. The relationship between these values can best be understood by reference to Fig. 3, which shows a typical variation of spot permeability with relative humidity at one particular temperature (isothermal conditions) for a material such as wood. The vapor permeability is shown to vary only moderately at low humidities, but to increase at an increasing rate as higher humidities are reached. The dry-cup test of this material carried out with 0 percent relative humidity one side and 50 percent on the other, will experience throughout its thickness, because of the variation in relative humidity, a variation in spot permeability. The average permeability $\bar{\mu}$, is by definition (Equation 3), given by $\frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2}$, and since at a fixed temperature there is a linear relationship between vapor pressure and relative humidity, this expression can be seen to correspond to the mean height of the area under the spot permeability curve, between the appropriate relative humidity limits. The average permeability as found for the dry-cup conditions should therefore have the value $\bar{\mu}_1$. Similarly for the wet-cup test between 50 percent and 100 percent relative humidity, the value should be $\bar{\mu}_2$. It is not uncommon for these values for wood and wood-fiber materials to be in the ratio of 1 to 3, or higher. (See Table 1.)

The average permeability $\bar{\mu}$ for any other relative humidities at a particular temperature is given by the mean height of the area under the curve of spot permeability for the material at that temperature, between the appropriate limits of relative humidity. Only average permeabilities (or permeances) are measurable directly in practical tests. However, if several average permeabilities at different relative humidities are known, and can be plotted as for the wet-cup and dry-cup tests shown in Fig. 3, it is possible to construct, by trial and error, a spot permeability curve which will satisfy the condition that the average height of the curve between the appropriate limits for each test must equal the value found in each test. Separate curves are required for each temperature so that a large number of permeance cup tests would be required to cover a range of conditions of both temperature and humidity.

Experience to date shows that the effect of temperature is quite moderate and, for some purposes, differences in temperature at which tests are run may be ignored. Corrections for temperature have been made with some success in the case of certain materials by the use of an equation based on activation energy[7] which states:

$$\mu = \mu_\infty e^{-(E/RT)} \qquad (8)$$

where, in appropriate units,

μ_∞ = permeability at $T = \infty$.
R = gas constant.
E = activation energy.
e = Naperian base of logarithms = 2.718.
T = absolute temperature.

Applications of this equation may be limited to materials such as resins, rubbers, and polymers in which the water molecules enter and move through the molecular structure by a process known as activated diffusion. It may serve also as a useful approximation in other cases.

By use of Equation 8, spot permeability curves for a variety of temperatures can be constructed from a curve for one temperature, provided only that two tests at different temperatures can be run, from which E; the activation energy, can be evaluated. In this way it becomes possible to describe the permeability of a material with reasonable completeness from

the results of as few as five single tests at carefully selected conditions.

No method has yet been found, other than by direct testing for a particular set of conditions, of predicting the effective permeabilities for conditions of temperature gradient along with a humidity (or vapor-pressure) gradient, from data obtained under other conditions, even though this is the general situation in practice. A very considerable amount of information is available on the permeances and permeabilities of various materials, but these are frequently obtained at different conditions so that the results cannot be compared directly, nor do they often give a coverage of a range of conditions to permit construction of basic curves of spot permeability or permeance.

Since dry-cup and wet-cup tests are much easier to carry out than tests at intermediate humidities, many of the data available have been obtained in this way. In the absence of

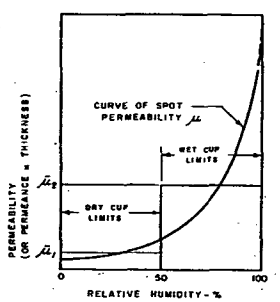

Fig. 3 .... Relation between Dry and Wet Cup Tests and the Spot Permeability for a Material such as Wood

data obtained from tests duplicating the conditions of temperature and relative humidity in service, the permeance of a piece of material may be judged adequately for many purposes if it is tested by both dry and wet methods. It is obvious that any statement of permeance of a specimen should include the conditions of test.

Method of test E96-53T of the American Society for Testing Materials describes procedures for testing for water-vapor transmission of materials in sheet form under five different test conditions. These include the dry-cup and wet-cup methods, based on 50 percent relative humidity outside the cup, at either 73.4 or 90 F, and a fifth condition at an elevated temperature of 100 F with relative humidities of 0 and 90 percent on either side of the sheet. Standard T448m-49 of the Technical Association of the Pulp and Paper Industry covers the determination of water-vapor transmission of paper and paperboard, and calls for the dry-cup method at 73.4 F, based on 50 percent relative humidity outside the cup. *ASTM Standard* C355-54T covers tentative methods of test for water vapor transmission of materials used in building construction.

Unfortunately, there is no general agreement as yet to report results as coefficients of permeance, or of permeability where appropriate, as adopted in this chapter, or to use the same basic units. Test data are frequently reported in terms of weight transmitted per (unit area) (unit time). Such data may be called *water-vapor transmission data* or WVT data and values are either high or low depending on the difference of vapor pressure chosen for the test. When this difference is known, WVT data can be converted to permeance, care being taken if conversion of the basic units (weight, area and time) is also required. The following formula applies:

$$\text{Permeance} = \frac{\text{WVT rating}}{\Delta p} \qquad (9)$$

where

WVT rating = weight of vapor transmitted, grains per (sq ft) (hour).

Δp = vapor-pressure difference in the test, in inches of mercury.

Permeance is expressed in perms.

Table 2 presents the conversion factors applicable to the commonly used units and test methods. Table 1 presents some data on typical building materials showing, in each case, the source and method and, where applicable, the thickness tested.

Water-proofed building papers are listed in *Federal Specifications* UU-P-147, May 24, 1948, according to water-vapor resistance required as:

Class A. For uses where a high degree of water-vapor resistance is required.

Class B. For uses where a lower degree of water-vapor resistance and of water resistance is required.

Class C. For uses where a moderate degree of water-resistance is required.

Class D. For uses where low resistance to water vapor is required.

It may be noted that a paper may be *water-proof*, i.e. possess water resistance, and still have low water-vapor resistance.

Detail requirements in these specifications are given as follows, the specified WVT Test being a dry method at 73 F.

Class A paper shall have a minimum tensile strength in each direction of either 35 lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 24 hr, and a maximum water vapor permeability (WVT) of 4 grams per (square meter) (24 hr) i.e. 0.576 perm.

Class B paper shall have a minimum tensile strength in each direction of either 35 lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 16 hr, and a maximum water-vapor permeability (WVT) of 6 grams per (square meter) (24 hr) i.e. 0.864 perm.

Class C paper shall have a minimum tensile strength in each direction of either 35 lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 8 hr.

Class D paper shall have a minimum tensile strength in each direction of 20 lb per inch width. The paper shall have a minimum water resistance of 10 min., a minimum water-vapor permeability (WVT) of 35 grams per (square meter) (24 hr) i.e. 5.04 perms.

VISIBLE CONDENSATION

Just as moisture collects on the outer surface of a glass of cold water, so does it also condense on other cold materials. In winter, visible condensation may collect on cold closet walls and attic roofs and is commonly observed on frosted window panes. Although condensation, if liquid, may enter an unpainted surface as fast as it forms and thus be unseen, any condensation on a visible surface will for convenience

here be called *visible condensation* to distinguish it from *concealed condensation*. Within residences and public buildings, visible condensation in winter may damage decorative finishes and window sash.

Interior visible condensation occurs when any surface is colder than the dew point of the near-by air. The temperature of any such surface—wall, roof, or glass—is dependent upon the air temperature inside and outside the building and the heat transfer coefficient U of the surface structure. Based on a value of 1.65 for the inside surface conductance, Fig. 4 shows the relative humidity in a room at 70 F at which visible condensation will appear at various U values. The curves for single and double glass at their usual U values are included. It should be noted that U values as commonly used are an average for a large area within which there may be spots, such as the studs in an insulated wall, where the transmittance is higher. The inside surface temperature of a wall will, in general, be lower at the bottom due to such things as stratification of inside air and the effects of air leakage and of convection in walls with air spaces. Since condensation appears at any sufficiently cold spot, values from Fig. 4 can be applied only with caution. As a result, the limit of relative humidity for a non-homogeneous wall is lower than might be inferred from its average U value.

Normally, glass is the most likely spot in a heated room for appearance of condensation, but an uninsulated wall surface shielded from radiation by furniture, may be equally cold. In some cases where condensation is barely avoided, the surface, being but little warmer than the dew-point temperature, is exposed to moisture damage—such as swelling, mold or discoloration.

Visible condensation may occur also in summer. It is often seen on basement concrete walls and floors that are cooled by the earth and which being massive, tend to hold a constant temperature from day to day while the weather dew-point temperature rises. When no water vapor is released in the space, the dew point tends to equal that of the outdoors (though it is likely to lag when there is slight ventilation). At times the dew-point temperature rises above the temperature of walls and floors with resulting condensation. If the basement is decorated the trouble may be serious. As an operating problem, the solution may be to reduce ventilation at times of high weather dew point, to warm the walls, or to dehumidify the space. Warming the walls, a slow process at best, is generally accomplished in favorable climates by excess ventilation. In a climate having low temperature at night, it may be feasible to ventilate only at night and thus reduce the moisture content of hygroscopic materials which will then act as desiccants to retard the dew-point rise during the day. In basement walls and floors insulation should be applied in the concrete or on its outside. Insulation placed on the inside of such walls eliminates visible condensation but fos-

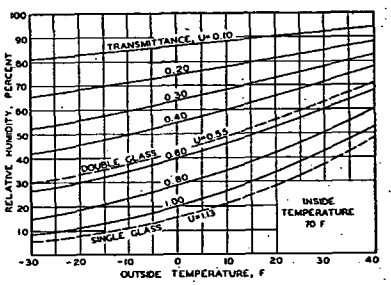

Fig. 4 .... Relative Humidity at Which Visible Condensation Will Appear on Inside Surface

ters concealed condensation. The control of the latter will be discussed. A practical and fully effective technique for such control has, however, not been developed. Usually, sub-surface dwellings designed for occupancy should be dehumidified.

A similar situation is seen in dwellings with concrete floor slabs laid on the ground where such slabs are not a part of the heating system. In a northern climate where high dew-point temperatures occur in summer, condensation or very high relative humidity may damage rugs which are themselves contributors to the trouble since they reduce the floor slab temperature. Slab floors above grade are not so serious a problem as floor slabs on grade but their response to air temperature change is slow. Faster warming is accomplished by the removal of rugs and abundant ventilation at proper times. In their design, floor slabs should have as low specific heat and as high thermal resistance as is consistent with other requirements. Suitable insulation below the slab, especially well-drained gravel, will help somewhat. A top surface cover of insulating value that is unaffected by water on its lower side would be desirable in the less favorable northern climates.

The avoidance of interior visible condensation is partly a construction and partly an operating problem. It is accomplished by reducing the interior dew-point temperature or by raising the surface temperatures that are below the dew point, or both. The dew-point temperature may be lowered by giv-

ing attention to the sources of the moisture, and in winter, may be controlled by ventilation, or possibly by some moisture absorption process. The temperatures of the inside room surfaces in winter may be increased by adding insulation to outside walls, by double glazing of windows, by circulating warm air over the surface, or perhaps by direct heating of the surface. The most expedient method of overcoming a surface condensation difficulty will depend upon special conditions surrounding the problem.

CONCEALED CONDENSATION IN HEATED BUILDINGS

Water vapor produced in a building necessarily raises the vapor pressure above that outdoors thus providing the force that causes its diffusion into exterior walls. The amount of vapor-pressure rise in the building depends on the amount of vapor produced and inversely on its chance to escape. The resulting balance may be expressed in terms of relative humidity if the inside temperature is 70 F. The relative humidity in heated buildings covers nearly all of the possible range. In zero weather it may be only 10 percent in an office, and 85 percent in an industrial plant where humidification is required for a process, or where vapor release is incidental to a process. In residences the relative humidity in cold winter weather ranges from 10 percent to 60 percent, the latter figure applying to a very small, crowded and unventilated dwelling. A 40 percent level is considered representative of a substantial number of modern tightly constructed small houses although the average house relative humidity is probably below 25 percent. Surveys in residences show that the relative humidity increases as would be expected in warmer weather. Fig. 5 represents the results of one such survey.[8]

When water vapor is allowed to enter a wall and condensation occurs on its outer cold elements, it appears as frost or liquid. If the weather temperature rises frequently, frost melts and becoming liquid, is likely to penetrate capillary materials like wood, or run down when the surface is nonabsorbing or is already saturated with water. In weather that is continuously cold for a long period, the frost may build back into a cavity or fibrous insulation and, when it reaches a warmer plane, will run to lower, cooler levels where it forms a mass of ice. Water seepage to the weather side may occur harmlessly in masonry walls when the weather is above freezing but water seepage into the building must obviously be avoided. In typical frame construction with wood sheathing which has large water absorbing capacity, seepage is rare and occurs only after a long period of steady cold weather. More generally, moisture accumulates in wood sheathing and siding through the colder months and reaches a peak in late winter, after which the drying of spring and summer completes the annual cycle.[16] The average winter temperature and its duration are factors in the condensation problem. In Fig. 6 the map of the United States is divided into condensation zones based on winter weather conditions. The solid lines separating the zones follow state lines, and are those recommended by the Housing and Home Finance Agency for the guidance of owners, builders, and architects.[17] The dotted lines are the −20 F, 0 F, and +20 F isotherms of winter design temperature taken from Fig. 1, Chapter 12. It will be noted that there is reasonably good correlation between the zones determined by the two sets of lines. Zone I roughly includes those areas where the design temperature is −20 F or colder; Zone II those for which the design temperature is zero to −20 F, and zone III those at zero and warmer. Within each zone, similar degrees of condensation trouble are to be expected, and similar corrective measures apply.

In roofs, the condensation problem is much the same as in walls. The roof covering may be even more resistant to the escape of vapor than wall coverings such as paint; and while paint is likely to be ruptured by excessive moisture, no such relief occurs in roofs. Thus roofs furnish conspicuous examples of rapid decay in lumber.

In crawl spaces over uncovered damp ground, a large water evaporation sometimes occurs and causes condensation on the outer ends of floor joists and other members that are below the floor line and near the outdoors. Water vapor from the crawl space may also enter walls, be transported by rising air in a stack effect, and even reach the attic by this route when the wall structure permits. Ventilation, as discussed later in this chapter, is an important correction factor in these cases.

Insulation in a wall or roof reduces heat loss and lowers the temperature of the outer elements of the structure, thus increasing the possibility of condensation if the vapor path to the cold surface is not blocked. Since low vapor resistance is a characteristic of fibrous insulation, the needed vapor resistance must be provided by other means. It is to be noted that, in typical residential conditions, condensation does not occur in fibrous insulation itself, except when frost has formed on sheathing and gradually built backward among the fibers. Wet insulation may result from this condition or from liquid condensation seeping down from a higher level.

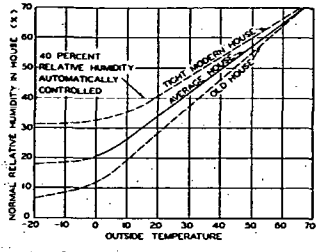

Fig. 5 .... Relative Humidity in Dwellings

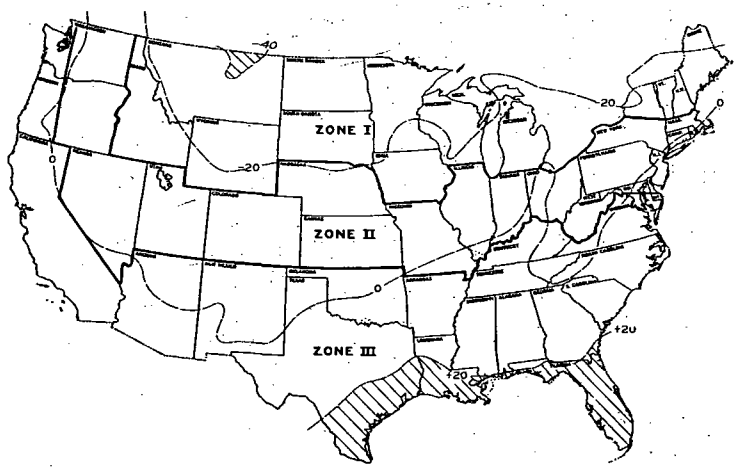
CONTROL OF CONCEALED CONDENSATION

An excessive accumulation of moisture in walls (or roofs) can be prevented by one or more of the following measures: (1) providing a vapor barrier to limit vapor entrance into the wall, (2) ventilating the building to reduce vapor pressure therein, or (3) ventilating the wall cavity to remove vapor that has entered.

1. *Vapor Barrier.* A vapor barrier is the principal and most obvious correction, but each measure is more effective if aided by the effect of another. In habitations, some ventilation of the living space, either incidental or planned, is necessary. Also, a small amount of cavity ventilation is essential in cases where the vapor inflow is not completely stopped and the moisture storing capacity of the outer wall elements is slight. This applies to some prefabricated designs using metal siding.

Vapor-barrier sheets are often built into the wall near the warm surface. In wood frame walls they may be applied to the inside surface of the studs. They are sometimes attached to the warm side of the insulating materials, or they may be applied on the cold side of plaster base materials. Special designs may be attached like wall paper to the inside of the wall, when satisfactory from the decorative view point. Sheet barriers often contain asphalt as the vapor-resisting ingredient; metal foils, so placed that they are not too cold, may also be used.

The interior wall board or finish material may itself be vapor resistant, or a barrier coating may be applied to its concealed side if that side will not be too cold. The interior finished surface may be coated with a suitable paint having the required vapor resistance and also serving as the decorative finish, or it may be covered by another coat.



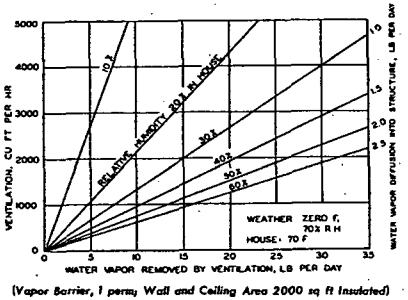
A paint coat on the interior finish, though of adequate resistance, is not likely to be as effective as a sheet barrier properly applied during the wall construction. This applies especially to houses of more than one story having cavities in ceilings which open into the outside walls. Such cavities allow vapor entering the ceiling to diffuse or be transported to the cold areas. Stoppage of this path is difficult and requires normally the painting of the ceiling as well as the walls. Similar treatment may be required on internal partitions, or at least the first stud space adjacent to a cold wall.

The necessary barrier resistance depends on a number of factors. When the vapor flow occurs in annual cycles as in heated buildings, the requirement is not as exacting as it is for a cold storage room where there is no chance for drying out an accumulation of moisture. In a heated structure covered on the outside with materials highly resistant to water vapor such as paint or roll roofing, the winter season is a time of moisture accumulation in the cold outer elements and their safe moisture holding capacity is an important factor in determining the barrier requirement.[16] A house without sheathing requires a better barrier. A prefabricated design with only a sheet of metal outside of insulation requires very high barrier resistance. The interior vapor pressure and the length and severity of the winter are also important.

For typical frame dwellings with wood sheathing and siding in the northern United States, a barrier permeance of one perm or less has been found satisfactory. There are cases, however, in residential construction where a one perm barrier would not be adequate and there are also many industrial applications in which a very much higher vapor resistance is required. In any event, the choice of an adequate barrier implies that its permeance be definitely established. The usually accepted test procedure for this purpose is a dry method at a temperature of 70 F to 80 F. If obtainable at reasonable cost (including good application), a barrier better than required should be chosen for any construction. Despite the theoretical possibility of safely discharging some vapor through a wall, a higher-than-minimum permeance is not preferred.

An exact statement showing which buildings require a vapor barrier is not readily formulated. However, in view of the distressing results its omission may bring, it is tentatively recommended that the walls of every well constructed modern dwelling include a vapor barrier when the construction includes any material that would be damaged by moisture or its freezing. This applies to all condensation zones in Fig. 6 when the *U* value for the wall is lower than 0.25 Btu per (sq ft) (hr) (F deg), and it applies in Zone I and Zone II to walls of higher transmittance.

In applying vapor resistance to a wall, there are certain



Zones include Areas with Design Temperatures about as follows: Zone I, −20 F and lower; Zone II, 0 F to −20 F; and Zone III, above 0 F. Note that cross hatched areas are outside of Zones I and III.

Fig. 6 .... Condensation Zones in the United States

fundamental principles that should be followed. First, the vapor barrier should be placed as near to the warm surface of the wall as practicable. Second, it should be continuous with no direct openings through the barrier. Good workmanship and application are very important. Workmanship that leaves two openings through the barrier, or around its margin, at different levels, connecting air spaces at only slightly different temperatures, leaves a path for thermosyphon air rotation which will transport large amounts of water vapor from the warmer space to the colder. If a membrane barrier is used back of the plaster or interior finish, its joints should be made over some solid framing member, and not between the studs or in similar places. Usually a two-inch lap over a framing member will make a sufficiently tight joint when the interior finish is applied. Such a lap, however, without backing would not be adequate. Barriers attached to the warm side of insulation should form a continuous unbroken membrane over the entire insulated area. Edges should be lapped over framing members; ends of strips should be fastened by lapping over plates or headers. All openings for electrical fixtures and joints around window and door casings should be carefully sealed. Holes accidentally made in the barrier should be sealed.

2. *Ventilation of Living Space.* The second measure listed for the control of concealed condensation is ventilation of the house. This measure is obviously necessary as an accompaniment to a vapor barrier since, if the barrier blocks entrance into the walls, the water vapor must be removed by other means. No great volume of air change is necessary, however, and normal infiltration alone is frequently all that is required in winter weather.

The effectiveness of ventilation is shown in Fig. 7, which also shows the small amount of water vapor escaping into the barrier-equipped, well-insulated walls and ceilings (2000 sq ft) of a typical small dwelling, the floor being neglected. Evidently, ventilation of 2000 cfh will remove 21 lb of vapor per day with the relative humidity at 40 percent, while at the same time 1.5 lb escapes into the structure. The total vapor production (22.5 lb) is a typical amount. Double glass will be barely safe from visible condensation as will be seen in Fig. 4. By reference to Chapter 6, 2000 cfh appears to be near the minimum for odor control, and ventilation would have to be higher when cooking is done. By reference to Chapter 11, it appears that usual infiltration will normally supply the necessary air change, but that supplementary ventilation may

(Vapor Barrier, 1 perm; Wall and Ceiling Area 2000 sq ft Insulated)

Fig. 7 .... Water Vapor Balance in a Dwelling

be necessary in kitchen and laundry for proper vapor control and for the reduction of peaks in relative humidity that would otherwise occur in those areas.

3. *Ventilation of Structure.* The third measure listed for the control of concealed condensation is ventilation of the structure itself. It is effective in certain cases especially as a supplement to warm-side vapor resistance which is considerable but not of itself fully adequate. Air from outdoors is used. The vents must be shielded from the entrance of rain and insects.

Attics and crawl spaces may be considered as parts of the structure, and for these portions ventilation is practically a necessity. Attic ventilation has long been an established practice but its effectiveness is likely to be diminished by the newer practice of adding insulation to ceilings. Insulation requires added ventilation which in turn necessitates adequate insulation. The recommended ventilation shown in Table 3 for dwellings[17] is based on such insulation. The *net area* refers to the total of all openings free from obstructions. The use of louvers and 8-mesh screen (usually recommended) requires a gross area 2.25 times that listed. In Zone I of Fig. 6 a ceiling vapor barrier is recommended for all constructions. It is also necessary that stray openings from walls into the attic, or around a loose fitting attic door be avoided. The *stack effect* allows a large inflow of warm air from the dwelling, transporting much vapor to a danger area. More desirable ventilation of the house can be arranged.

Crawl spaces under dwellings where the earth is damp and uncovered require a high rate of ventilation. At least four

Table 3 .... Recommended Good Practice[17] for Loft and Attic Ventilation[a]

Flat Roof—Slope Less than 3 Inches in 12 Inches
Condensation Zone I[c]: Total net area of ventilation should be $\frac{1}{300}$th[b] distributed uniformly at the eaves *plus* a vapor barrier in the top story ceiling. Free circulation must be provided through all spaces.
Condensation Zone II and III: Same as for Zone I.
Gable Roof—Slope over 3 Inches in 12 Inches
Condensation Zone I: Total net area of at least 2 louvers on opposite sides located near the ridge to be $\frac{1}{300}$th[b] *plus* a vapor barrier in the top story ceiling.
Condensation Zone II: Same ventilation as for Zone I. A vapor barrier is not considered necessary.
Condensation Zone III: Same as for Zone II.
Hip Roof
Condensation Zone I: Total net area of ventilation should be $\frac{1}{300}$th[b] with $\frac{1}{600}$th[b] distributed uniformly at the eaves *and* $\frac{1}{600}$th[b] located at the ridge with all spaces interconnected. A vapor barrier should also be used in the top story ceiling.
Condensation Zone II: Same ventilation as for Zone I. A vapor barrier is not considered necessary.
Condensation Zone III: Same as for Zone II.
Gable or Hip Roof—With Occupancy Contemplated
Condensation Zone I: Total net area of ventilation should be $\frac{1}{300}$th[b] with $\frac{1}{600}$th[b] distributed uniformly at the eaves and $\frac{1}{600}$th[b] located at the ridge with all spaces interconnected. A vapor barrier should also be used on the warm side of the top full story ceiling, the dwarf walls, the sloping part of the roof, and the attic story ceiling.
Condensation Zone II: Same as for Zone I.
Condensation Zone III: Same as for Zone I except that a vapor barrier is not considered necessary if insulation is omitted.

[a] It is recognized that in many areas increased ventilation may be desirable for summer comfort. For winter comfort, insulation is recommended between a living space and a loft or attic ventilated at these rates.

[b] Refers to area enclosed within building lines at eave level.

[c] The zone numbers refer to Fig. 6.

openings, one at each corner, as high as possible, should be provided.[17] Their total net area may be calculated by the formula:

$$a = \frac{2L}{100} + \frac{A}{300} \qquad (10)$$

where:

L = the perimeter of the crawl space, linear feet.

A = the area of the crawl space, square feet.

a = the total net area of all vents, (or the gross area if a 4-mesh screen is used) square feet.

This ventilation is usually sufficient but cools the first floor so much that insulation is needed. A better treatment is a cover on the damp ground. This cover may be a concrete slab, or merely heavy roll roofing laid on a graded surface with its edges lapped 2 in. (but not necessarily cemented). With this barrier, the vent area may be reduced to 10 percent of that calculated by Equation 10.

In building walls, cavity ventilation can be applied in a moderate climate as the sole vapor control system. In general, however, air passages in walls designed to remove an unrestricted vapor supply are unduly large and may waste considerable heat. On the other hand, a barrier as the only control measure would, in some cases, require so high a resistance as to be impractical. Ventilation of the structure in conjunction with a vapor barrier, is a procedure with important applications, but its general utility has not been fully investigated. Ventilation is most effective when each structural space has a clearly defined air passage with an inlet and outlet. In walls a small thermosyphon effect may be utilized by locating one vent at the bottom and one at the top of each space.

The best time to vapor-proof a building is during its construction. After a building is completed, ventilation of the occupied space is the most easily applied of the three basic control measures. Paint that is chosen for its low vapor permeance can be applied as a barrier on the interior with good results, care being taken that all areas, including parts of partitions and ceilings which offer an indirect vapor path to the cold wall, are covered. Ventilation of the wall cavity is effective in certain cases especially to supplement the foregoing measures. When such venting is required, each cavity space isolated by framing should be separately vented with an inlet and outlet judiciously placed, to accomplish proper air change.

CONDENSATION IN COOLED STRUCTURES

Water vapor is sometimes an even greater problem in cooled than in heated structures, but the basic facts of its migration and condensation on cold surfaces are the same. Refrigerators, cold pipes, and cold vessels all require insulation and should be provided with a vapor barrier. The barrier, as always, should be placed on the warm side of the insulation and as close as possible to the warm surface of any enclosure. It resists the movement of water vapor toward the colder parts of the structure, and its job is even more exacting than that required in residential construction. In the case of an insulated cold pipe line, the process is likely to be uninterrupted for years and there is no chance for vapor that enters the insulation to dry out periodically. Also, no vapor can escape from the cold side, if this is a metal (vapor tight) pipe. For such an application vapor control requires insulating material that is itself very highly resistant to water vapor or a coating whose permeance is the minimum obtainable, not over 0.1 perm. Metal coverings are desirable but difficult to apply.

Similar considerations apply in the case of cold rooms whether constructed inside a heated building or as a separate building. In the latter case, cold rooms operating above freezing provide some periods of vapor reversal in winter but such drying can be of little help. Refrigerators, however, if lined with cement or other vapor permeant material, will allow slight amounts of vapor to pass and to that extent reduce the accumulation of moisture that may have penetrated the barrier. While this is helpful, emphasis must be placed on an adequate warm-side barrier not greater than 0.1 perm.

Summer air cooling for comfort does not normally create serious vapor problems in exterior walls and ceilings. Normally the cooled air is little, if any, colder than the dew point of the outdoor atmosphere and there are no areas of condensation. The design dry-bulb and design wet-bulb temperatures in common use as given in Table 2, Chapter 13, tend to bear this out. For the 315 cities in the United States, for which design values are given, only 78 have design wet-bulb temperatures in common use over 75 F. Outdoor dew-point temperatures, especially peak values, may exceed the design wet-bulb temperatures in common use, but these will seldom be greatly in excess of 75 F for any prolonged period of time. Condensation within exterior walls which are exposed to indoor air at 75 F will seldom be as serious as for the winter condition.

A vapor barrier to prevent condensation within exterior walls under summer cooling conditions would normally be located on the outside of the insulation, whereas the location for the winter condition is on the inner side. The use of vapor barriers at both locations is not without difficulty because they not only restrict the entry of moisture into the insulation but also restrict the escape of any moisture. It is generally considered best in dwelling construction to locate the vapor barrier for the more serious case of condensation in winter, and to disregard the summer case even when some condensation may be expected. The corresponding situation in cold-storage buildings in which there may be a much more serious reversal of vapor flow conditions from winter to summer poses a wall design problem that has not yet been fully resolved.

Some observations made by the National Research Council of Canada, but not yet publicly reported, would indicate that serious wetting within walls can occur in summer under special conditions. The walls of test huts of brick masonry, but finished inside with strapping, insulation, vapor barrier, and plasterboard interior finish, were opened during a sunny period that followed a rain. Extensive wetting was observed in the insulation, and particularly on the back of the vapor barrier. The brick wall which was unusually absorptive had taken on substantial quantities of water during the period of rainfall. Subsequent heating by the sun had driven the moisture as vapor into the wall where it condensed and caused serious wetting. The construction in question did not have protection for the strapping and insulation in the form of parging or paper on the inside of the brick. Walls having absorptive exterior coverings capable of absorbing and storing considerable quantities of water during a rain and providing little resistance to vapor flow into the insulation from the outdoors, may experience serious interior wetting by condensation under such unusual conditions. No wetting occurred in a construction similar to that described above when a saturated sheathing paper was used between the insulation and the brick. It would appear that the provision of moderate resistance to vapor flow such as that provided

by parging or a good exterior grade sheathing paper on the outside of the insulation can be effective in such cases.

Vapor which diffuses inwards under cooling conditions adds to the cooling load. Vapor barriers in walls installed for winter conditions are a help in reducing this. However, if condensation does occur on the back of a vapor barrier installed on the inside of the insulation, the latent heat which is then released on the inside of the insulation may add to the heat gain through the wall.

CHAPTER 11

INFILTRATION AND VENTILATION

Causes of Infiltration, Infiltration Due to Wind Pressure, Infiltration Due to Temperature Difference, Sealing of Vertical Openings, Infiltration Measurement, Natural Ventilation, Wind Forces, Temperature Difference Forces, Heat Removal, Effect of Unequal Openings, Combined Wind and Temperature Forces, Types of Openings, General Ventilation Rules, Ventilation of Animal Shelters, Garage Ventilation

INFILTRATION is the air leakage through cracks and interstices, around windows and doors, and through floors and walls. Its magnitude depends on the structural design, workmanship, and condition of the building. The rate of infiltration cannot be controlled by the inhabitants of the building to any considerable extent. Natural ventilation is the controlled displacement of air through openings, such as windows, doors, and ventilators as well as through combustion heating devices.

CAUSES OF INFILTRATION

The air leakage which takes place through various apertures in buildings must be estimated in heating and cooling calculations and enough heating or cooling capacity provided to offset the heat lost or gained by the air leakage. The rate of air flow into and out of a building depends on the magnitude of the pressure difference between the inside and outside of the structure and on the resistances presented to this pressure difference. The pressure difference exerted on the building walls by the air may be caused either by wind or by a difference in density of the air inside and outside the building. The effect of the wind depends on the interrelation of the speed and direction of the wind and the exposure of the building. The effect of the difference in the density of the air depends on the magnitude of the indoor-outdoor temperature difference, the height of the rooms, the shape of the openings, and their elevation in the room or building. The effect of the difference in density is often referred to as the chimney or stack effect. The pattern of air flow through any part of the structure depends on both the pressure difference and the openings. In general, when the pressure difference is the result of wind pressure, air will enter the building through openings in the windward walls and leave through openings in the leeward walls or through ventilating ducts in the roof. When the pressure difference is caused by the indoor-outdoor temperature difference the flow will be along the path of least resistance from inlets at lower levels to outlets at higher levels in a heated building or in the opposite direction for an air-conditioned building.

An exact estimate of the amount of infiltration under design conditions is difficult to make. The complicating factors include (1) variations in building construction, particularly as to width of crack or size of openings through which air leakage takes place; (2) variations in wind velocity and direction; (3) exposure of the building with respect to air leakage openings, and with respect to adjoining buildings; (4) variations in outdoor temperatures which influence the chimney effect; (5) relative area and resistance of openings on the windward and leeward sides, and on the lower floors and on the upper floors; and (6) influence of a planned air supply and the related outlet vents. Tight construction is essential for preventing large heat loss due to infiltration.

In view of the meager information available on infiltration, a cooperative investigation was undertaken in 1954 in which the infiltration rates of residences were obtained by actual measurement.[1, 2] In 1956 a study was started at the ASHAE Research Laboratory to obtain additional information on infiltration through building entrances.[3] These studies are yielding quantitative information on factors affecting infiltration rates, but more data are still needed.

INFILTRATION DUE TO WIND PRESSURE

The wind causes a pressure to be exerted on one or two sides of a building. As a result, air comes into the building on the windward side through cracks or porous construction, and a similar quantity of air leaves on the leeward side through like openings. In general, the resistance to air movement is similar on the windward to that on the leeward side. This causes a building up of pressure within the building, and a lesser air leakage than that experienced in single wall tests as determined in the laboratory. It is assumed that actual building leakages, owing to this building up of pressure, will be 80 percent of laboratory test values. While there are cases where this is not true, tests in actual buildings substantiate the factor for the general case. Mechanical ventilating systems are frequently designed to produce positive or negative pressures in an enclosure, which are greater or lower than prevalent wind pressures. In such designs, if the specified rate at which air is to be supplied to, or removed from, the enclosure by positive means, exceeds the infiltration rate, it is common practice to use the greater value in determining the heating capacity to warm the outdoor air.

Infiltration Through Walls

Data on infiltration through brick and frame walls are given in Table 1.[4] The brick walls listed in this table are walls that show poor workmanship, and which are constructed of porous brick and lime mortar. For good workmanship, the leakage through hard brick walls with cement-lime mortar does not exceed one-third the values given. These tests indicate that plastering reduces the leakage by about 96 percent; a heavy coat of cold water paint, 50 percent; and three coats of oil paint carefully applied, 28 percent. The infiltration through walls ranges from 6 to 25 percent of that through windows and doors in a 10-story

Table 1 .... Infiltration Through Walls[a]

Expressed in cubic feet per (square foot) (hour)

Type of Wall		Wind Velocity, Miles per Hour					
		5	10	15	20	25	30
Brick Wall[b]							
8¼ in.	Plain	2	4	8	12	19	23
	Plastered[c]	0.02	0.04	0.07	0.11	0.16	0.24
13 in.	Plain	1	4	7	12	16	21
	Plastered[c]	0.01	0.01	0.03	0.04	0.07	0.10
	Plastered[d]	0.03	0.10	0.21	0.36	0.53	0.72
Frame Wall, lath and plaster[e]		0.03	0.07	0.13	0.18	0.23	0.26

[a] The values given in this table are 20 percent less than test values to allow for building up of pressure in rooms, and are based on test data reported in the papers listed in chapter footnotes.

[b] Constructed of porous brick and lime mortar—workmanship poor.

[c] Two coats prepared gypsum plaster on brick.

[d] Furring, lath, and two coats prepared gypsum plaster on brick.

[e] Wall construction: bevel siding painted or cedar shingles, sheathing, building paper, wood lath, and three coats gypsum plaster.

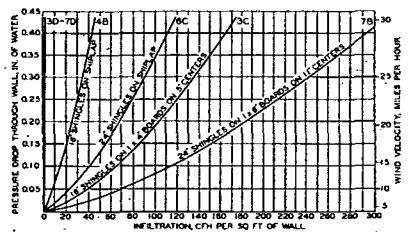
office building, with imperfect sealing of plaster at the baseboards of the rooms. With perfect sealing the range is from 0.5 to 2.7 percent; or a practically negligible quantity, which indicates the importance of good workmanship for proper sealing at the baseboard. It will be noted from Table 1 that the infiltration through properly plastered walls can be neglected.

The value of building paper, when applied between sheathing and shingles, is indicated by curve 3D-7D, Fig. 1, which represents the effect on outside construction only, without lath and plaster. The effectiveness of plaster properly applied is no justification for the use of low grade building paper, or of the poor construction of the wall containing it. Not only is it difficult to secure and maintain the full effectiveness of the plaster, but also it is highly desirable to have two points of high resistance to air flow with an air space between them. The infiltration indicated in Fig. 1 is that determined in the laboratory, and *should be multiplied by the factor* 0.80 to give proper working values.

Window and Door Leakage

There are two methods of estimating air leakage through window and door cracks, namely, (1) the crack method, and (2) the air change method. The crack method is generally regarded as being more accurate than the air change method, provided the variables, such as crack width and clearance, can be properly evaluated.

Crack Method



The crack method is based on known air leakage factors for various types of windows, and widths of crack and clearance. The wind velocity and length of crack are also considered when the crack method is employed. The amount of infiltration for various types of windows is given in Table 2.[a] The fit of double-hung wood windows is determined by crack and clearance. Crack thickness is equivalent to one-half the difference between the inside window frame dimension and the outside sash width. The difference between the width of the window frame guide and the sash thickness is considered as the clearance. The length of the perimeter opening or crack for a double-hung window is equal to three times the width, plus two times the height, or in other words, it is the outer sash perimeter length, plus the meeting rail length. All of the window crack in any given room is not necessarily used in estimating the infiltration heat loss by the crack method. The length of crack to be selected in any given case depends on the number of exposed sides, as explained in Chapter 12.

Values of leakage shown in Table 2 for the average double-hung wood window were determined by using, on nine windows tested in the laboratory, the average measured crack and clearance of a large number of windows found in a field survey. In addition, the table gives figures for a poorly fitted window. All of the figures for double-hung wood windows are for the *unlocked* condition. Just how a window is closed, or fits when it is closed, has considerable influence on the leakage. The leakage will be high if the sash are short, if the meeting rail members are warped, or if the frame and sash are not fitted squarely to each other. It is possible to have a window with approximately the average crack and clearance that will have a leakage at least double that of the figures shown. Values for the average double-hung wood window in Table 2 are considered to be easily obtainable figures, provided the workmanship on the window is good. Should it be known that the windows under consideration are poorly fitted, the larger leakage values should be used. Locking a window generally decreases its leakage, but in some cases may push the meeting rail members apart and increase the leakage. On windows with large clearances, locking will usually reduce the leakage.

Wood casement windows may be assumed to have the same unit leakage as for the average double-hung wood window when properly fitted. Locking, a normal operation in the closing of this type of window, maintains the crack at a low value.

For a metal pivoted sash, the length of crack is the total perimeter of the movable or ventilating sections. Frame leakage on steel windows may be neglected when they are properly grouted with cement mortar into brick work or concrete. When they are not properly sealed, the linear feet of sash section in contact with steel work at mullions should be figured at 25 percent of the values given in Table 2 for industrial pivoted windows.

When storm sash are applied to well fitted windows, some reduction in infiltration is secured; the application of the sash provides an air space which reduces the heat transmission and helps prevent the frosting of the windows.[a] By applying storm sash to poorly fitted windows, a reduction in leakage of 50 percent may be obtained, the effect, so far as air leakage is concerned, being roughly equivalent to that obtained by the installation of weatherstrips.

3D-7D: 3-D-16 inch shingles on 1 x 4 inch boards on 5 inch centers with paper, 7-D-16 inch shingles, shiplap and paper.

Fig. 1 .... Infiltration Through Various Types of Shingle Construction

Table 2 .... Infiltration Through Windows

Expressed in cubic feet per foot of crack per hour[a]

Type of Window	Remarks	Wind Velocity, Miles per Hour					
		5	10	15	20	25	30
Double-Hung Wood Sash Windows (Unlocked)	Around frame in masonry wall—not calked[b]	3	8	14	20	27	35
	Around frame in masonry wall—calked[b]	1	2	3	4	5	6
	Around frame in wood frame construction[b]	2	6	11	17	23	30
	Total for average window, non-weatherstripped, 1/16-in. crack and 3/64-in. clearance.[c] Includes wood frame leakage[d]	7	21	39	59	80	104
	Ditto, weatherstripped[d]	4	13	24	36	49	63
	Total for poorly fitted window, non-weatherstripped, 3/32-in. crack and 3/32-in. clearance.[c] Includes wood frame leakage[d]	27	69	111	154	199	249
	Ditto, weatherstripped[d]	6	19	34	51	71	92
Double-Hung Metal Windows[f]	Non-weatherstripped, locked	20	45	70	96	125	154
	Non-weatherstripped, unlocked	20	47	74	104	137	170
	Weatherstripped, unlocked	6	19	32	46	60	76
Rolled Section Steel Sash Windows[k]	Industrial pivoted, 1/16-in. crack[e]	52	108	176	244	304	372
	Architectural projected, 1/32-in. crack[h]	15	36	62	86	112	139
	Architectural projected, 3/64-in. crack[h]	20	52	88	116	152	182
	Residential casement, 1/64-in. crack[i]	6	18	33	47	60	74
	Residential casement, 1/32-in. crack[i]	14	32	52	76	100	128
	Heavy casement section, projected, 1/64-in. crack[j]	3	10	18	26	36	48
	Heavy casement section, projected, 1/32-in. crack[j]	8	24	38	54	72	92
Hollow Metal, Vertically Pivoted Window[f]		30	88	145	186	221	242

[a] The values given in this table, with the exception of those for double-hung and hollow metal windows are 20 percent less than test values to allow for building up of pressure in rooms, and are based on test data, reported in the papers listed in chapter footnotes.

[b] The values given for frame leakage are per foot of sash perimeter, as determined for double-hung wood windows. Some of the frame leakage in masonry walls originates in the brick wall itself, and cannot be prevented by calking. For the additional reason that calking is not done perfectly and deteriorates with time, it is considered advisable to choose the masonry frame leakage values for calked frames as the average determined by the calked and non-calked tests.

[c] The fit of the average double-hung wood window was determined as 1/16-in. crack and 3/64-in. clearance by measurements on approximately 600 windows under heating season conditions.

[d] The values given are the totals for the window opening per foot of sash perimeter, and include frame leakage and so-called *elsewhere leakage*. The frame leakage values included are for wood frame construction, but apply as well to masonry construction assuming a 50 percent efficiency of frame calking.

[e] A 1/32-in. crack and clearance represent a poorly fitted window, much poorer than average.

[f] Windows tested in place in building, so that no reduction from test values is necessary, as mentioned in footnote a.

[g] Industrial pivoted window generally used in industrial buildings. Ventilators horisontally pivoted at center or slightly above, lower part swinging out.

[h] Architecturally projected made of same sections as industrial pivoted, except that outside framing member is heavier, and it has refinements in weathering and hardware. Used in semi-monumental buildings such as schools. Ventilators swing in or out and are balanced on side arms. 1/32-in. crack is obtainable in the best practice of manufacture and installation, 3/64-in. crack considered to represent average practice.

[i] Of same design and section shapes as so-called *heavy section casement*, but of lighter weight. 1/64-in. crack is obtainable in the best practice of manufacture and installation, 1/32-in. crack considered to represent average practice.

[j] Made of heavy sections. Ventilators swing in or out and stay set at any degree of opening. 1/64-in. crack is obtainable in the best practice of manufacture and installation, 1/32-in. crack considered to represent average practice. Known as Intermediate Windows by steel window manufacturers.

[k] With reasonable care in installation, leakage at contacts where windows are attached to steel framework and at mullions, is negligible. With 1/64-in. crack, representing poor installation, leakage at contact with steel framework is about one third, and at mullions, about one-sixth of that given for industrial pivoted windows in the table.

Door Leakage

Doors vary greatly in fit because of their large size and tendency to warp. For a well fitted door, the leakage values for a poorly fitted double-hung wood window may be used. If poorly fitted, twice this figure should be used. If weatherstripped, the values may be reduced one-half. A single door that is frequently opened, as might be the case in a store, should have a value applied three times that for a well fitted door. This extra allowance is for opening and closing losses, and is kept from being greater by the fact that doors are not used as much in the coldest and windiest weather.

The infiltration rate through swinging and revolving doors is generally a matter of judgment by the engineer making *cooling* load determinations. In the absence of adequate research data, the values given in Table 3 may be used to represent current engineering practice. Some tests of infiltration through swinging and revolving doors have been reported.[a] The data in Table 3 are indicative of what might be expected in this connection, but it should be noted that Table 3 is based on a no-wind condition, and therefore is not directly applicable to *heating* design.

A wide range of infiltration rates would be expected for swinging doors because of variations in the indoor-outdoor pressure difference caused by wind, temperature differences, and the degree to which a heating or an air-conditioning

Table 3 .... Infiltration Through 72-Inch Revolving Door and 36-Inch Swinging Door[a, b]
(Cubic feet per person per passage)

Usage	Freely-Revolving Door	Door Equipped with Brake
Infrequent	75	60
Average	60	50
Heavy	40	40
36-Inch Swinging Door	20 to 100	

[a] These figures are based on the assumption that there is no wind pressure and that swinging doors are in use in one wall only. Any swinging doors in other walls should be kept closed to insure air conditioning in accordance with these recommended standards.

[b] From *Application Engineering Standards for Air Conditioning for Comfort* 1947, Air Conditioning & Refrigeration Institute Inc., Washington, D. C. and from experimental data of National Bureau of Standards. Used by permission.

system tended to raise or lower the inside pressure by blower action. The frequency of door usage would also affect the amount of leakage per passage.

Air Change Method

The amount of air leakage may be estimated by assuming a certain number of air changes per hour for each room, the number of changes assumed being dependent upon the type, use, and location of the room, as indicated in Table 4. Where it is not possible to determine or predetermine with accuracy the width of crack or clearance of windows, or when other sources of air leakage cannot readily be evaluated, as is often the case, the use of the air change method may be justified.[a]

The values in Table 4 may be used with reasonable accuracy for residences, and are the requirements for each room. The total infiltration allowance for the entire building should be one-half the sum of the infiltration allowances of the individual rooms, since whatever air enters on the windward side, generally leaves the building on the leeward side, and the infiltration requirements therefore do not exist simultaneously on all sides or in all rooms. An allowance of one air change per hour for all sources of air leakage for the entire volume may be considered average for a well constructed residence.

The air leakage, due to opening and closing of doors in vestibules, is sometimes based on the air change method, even though the air leakage estimates for other rooms are based on the crack method. Except for vestibules and reception halls, it is not advisable to attempt to apply the air change method to factories and industrial and commercial buildings, because of the wide variations in the type and percentage of fenestration which is the principal source of air leakage in such buildings.

INFILTRATION DUE TO TEMPERATURE DIFFERENCE

The air exchange due to temperature difference, indoor to outdoor, is a chimney effect, causing air to enter through openings at lower levels, and to leave at higher levels[a] when the building is heated or causing flow in the reverse direction when the building is cooled. This air exchange is usually of considerable importance in tall, single-story buildings with openings near the ground level and near the ceiling; it should also be considered in tall, multi-story buildings unless the sealing between various floors is nearly perfect; and may be appreciable in one-story buildings with basements and attics.

The flow of air through a building under the influence of indoor-outdoor temperature difference is quite complex except for single-story structures without a basement or attic. It can best be understood by visualizing the building as a complex chimney with a number of passages and a number of restrictions. The basement represents the lower section of this imaginary chimney with air moving inward through cracks in the walls and around windows and doors. The air then moves upward through cracks and openings in the floor which acts like a damper in the chimney. Above the floor the chimney has many parallel passages consisting of the several rooms and the hollow wall spaces in certain types of construction. These separate passages are all interconnected by cracks and also communicate with the outdoors through cracks and fissures. The ceiling acts as another damper with air flowing upward through various cracks and openings. This condition is repeated in every story of a multi-story building and can be further complicated by open stairways, elevator shafts, and utility ducts. The attic finally represents the union of all the parallel passages in the chimney with the outward flow of air being again restricted by the roof construction.

Since the chimney effect in a building produces a negative pressure and an inward flow of air at the lower levels and positive pressure and outward flow at the higher levels, a neutral zone[m] exists near midheight where there is no pressure difference between indoors and outdoors, if the openings are about uniformly distributed in a vertical direction. At the neutral zone there would be no air flow through openings in the outside walls as a result of temperature differences.

The infiltration caused by the indoor-outdoor temperature differences can be calculated by means of the crack method described earlier in this chapter for determining the infiltration caused by wind pressure. This is done by determining the equivalent wind velocity that would produce the same rate of infiltration as was caused by the prevailing temperature difference. It is recommended that one-half the total crack length of the building be used for this computation. To determine the infiltration caused by the temperature difference, one-half the crack length of the building is multiplied by the infiltration coefficient from Table 2

Table 4 .... Air Changes Taking Place under Average Conditions in Residences, Exclusive of Air Provided for Ventilation[a]

Kind of Room or Building	Number of Air Changes Taking Place per Hour
Rooms, 1 side exposed	1
Rooms, 2 sides exposed	1½
Rooms, 3 sides exposed	2
Rooms, 4 sides exposed	2
Rooms with no windows or outside doors	½ to ¾
Entrance Halls	2 to 3
Reception Halls	2
Bath Rooms	2

[a] For rooms with weatherstripped windows or storm sash, use ½ these values, where applicable, but never less than ½ air change.

corresponding to the equivalent wind velocity computed from the following equation developed from basic relationships between velocity, pressure, density, and temperature.

$$V_e = B\sqrt{h(t_i - t_o)} \qquad (1)$$

where

- V_e = equivalent wind velocity corresponding to the temperature difference $(t_i - t_o)$, miles per hour.
- h = height of rooms, feet.
- t_i = indoor temperature, Fahrenheit.
- t_o = outdoor temperature, Fahrenheit.
- B = a constant to account for leakage through floor and ceiling and for the number of stories in the building.

The constant B would be 0.12 for a single-story building or for any story of a multi-story building whose floor and ceiling were impervious to air, whereas the value of B has been found to be approximately unity for a single-story frame building with basement and attic having double wood flooring, plastered ceiling, and the walls finished with plasterboard on the inside. The value of this constant would increase as the number of stories increases and for stories farther removed from the neutral zone in either direction in buildings that lack perfect sealing between stories.

Sealing of Vertical Openings

In tall, multi-story buildings, every effort should be made to seal off vertical openings, such as stair-wells and elevator shafts, from the remainder of the building. Stair-wells should be equipped with self-closing doors, and, in exceptionally high buildings, should be closed off into sections of not over 10 floors each. Plaster cracks should be filled. Elevator enclosures should be tight, and solid doors should be used.

If the sealing of the vertical openings is made effective, no allowance need be made for the chimney effect. Instead, the greater wind movement at the greater heights makes it advisable to install additional heating surface on the upper floors above the level of neighboring buildings, this additional surface being increased as the height is increased. One arbitrary rule is to increase the heating surface on floors above neighboring buildings by an amount ranging from 5 percent to 20 percent. This extra heating surface is required only on the windward side and on windy days, and hence, automatic temperature control is especially desirable with such installations.

In stair-wells that are open through many floor levels, although closed off from the remainder of each floor by doors and partitions, the stratification of air makes it advisable to increase the amount of heating surface at the lower levels, and to decrease the amount at higher levels. One rule is to calculate the heating surface of the entire stair-well in the usual way, and to place 50 percent of this in the bottom third, the normal amount in the middle third, and the balance in the top third.

Infiltration and Air for Combustion

Infiltration in buildings normally supplies the air required for combustion by fuel-burning appliances, but in some cases weatherstripping, sealing, and calking may reduce infiltration to the point that special openings must be provided to supply adequate air to the heating appliances. This need for combustion air is recognized in various building codes. For instance, the State Building Construction Code of New York State for One- and Two-Family Dwellings[13] requires that an air inlet area not less than the area of the smoke pipe connection be provided if adequate air supply at all times is not assured. Similarly, the same code for multiple dwellings requires a permanent opening to the outdoor air for rooms containing fuel-burning appliances having a gross capacity in excess of 250,000 Btuh.

NATURAL VENTILATION

Ventilation by natural forces finds application in industrial plants, public buildings, schools, dwellings, garages, and in farm buildings.

The natural forces available for moving air into, through, and out of buildings are: (*a*) wind forces, and (*b*) the difference in temperature between the air inside and outside a building. The air movement may be caused by either of these forces acting alone, or by a combination of the two, depending upon atmospheric conditions, building design, and location. The ventilating results obtained will vary, from time to time, due to variation in the velocity and direction of the wind, and the temperature difference. The arrangement, location, and control of the ventilating openings should be such that the two forces act cooperatively rather than in opposition.

WIND FORCES

In considering the use of natural wind forces for producing ventilation, account must be taken of: (1) average wind velocity; (2) prevailing wind direction; (3) seasonal and daily variations in velocity and direction; and (4) local wind interference by nearby buildings, hills, or other obstructions of similar nature.

Values are given in Table 2, Chapter 13, for the average wind velocities for the months June to September in various localities throughout the United States, while Table 1, Chapter 12, lists similar values for the winter. In almost all localities, the summer wind velocities are lower than those in the winter, and in about two-thirds of the localities the prevailing direction is different during the summer and winter. While the tables give no average velocities below 5 mph, there will be times when the velocity is lower, even in localities where the seasonal average is considerably above 5 mph. There are relatively few places where the velocity falls below one-half of the average for many hours per month. Consequently, if the natural ventilating system is designed for wind velocities of one-half of the average seasonal velocity, it should prove satisfactory in almost every case.

Equation 3 may be used for calculating the quantity of air forced through ventilation openings by the wind, or for determining the proper size of such openings to produce given results:

$$Q = EAV \qquad (3)$$

where

- Q = air flow, cubic feet per minute.
- A = free area of inlet openings, square feet.
- V = wind velocity, feet per minute, = miles per hour × 88.
- E = effectiveness of openings. (E should be taken at 0.50 to 0.60 for perpendicular winds, and 0.25 to 0.35 for diagonal winds.)[12]

The precision of results obtained by the use of Equation 3, depends upon the placing of the openings, as the formula assumes that ventilating openings have a flow coefficient

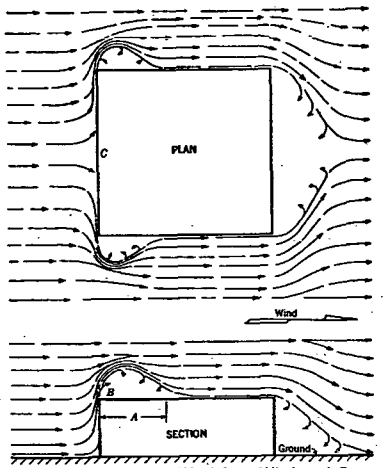


Fig. 2 .... The Jump of Wind from Windward Face of Building. (A—Length of Suction Area; B—Point of Maximum Intensity of Suction; C—Point of Maximum Pressure)

slightly greater than that of a square-edged orifice. If the openings are not advantageously placed with respect to the wind, the flow per unit area of the openings will be less and, if unusually well placed, the flow will be slightly more than that given by the formula. Inlets should be placed to face directly into the prevailing wind, while outlets should be placed in one of the five places listed:

1. On the side of the building directly opposite the direction of the prevailing wind.
2. On the roof in the low pressure area caused by the jump of the wind (see Fig. 2).
3. On the sides adjacent to the windward face where low pressure areas occur.
4. In a monitor on the side opposite from the wind.
5. In roof ventilators or stacks.

TEMPERATURE DIFFERENCE FORCES[10]

The stack effect produced within a building, when the outdoor temperature is lower than the indoor temperature, is due to the difference in weight of the warm column of air within the building and cooler air outdoors. The flow due to stack effect is proportional to the square root of the draft head, or approximately

$$Q = 9.4A\sqrt{h(t_i - t_o)} \qquad (4)$$

where

Q = air flow, cubic feet per minute.
A = free area of inlets or outlets (assumed equal), square feet.
h = height from inlets to outlets, feet.
t_i = *average* temperature of indoor air in height h, Fahrenheit.
t_o = temperature of outdoor air, Fahrenheit.
9.4 = constant of proportionality, including a value of 65 percent for effectiveness of openings. This should be reduced to 50 percent (constant = 7.2) if conditions are not favorable.

HEAT REMOVAL

In problems of heat removal, knowing the amount of heat to be removed and having selected a desirable temperature difference, the amount of air to be passed through the building per minute, to maintain this temperature difference, can be determined by means of Equation 5.

$$Q = \frac{H}{C_p \times \rho \times 60(t_i - t_o)} = \frac{H}{1.08(t_i - t_o)} \qquad (5)$$

where

Q = air removed, cubic feet per minute.
H = heat removed, Btu per hour.
C_p = specific heat of air at constant pressure, 0.24.
ρ = density of standard air, 0.075 pounds per cubic foot.
$t_i - t_o$ = indoor-outdoor temperature differences, Fahrenheit.

EFFECT OF UNEQUAL OPENINGS

The largest flow per unit area of openings is obtained when inlets and outlets are equal, and the preceding equations are based on this condition. Increasing outlets over inlets, or vice-versa, will increase the air flow, but not in proportion to the added area. When solving problems having an unequal distribution of openings, use the smaller area, either inlet or outlet, in the equations, and add the increase as determined from Fig. 3.

COMBINED FORCES OF WIND AND TEMPERATURE

Equations have already been given for determining the air flow due to temperature difference and wind. It must be remembered that when both forces are acting together, even without interference, the resulting air flow is not equal to the sum of the two estimated quantities. The flow

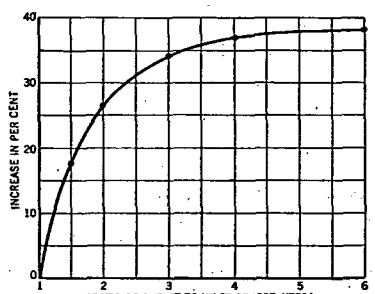

Fig. 3 .... Increase in Flow Caused by Excess of One Opening Over Another

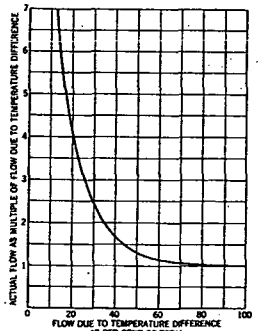

Fig. 4 .... Determination of Flow Caused by Combined Forces of Wind and Temperature Difference

through any opening is proportional to the square root of the sum of the heads acting on that opening.

When the two heads are about equal in value, and the ventilating openings are operated so as to coordinate them, the total air flow through the building is about 10 percent greater than that produced by either head acting independently under conditions ideal to it. This percentage decreases rapidly as one head increases over the other. The effect of the larger head will predominate.

The wind velocity and direction, the outdoor temperature, or the indoor distribution, cannot be predicted with certainty, and refinement in calculations is not justified; consequently, a simplified method can be used. This may be done by using the equations and calculating the flows produced by each force separately, under conditions of openings best suited for coordination of the forces. Then, by determining the ratio of the flow produced by temperature difference to the sum of the two flows, the actual flow due to the combined forces can be approximated from Fig. 4.

Example 1: Assume a drop forge shop, 200 ft long, 100 ft wide, and 30 ft high. The cubical content is 600,000 cu ft, and the height of the air outlet over that of the inlet is 30 ft. Oil fuel of 18,000 Btu per lb is used in this shop at the rate of 15 gph (7.75 lb per gal). Desired summer temperature difference is 10 deg, and the prevailing wind is 8 mph perpendicular to the long dimension. What is the necessary area for the inlets and outlets, and what is the rate of air flow through the building?

Solution for Temperature Difference Only: The heat $H = 15 \times 7.75 \times 18{,}000 = 2{,}092{,}500$ Btu per hr.

By Equation 5, the air flow required to remove this heat with an average temperature difference of 10 deg is

$$Q = \frac{H}{1.08(t_i - t_o)} = \frac{2{,}092{,}500}{1.08 \times 10} = 193{,}750 \text{ cfm.}$$

This is equal to about 20 air changes per hour. From Equation 4, the inlet (or outlet) opening area should be

$$A = \frac{Q}{9.4\sqrt{h(t_i - t_o)}} = \frac{193{,}750}{9.4\sqrt{30 \times 10}} = 1190 \text{ sq ft}$$

The flow per square foot of inlet or outlet would be $193{,}750 \div 1190 = 162.5$ cfm, with all windows open.

Solution for Wind Only: With 1,190 sq ft of inlet openings distributed around the side walls, there will be about 400 sq ft in each long side and 195 sq ft in each end. The outlet area will be equally distributed on the two sides of the monitor, or 595 sq ft on each side. With the wind perpendicular to the long side, there will be 400 sq ft of opening in its path for inflow, and 595 in the lee side of the monitor for outflow with the windward side closed. The air flow, as calculated by Equation 3, will be:

$$Q = 0.60 \times 400 \times 704 = 168{,}960 \text{ cfm.}$$

This gives 16.9 air changes per hour, which should be more than ample when there is no heat to be removed.

Solution for Combined Heads: Since the windward side of the monitor is closed when the wind is blowing, the flow due to temperature difference must be calculated for this condition, using Fig. 3. This chart shows that, when inlets are twice the size of the outlets, in this case 1,190 sq ft in the side walls and 595 sq ft in the monitor, the flow will be increased 26.5 percent over that produced by equal openings. Using the smaller opening and the flow per square foot obtained previously, the calculated amount for this condition will be

$$595 \times 163 \times 1.265 = 122{,}700 \text{ cfm.}$$

Adding the two computed flows:

Temperature Difference	= 122,700	= 42	percent.
Wind	= 168,960	= 58	percent.
Total	291,660	= 100	percent.

From Fig. 4 it is determined that, when the flow due to temperature difference is 42 percent of the total, the actual flow due to the combined forces will be about 1.6 times that calculated for temperature difference alone, or 196,300 cfm.

The original flow due to temperature difference alone was 193,750 cfm with all openings in use. The effect of the wind is to increase this to 196,300 cfm, even though half of the outlets are closed.

A factor of judgment is necessary in the location of the openings in a building, especially those in the roof, where heat, smoke, and fumes are to be removed. Usually, windward monitor openings should be closed, but if the wind is low enough for the temperature head to overcome it, all windows may be opened.

TYPES OF OPENINGS

Types of openings may be classified as: (1) windows, doors, monitor openings, and skylights; (2) roof ventilators; (3) stacks connecting to registers; and (4) specially designed inlet or outlet openings. The various types and principles of operation are discussed in following paragraphs.

Windows, Doors, and Skylights

Windows have the advantage of transmitting light, as well as providing ventilating area, when open. Their movable parts are arranged to open in various ways; they may open by sliding either vertically or horizontally, by tilting on horizontal pivots at or near the center, or by swinging on pivots at the top, bottom, or side. Regardless of their design, the air flow per square foot of opening may be considered to be the same under the same conditions. The type of pivoting should receive consideration from the standpoint of weather protection, and certain types may be advantageous in controlling the distribution of incoming air. Deflectors are sometimes used for the same purpose and should be considered a part of the ventilation system.

Roof Ventilators

The function of a roof ventilator is to provide a storm and weatherproof air outlet. They are actuated by the same

forces of wind and temperature head that create flow through other types of openings. The capacity of a ventilator depends upon four things: (1) its location on the roof; (2) the resistance it and the ductwork offer to air flow; (3) the height of draft; and (4) the efficiency of the ventilator in utilizing the kinetic energy of the wind for inducing flow by centrifugal or ejector action.

For maximum flow induction, a ventilator should be located on that part of the roof where it will receive the full wind without interference. If ventilators are installed within the suction region created by the wind passing over the building, or in a light court, or on a low building between two high buildings, their performance will be seriously influenced. Their normal ejector action, if any, may be completely lost.

The base of the ventilator should be of a taper-cone design to produce the effect of a bell-mouth nozzle whose coefficient of flow is considerably higher than that of a square-entrance orifice. If a grille is provided at the base, or if the base or structural members present obstructions, additional resistance is introduced, and the base opening should be increased in size accordingly.

Air inlet openings located at lower levels in the building, should be at least equal to, and preferably larger than, the combined throat areas of all roof ventilators. The air discharge by a roof ventilator depends on wind velocity and temperature difference, and, in general, its performance will be the same as any monitor opening located in the same place but, due to the four capacity factors already mentioned, no simple formula can be devised for expressing ventilator capacity.

Roof ventilators may be classified as stationary, pivoting, or oscillating, and rotating. Generally, these have a round throat, but the continuous-ridge ventilator would fall in the stationary classification. When selecting roof ventilators, some attention should be given to ruggedness of construction, storm-proofing features, dampers and damper-operating mechanisms, possibility of noise, original cost, and maintenance.

Natural ventilation units may be used to supplement power-driven supply fans, and under favorable weather conditions it may be possible to stop the power-driven units. Units are not subject to code tests for ratings. Generally, they must be selected from manufacturers' tables. It is, therefore, very important to consider the reliability of the ratings used.

Controls

Gravity ventilators may have dampers controlled by hand, thermostat, or wind velocity, in combination with a fan. The thermostat station may be located anywhere in the building, or it may be located within the ventilator itself. The purpose of wind velocity control is to obtain a definite volume of exhaust regardless of the natural forces, the fan motor being energized when the natural exhaust capacity falls below a certain minimum, and again shut off when the wind velocity rises to the point where this minimum volume can be supplied by natural forces.

Stacks

Stacks or vertical flues are really chimneys which function through the effects of the wind and temperature difference. Like the roof ventilator, the stack outlet should be located so that the wind may act upon it from any direction. With little or no wind, the chimney effect depends entirely on temperature difference to produce a removal of air from the rooms where the inlet openings are located.

GENERAL VENTILATION RULES

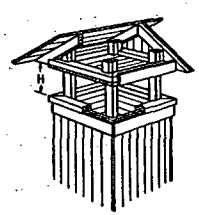
A few of the important considerations, in addition to those already outlined, are:

1. Inlet openings in the building should be well distributed, and should be located on the windward side near the bottom, while outlet openings are located on the leeward side near the top. Outdoor air will then be supplied to the zone to be ventilated.

2. Inlet openings should not be obstructed by buildings, trees, sign boards, etc., outdoors, nor by partitions indoors.

3. Greatest flow per square foot of total opening is obtained by using inlet and outlet openings of nearly equal areas.

4. In the design of window ventilated buildings, where the direction of the wind is quite constant and dependable, the orientation of the building, together with amount and grouping of ventilation openings, can be readily arranged to take full advantage of the force of the wind. Where the wind's direction is quite variable, the openings should be arranged in side walls and monitors so that, as far as possible, there will be approximately equal areas on all sides. Thus, no matter what the wind's direction, there will always be some openings directly exposed to the pressure force, and others to a suction force, and effective movement through the building will be assured.



5. Direct short circuits between openings on two sides at a high level may clear the air at that level without producing any appreciable ventilation at the level of occupancy.

6. In order that temperature difference may produce a motive force, there must be vertical distance between openings. That is, if there are a number of openings available in a building, but all are at the same level, there will be no motive head produced by temperature difference, no matter how great the difference might be.

7. In order that the force of temperature difference may operate to maximum advantage, the vertical distance between inlet and outlet openings should be as great as possible. Openings in the vicinity of the neutral zone are least effective for ventilation.

8. In the use of monitors, windows on the windward side should usually be kept closed, since, if they are open, the inflow tendency of the wind counteracts the outflow tendency of temperature difference. Openings on the leeward side of the monitor result in cooperation of wind and temperature difference.

9. In an industrial building where furnaces that give off heat and fumes are to be installed, it is better to locate them in the end of the building exposed to the prevailing wind. The strong suction effect of the wind at the roof near the windward end will then cooperate with temperature difference,

The opening H should equal one-half the least dimension of the flue. Heavy insulation of the level deck is essential.

Fig. 5 . . . . Recommended Type of Cover for Wooden Outlet Flue

to provide for the most active and satisfactory removal of the heat and gas-laden air.

10. In case it is impossible to locate furnaces in the windward end, that part of the building in which they are to be located should be built higher than the rest, so that the wind, in splashing therefrom, will create a suction. The additional height also increases the effect of temperature difference to cooperate with the wind.

11. The intensity of suction, or the vacuum produced by the jump of the wind, is greatest just back of the building face. The area of suction does not vary with the wind velocity, but the flow due to suction is directly proportional to wind velocity.

12. Openings much larger than the calculated areas are sometimes desirable, especially when an increase in occupancy may occur, or when extremely hot days may be anticipated. In the former case, free openings should be located at the level of occupancy for psychological reasons.

13. In single story industrial buildings, particularly those covering large areas, natural ventilation must be accomplished by taking air in and out of the roof openings. Openings in the pressure zones can be used for inflow, and openings in the suction zone, or openings in zones of less pressure, can be used for outflow. The ventilation is accomplished by the manipulation of openings to get air flow through the zones to be ventilated.

VENTILATION OF ANIMAL SHELTERS[12]

Animal shelters require ventilation to remove moisture, odors and, in the case of dairy stables, excess heat.

Outlets. Outlet flues for natural draft systems should be round or approximately square. A thermal resistance ($1/U$) of not less than two is required in their side walls. They should extend at least two feet above the highest part of the roof. Only one outlet is recommended for each room or pen. The use of several outlet flues may result in excessive up-drafts in some flues, and down-drafts in others.

If flues have roofs or covers, these should be high enough to provide unobstructed openings on all sides, equal in height to one-half the least dimension of the flue, Fig. 5. A level, heavily insulated ceiling under the flue roof, and over the entire area of the flue, is important.

Inlets. Inlets should direct the incoming air vertically upward so as to avoid drafts on the animals, and to insure immediate mixing of incoming air with the room air. A reasonably uniform distribution around the stable or pen is desirable. Inlet flues, that deliver air close to the side walls, stimulate convection currents, which is desirable. When so placed, they also tend to bathe the side walls with cool air, thus reducing temperature difference between the inside and outside of the wall.

From the standpoint of air movement, insulation of inlet flues is not important. Condensation is, however, likely to occur on them, unless the thermal resistance of their walls is at least two.

Controls or throttling devices in inlet flues are seldom required. If used, they are best applied to the inlets and limited to the side of the building facing prevailing winter winds. They should be so made that an opening, at least one inch wide by the width of the flue, will always remain open.

Amounts of heat and water produced by livestock vary not only with the different kinds of animals, but also with age, weight, feed consumption, and production. These facts, and the vagaries of the weather, make exact calculations impossible. The following practical recommendations are based on numerous, carefully checked observations.

It is desirable to keep the relative humidity of livestock shelters below 85 percent. Temperatures may be as indicated in the discussion for each kind of animal.

Dairy Stables

The most commonly accepted temperatures for dairy stables, where cows are confined in stanchions or tie stalls, are from 45 to 55 F. These temperatures are readily maintained in winter weather by the body heat of the herd in well constructed, well stocked, and well ventilated stables. Stable volume in excess of 600 cu ft, and exposed wall area in excess of 130 sq ft per 1000 lb animal weight are, in general, undesirable.

Side walls should have an overall thermal resistance of from 2 to 5, depending on the temperature zone and wind exposure. Thermal resistance of the ceiling should be 50 percent greater than that of the side walls. In stables of this size and so insulated, a ventilation rate of 3200 to 3800 cfh per (1000 lb of animal) usually insures good conditions.

The following recommendations do not apply to so-called pen stables or loafing barns in which there is a thick manure and bedding pack on the floor, and in which doors are normally kept open.

Outlets. One flue will serve a stable 200 ft long. In stables over 120 ft long, the flue should be about midway between the ends or, if the stable is L-shaped, near the angle. In shorter stables, it may be at any convenient location.

The exhaust point in the stable should be not more than 18 in. above the floor. This permits removal of only the coolest air, and prevents rapid fluctuations in stable temperature.

A basic rule for finding the cross-section of the outlet flue is

$$A_o = \frac{176N}{\sqrt{h}} \qquad (6)$$

where

A_o = area of the outlet flue, square inches.
N = weight of animal population, thousands of pounds.
h = vertical distance from top of inlet flues to top of outlet flue, feet.

For large flues the flue area obtained from the basic formula may well be reduced according to the chart, Fig. 6, because of a decrease in friction.

Example 2: Assume a stable in which the vertical height from the top of the inlets to the top of the outlet flue is 32.5 ft, and in which 38 cows, averaging 1300 lb, will be housed. Determine required size of outlet flue.

Solution: From Equation 6

$$A_o = \frac{176 \times (38 \times 1.300)}{\sqrt{32.5}} = 1525 \text{ sq. in.}$$

From Fig. 6 the factor to be applied to this area is 94.5

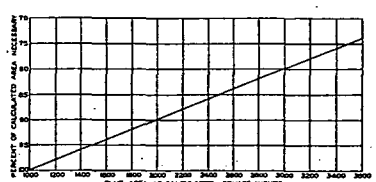


Fig. 6 . . . . Modification of Flue Area for Outlets Exceeding 1000 Sq In.

percent. Therefore, the area of flue required is 1525 × 0.945 = 1441 sq in.

Inlets. Inlet flues, each approximately 60 sq in. in area, have given good results. One such flue should be provided for each 3500 lb animal weight. They should deliver air from points 12 to 18 in. below the ceiling.

Sheep Barns

Shelters used for breeding and feeding stock usually have enough openings, so that no special provision for ventilation is required. Barns for winter lambing flocks, however, require ventilation systems. Fermentation in the floor pack of manure produces heat, vapor, and odor. These must be added to the ventilation load regularly produced by the animals.

Outlets. In practice, results obtained by the basic formula, Equation 7, when modified by the use of the chart, Fig. 6, have given good results:

$$A_o = \frac{4A_f}{\sqrt{h}} \quad (7)$$

where

A_o = area of the outlet, square inches.
A_f = floor area, square feet.
h = vertical height from top of inlet openings to top of outlet flue, feet.

The bottom of the outlet flue should be 15 to 24 in. above the surface of the manure pack.

Inlets. Provide one inlet, 60 sq in. in area, for each 150 sq ft of floor area. Inlets should be well distributed around the side walls, and designed to deliver air near the ceiling (see section on Dairy Stables).

Swine Barns

Community swine barns, because of the extent of slop feeding and the absence of daily cleaning of the pens, are the most difficult farm buildings to ventilate satisfactorily. Farrowing pens, to which supplemental heat is supplied, present less of a problem. In all cases, good floor drainage to remove urine and excess spilled water is important.

Temperatures of from 50 to 55 F are usually recommended for farrowing pens. It is desirable to maintain temperatures above freezing in all other pens in community houses. For barns that are well stocked and adequately ventilated, this requires walls with an overall thermal resistance of from 3 to 6, and ceilings with 40 to 50 percent greater resistance.

Outlets. The outlet flue should draw air from a level of 15 to 18 in. above the floor. Equation 8 is the basic formula for flue area, and gives reasonably good results when modified according to the chart, Fig. 6.

$$A_o = \frac{5 \times A_f}{\sqrt{h}} \quad (8)$$

Inlets. At least one inlet flue should be used for each pen. Swine are given or select definite nesting places, and care must be exercised to avoid having inlets located over them.

Total inlet area should be approximately 70 percent of outlet area. The area of individual inlets is best determined from the total area required, and the number that can be so installed as to meet previous specifications. Inlets should deliver air from points 12 to 15 in. below the ceiling, or from a level deflector on a sloping ceiling.

Poultry Laying Houses

From the standpoint of ventilation, poultry laying houses may be divided into cold houses and warm houses. The former are uninsulated, except in the ceiling. The indoor-outdoor temperature difference is seldom more that 5 F deg. In the warm house, because of insulation or supplemental heat, the temperature seldom falls below 32 F, and is usually above 45 F.

Outlets. The outlet flue is best placed near the middle of the pen. It is advisable to limit the length of pens to 80 ft.

The area of the outlet flue may be determined from Equation 9, and modified according to the chart, Fig. 6.

$$A_o = \frac{2.5 \times A_f}{\sqrt{h}} \quad (9)$$

For a cold house, the bottom of the flue should be at the level of the insulated ceiling. In warm houses, the bottom of the flue should be 12 to 15 in. above the level of the floor litter.

Inlets. Inlets may be approximately 60 sq in. in area. The total inlet area may be equal to 70 percent of the outlet area. Inlets in cold and in warm houses should deliver air from points 12 to 24 in. above the floor. In cold houses which normally do not have storm sash, windows may be raised enough to give the desired area, and be fitted with baffle boards to direct the air straight and upward.

In houses less than 20 ft in width, all inlets may be on one side. In wider houses, a rather uniform distribution of inlets is essential.

GARAGE VENTILATION

Because of hazards resulting from carbon monoxide and other physiologically harmful or combustible gases or vapors in garages, the importance of proper ventilation of these buildings cannot be over-emphasized. During the warm months of the year, garages are usually ventilated adequately because the doors and windows are kept open. The ASHAE Code of Minimum Requirements for Heating and Ventilating Garages,[14] adopted in 1935, specifies that openings for natural ventilation shall be distributed as uniformly as possible in at least two outside walls, and that the total area of such openings shall be equivalent to at least 5 percent of the floor area. The code further states that where it is impracticable to operate such a system of natural ventilation, a mechanical system shall be used, and shall provide for either the supply of 1 cfm of outdoor air for each square foot of floor area, or for exhaust of the same amount of air, discharging it to the outdoors as a means of flushing the garage.

Cooperative research[15] on garage ventilation, undertaken by the ASHAE Committee on Research at Washington University, St. Louis, Mo., and at the University of Kansas, and tests conducted at the ASHAE Research Laboratory, have resulted in authoritative papers on the subject.

Some of the conclusions based on work at these laboratories are:

1. Upward ventilation results in a lower concentration of carbon monoxide at the breathing line and a lower temperature above the breathing line, than does downward ventilation for the same rate of carbon monoxide production, air change, and the same temperature at the 30-in. level.

2. A lower rate of air change and a smaller heating load are required with upward than with downward ventilation.

3. In the average case, upward ventilation results in a lower concentration of carbon monoxide in the occupied portion of a garage, than that obtained with mixing of the exhaust gases and the air supplied. However, the variations in concentration from point to point, together with the possible failure of the advantages of upward ventilation to accrue, suggest the basing of garage ventilation on complete mixing, and an air change sufficient to dilute the exhaust gases to the allowable concentration of carbon monoxide.

4. The rate of carbon monoxide production by an idling car is shown to vary from 25 to 50 cfh, with an average rate of 35 cfh.

5. An air change of 350,000 cfh per idling car is required to keep the carbon monoxide concentration down to one part in 10,000 parts of air.

Individual Exhaust Ducts

Motor vehicle servicing areas may be provided with underground or overhead exhaust systems discharging outdoors. Each service location should be provided with a flexible branch duct, the inlet end of which is sized to slip over the tail pipe of the engine, or over any deflector attached to the tail pipe. The minimum branch size and ventilation rate for the largest class of vehicle regularly serviced at each location are shown in Table 5.

Table 5 .... Minimum Tail Pipe Connection Size and Ventilation Rate per Vehicle

Vehicle	Ventilation Rate, cfm	Flexible Pipe, Dia, in.	Diameter of Rigid Branch Connection to Flexible Pipe, in.
Auto up to 200 hp.....	100	3	4
Auto or truck above 200 hp.....	200	4	4½
Diesel truck or bus	400	4½	5½

Where each tail pipe exhaust branch is provided with an automatic device to close the branch inlet when it is not in use, the capacity of the fan for the system should be based on the maximum number of branches in simultaneous use. Where the branch inlets are open when not in use, the system capacity should be based on the total number of branches connected to the main.

Individual straight lengths of gas tight duct, not over 20 ft in length, terminating outdoors, may be provided where exhaust systems are not installed. The duct should fit tightly over the tail pipe and be of a diameter not less than the diameter of the tail pipe.

CHAPTER 12

HEATING LOAD

General Procedure, Design Outdoor Weather Conditions, Indoor Temperatures, Attic Temperatures, Temperatures in Unheated Spaces, Ground Temperatures, Basement Temperatures and Heat Loss, Heat Losses from Floor Slabs, Transmission Heat Loss, Infiltration Heat Loss, Selection of Wind Speeds, Auxiliary Heat Sources, Intermittently Heated Buildings, Residence Heat Loss Problems

PRIOR to designing a heating system, an estimate must be made of the maximum probable heat loss of each room or space to be heated, based on maintaining a selected indoor air temperature during periods of design outdoor weather conditions. The heat losses may be divided into two groups, namely: (1) the transmission losses or heat transmitted through the confining walls, floor, ceiling, glass, or other surfaces; and (2) the infiltration losses or heat required to warm outdoor air which leaks in through cracks and crevices, around doors and windows, or through open doors and windows, or heat required to warm outdoor air used for ventilation.

GENERAL PROCEDURE

The general procedure for calculating heat losses of a structure is:

1. Select the design outdoor weather conditions: temperature, wind direction, and wind speed. The data on climatic conditions given in Tables 1 and 2 will be helpful, but should be used with judgment as suggested in the section Design Outdoor Weather Conditions.

2. Select the indoor air temperature that is to be maintained in each room during the coldest weather. (See Table 3.)

3. Estimate temperatures in adjacent unheated spaces and the attic. (See section Attic Temperatures.) The attic temperature need not be estimated if the combined roof and ceiling coefficient is used.

4. Select or compute the heat transmission coefficients for outside walls and glass; also for inside walls, floors, or top-floor ceilings, if these are next to unheated space; include roof if next to heated space. (See Chapter 9. If the design wind speed is appreciably different from 15 mph, the appropriate change in the heat transmission coefficients in Tables 5 to 15 of Chapter 9 can be found in Table 20 of that chapter.)

5. Determine net area of outside wall, glass, and roof next to heated spaces, as well as any cold walls, floors, or ceilings next to unheated space. Such measurements are made from building plans, or from the actual building, using inside dimensions.

6. Compute the heat transmission losses for each kind of wall, glass, floor, ceiling, and roof in the building by multiplying the heat transmission coefficient in each case by the area of the surface in square feet, and the temperature difference between the indoor and outdoor air. (See Items 1, 2, and 3.)

7. Select unit values and compute the heat equivalent of the infiltration of cold air taking place around outside doors and windows. These unit values depend on the kind or width of crack, wind speed, and the temperature difference between the indoor and outdoor air; the result expresses the heat required to warm up the cold air leaking into the building per hour. (See Chapter 11.)

8. When positive ventilation using outdoor air is provided by an air heating or an air-conditioning unit, the heat required to warm the outdoor air to room temperature must be provided by the unit; if mechanical exhaust from the room is provided, in amount equal to the outdoor air drawn in by the unit, the natural infiltration losses must also be provided for by the unit. If no mechanical exhaust is used, and the outdoor air supply equals or exceeds the amount of natural infiltration that would occur without ventilation, the natural infiltration may be neglected.

9. The sum of the heat losses due to transmission (Item 6) through the outside walls and glass, as well as through any cold floors, ceilings, or roof, plus the heat equivalent (Item 7) of the cold air entering by infiltration, or required to replace mechanical exhaust, represents the total heat loss equivalent for any building.

10. In buildings that have a reasonably steady internal heat release of appreciable magnitude from sources other than the heating system, a computation of this heat release under design conditions should be made for deduction from the total of the heat losses computed in items 1–9. This is especially important for heating systems of high initial cost or those for which a demand charge is based on installed capacity.

DESIGN OUTDOOR WEATHER CONDITIONS

The ideal solution to the basic problem which confronts the designer of a heating system is to design a plant that has a capacity at maximum output just equal to the heating load which develops when the most severe weather conditions for the locality occur.

In most cases, economics interferes with the attainment of this ideal. Studies of weather records show that the most severe weather conditions do not repeat themselves every year. If heating systems were designed with adequate capacity for the maximum weather conditions on record, there would be considerable excess capacity during most of the operating life of the system.

The weather records of principal cities of the United States have been analyzed to determine the probability of occurrence of certain low temperatures. The results of this analysis appear in Table 1. Data for Canadian cities obtained by a different analytical method appear in Table 2.

Five probabilities of outdoor temperatures are offered for American cities and four for Canadian cities. The analytical methods used for determining the several design temperatures cited in Table 1 for U. S. and Table 2 for Canadian cities are described in the footnotes of the tables.

In many cases, occasional failure of a heating plant to maintain a pre-selected indoor design temperature during brief periods of severe weather is not critical. However, the successful completion of some industrial or commercial processes may depend upon close regulation of indoor temperatures. These are special cases and require extra study before assigning design temperatures.

Before selecting an outdoor design temperature from

Notes for Table 1

[a] Data compiled from U. S. Weather Bureau records by H. C. S. Thom.
[b] Col. 2. The stations followed by letter A are airport stations; all others are city office stations and are followed by the letter C.
[c] Col. 3. Elevations marked c are ground elevations at stations. All other elevations given are the actual elevations of the thermometer bulb above mean sea level.
[d] Wind speeds are from U. S. Weather Bureau records for the period ending February 1948.
[e] The winter design temperatures shown in Columns 4–8 inclusive for U. S. cities are minimum average daily temperatures that will recur with a probable frequency of once in the number of years shown at the head of the column based on the U. S. Weather Bureau records for the 30-year period between 1921 and 1950. For example, the temperatures in Column 6 will recur once every 13 years as minimum average daily values, the temperatures in Column 7, once every 10 years, etc.

Tables 1 or 2, a heating engineer should consider each of the following factors:

1. Is heat capacity of structure high or low?
2. Is structure insulated?
3. Is structure exposed to high wind?
4. Is the ventilation or infiltration load high?
5. Is there more glass area than normal in the structure?
6. During what part of the day will it be used?
7. What is the nature of occupancy?
8. Will there be long periods of operation at reduced indoor temperature?
9. What is the amplitude between maximum and minimum daily temperature in the locality?
10. Are there local conditions which cause significant variation from temperatures reported by Weather Bureau?
11. What auxiliary heating devices will there be in the building?
12. What is the expected cost of fuel or energy?

For the usual structure under typical conditions the ASHAE Technical Advisory Committee on Heating and Air Conditioning Loads recommends that the design temperatures in Column 6 be used for U. S. cities. The U. S. Weather Bureau data show that an average daily temperature lower than that shown in Column 6 will occur with a probability of once in 13 years.

If a careful study of preceding factors 1 to 12 shows that the indoor temperature of the structure in question will respond more quickly than normal to extreme outdoor temperatures that persist for less than twelve hours, then design temperatures from Columns 7 or 8 may be used. On the other hand, if the structure is less responsive than normal to changes in outdoor temperature, outdoor design temperatures from Columns 5 or 4 may be selected.

The designer must keep in mind, before reaching a final

Notes for Table 2 . . . . Winter Climatic Conditions[a]—Canada

[a] Data compiled from the *Climatological Atlas of Canada* for the years indicated.

[b] Col. 2. The stations followed by letter A are airport stations; all others are city office stations and are followed by letter C.

[c] Col. 3. The elevations listed are ground elevations of the station.

[d] Col. 4. The periods of record indicated apply only to the lowest temperature ever recorded shown in Col. 5, and generally extend from a summer month of the first year indicated through the spring months of the last year indicated.

[e] Average of readings of one lowest temperature obtained for each year for period of record. For Canada, in some cases, more than one location have been used.

[f] Most of the wind speeds are based on periods ending in 1947 which are somewhat shorter than the periods for the minimum temperatures. The three months, December, January, and February were used.

[g] The winter design temperatures shown in columns 7-10 inclusive for Canadian cities are the Fahrenheit temperature values at or below which 1, 2½, 5, and 10 percent, respectively, of the January hourly outdoor temperatures occur for the 10 years from 1941 to 1950. The tabulated values are based on hourly temperature observations for some of the cities and upon the difference between the mean monthly temperature and the design temperature for the remainder of the cities listed.

decision on outdoor design temperature, that if the indoor-outdoor design temperature difference is exceeded, the indoor temperature will fall. The question is to determine how large a drop will occur and whether it can be tolerated.

Finally, there is a factor, perhaps intangible, that should not be ignored. It is the performance expected by the owner from the system. In order to judge whether expected performance can be assured the designer needs a full understanding of the basis on which the capacities of all the system components are derived or determined, the limits of accuracy of published performance data, and the accelerating capability of certain types of equipment. There is no substitute for engineering judgment in problems of this type. Judgment is developed from experience and continued study.

Canadian Winter Design Temperatures

Canadian winter design temperatures are based on temperature frequencies and show the percentage of time that the temperature might be expected to fall below certain values. Since January is normally the coldest month of the winter in most of Canada, and to simplify the analysis and understanding, these values are based on January data only.[a] In using these values to calculate the heat loss of a building, the engineer is thus designing for the coldest month of the year.

Winter design temperature on a 2½ percent basis is the temperature value expressed in degrees Fahrenheit at or below which 2½ percent of the January outdoor temperatures occur. It is suggested that this 2½ percent basis value be normally used in Canada. However, the engineer has the opportunity of selecting the 5 or 10 percent basis value if it is not so important that the pre-selected indoor design temperature be maintained, or on the other hand the 1 percent basis value if cost is not as important as the maintenance of indoor temperatures.

INDOOR TEMPERATURES

The indoor air temperature that must be maintained within a building is understood to be the dry-bulb temperature at the breathing line, 5 ft. above the floor, or at the seating level, 30 in. above the floor, and not less than 3 ft from the outside walls. Indoor air temperatures usually specified, vary in accordance with the intended use of the building. Table 3 presents values that conform to good practice.

The proper dry-bulb temperature to be maintained depends upon the relative humidity and air motion, as explained in Chapter 6. In other words, a person may feel warm or cool at the same dry-bulb temperature, depending on the relative humidity and air motion. The optimum winter

[a] The most comfortable dry-bulb temperature to be maintained depends on the relative humidity and air motion. These three factors considered together constitute what is termed the *effective temperature*. (See Chapter 6.) When relative humidity is not controlled separately, optimum dry-bulb temperature for comfort will be slightly higher than shown in Table 3.

effective temperature for sedentary persons, as determined at the ASHAE Research Laboratory, is 67–68 ET.

As explained in Chapter 6 for so-called still air conditions, a relative humidity of approximately 50 percent is required to produce an effective temperature of 68 ET when the dry-bulb temperature is 72.5 F. However, even where provision is made for artificial humidification, the relative humidity is seldom maintained higher than 40 percent during the extremely cold weather, and where no provision is made for humidification, the relative humidity may be 20 percent or less. Consequently, in using the values listed in Table 3, consideration should be given to the actual relative humidity to be maintained, if provision is to be made for humidification. If no humidification is to be provided, the higher temperatures may not even produce comfort on cold days; if humidity is to be maintained at 50 percent, the lower temperatures will apply.

In rooms having large glass areas, when sun is not shining, or in rooms with walls having a high heat transmission coefficient, the lowered surface temperature will cause a feeling of coolness even though the air temperature in the room is at or above the temperatures indicated in the table. In rooms of this character, it is desirable to design for even higher temperatures than those listed, unless a compensating higher temperature surface is installed to offset the low-temperature surfaces.

The indoor temperatures specified in Table 3 may be used for panel heated spaces as well as for spaces heated by warm air, radiators, or convectors. It is true that warm panel surfaces tend to produce a comfortable environment at a lower room-air temperature than when warm panels are not present, but field experience in the United States has indicated that actual reductions in air temperature are slight in operation.

Temperature at Proper Level. In making the actual heat loss computations, however, for the various rooms in a building it is often necessary to modify the temperatures given in Table 3 so that the air temperature at the proper level will be used. By *air temperature at the proper level* is meant, in the case of walls, the air temperature at the mean height between floor and ceiling; in the case of glass, the air temperature at the mean height of the glass; in the case of roof or ceiling, the air temperature at the mean height of the roof or ceiling above the floor of the heated room; and in the case of floors, the air temperature at the floor level.

Temperature at Ceiling. The air temperature at the ceiling is generally higher than at the breathing level due to stratification of air resulting from the tendency of the warmer or less dense air to rise. An allowance for this fact should be made in calculating ceiling heat losses, particularly in the case of high ceilings. However, the exact allowance to be made may be somewhat difficult to determine as it depends on many factors, including (1) the type of heating system, (2) ceiling height, and (3) the indoor-outdoor temperature differential. The type of heating system is particularly important, as the temperature gradient from floor to breathing level to ceiling may depend to a large extent on whether a direct radiation, unit heater, or warm air system is used, and in the latter case, whether the air is moved mechanically or by gravity. The temperature of the heating medium is also a factor.

It is impracticable to establish rigid rules for determining the temperature difference to use in all cases. However, for residences and structures having ceiling heights under 10 ft, the comparatively small temperature differential between the breathing level and ceiling generally may be neglected without serious error. For higher ceilings, an allowance of approximately 1 percent per foot of height above the breathing level may be made for ceiling heights up to 15 ft and approximately $\frac{1}{16}$ of 1 deg per foot of height above this level. The values in Table 4 are calculated on this basis. For direct radiation and gravity warm air systems, the allowance should be increased from 50 percent to 100 percent over those given in Table 4. These rules should, however, be used with considerable discretion, as they do not apply to some types of heating systems such as those using panel and baseboard radiation, where very low temperature differences between the floor and the ceiling may exist.

Temperature at Floor Level. According to tests at the University of Illinois,[5, 6, 8] the temperature at the floor level ranged from about 2 to 6 deg below that at the breathing level, or somewhat greater than the difference between the breathing level and ceiling temperatures. Tests at the University of Wisconsin[7] indicated a somewhat smaller differential between the floor and breathing level temperatures. As a general rule, if the breathing level to ceiling temperature differential is neglected (as with ceiling heights under 10 ft), the breathing-level-to-floor differential may also be neglected, as the two are somewhat compensating, especially where both floor and ceiling losses are calculated for the same space. In other cases, the 10 ft temperature differentials in Table 4 may be used in arriving at the floor heat loss, these differentials to be subtracted from the breathing level temperature.

ATTIC TEMPERATURES

Frequently, it is necessary to estimate the attic temperature, and in such cases Equation 1 can be used for this purpose:

$$t_a = \frac{A_c U_c t_c + t_o(A_r U_r + A_w U_w + A_g U_g)}{A_c U_c + A_r U_r + A_w U_w + A_g U_g} \qquad (1)$$

where

t_a = attic temperature, Fahrenheit.
t_c = indoor temperature near top floor ceiling, Fahrenheit.
t_o = outdoor temperature, Fahrenheit degrees.
A_c = area of ceiling, square feet.
A_r = area of roof, square feet.
A_w = area of net vertical attic wall surface, square feet.
A_g = area of attic glass, square feet.
U_c = coefficient of transmission of ceiling, based on surface conductance of 2.20 (upper surface, see Chapter 9). 2.20 = reciprocal of one-half the air space resistance.
U_r = coefficient of transmission of roof, based on surface conductance of 2.20 (lower surface, see Chapter 9).
U_w = coefficient of transmission of vertical wall surface.
U_g = coefficient of transmission of glass.

Example 1. Calculate the temperature in an unheated attic, assuming the following conditions: $t_c = 70$; $t_o = 10$; $A_c = 1000$; $A_r = 1200$; $A_w = 100$; $A_g = 10$; $U_c = 0.50$; $U_r = 0.40$; $U_w = 0.30$; $U_g = 1.13$.

Solution: Substituting these values in Equation 1:

$$t_a = \frac{(1000 \times 0.40 \times 70) + 10[(1200 \times 0.50) + (100 \times 0.30) + (10 \times 1.13)]}{(1000 \times 0.40) + (1200 \times 0.50) + (100 \times 0.30) + (10 \times 1.13)}$$

$$t_a = \frac{34{,}413}{1041} = 33.1 \text{ F.}$$

Equation 1 neglects the effect of any interchange of air such as would take place through attic vents or louvers intended to preclude attic condensation. Test data[9, 10] indicate reduction in temperature difference between attic air and weather is linear with attic ventilation rates between 0 and 0.5 cfm per sq ft of ceiling area. A ventilation rate of 0.5 cfm per sq ft reduces this attic-to-weather temperature difference approximately 50 percent, while a ventilation rate of 0.1 cfm per sq ft reduces this temperature difference about 10 percent. When attic ventilation meets the requirements of Table 3 in Chapter 10, 0.5 cfm per sq ft is the approximate ventilation rate under design conditions. Therefore, the attic temperature found from Equation 1 above can be reduced accordingly, depending upon the estimated ventilation rate. However, since this affects the overall heat loss of a residence with an insulated ceiling only one or two percent, it can be neglected without serious error.

Neither does this equation take into consideration such factors as heat exchange between chimney and attic or solar radiation to and from the roof. Because of these latter effects, actual attic temperatures are frequently higher than the calculated values using Equation 1. The attic temperature may be calculated in the usual manner by means of Equation 1, allowing the full value of the roof. The error resulting from this assumption will generally be considerably less than if the roof were neglected (as is sometimes the practice) and the attic temperature assumed to be the same as the outdoor temperature. When relatively large louvers are installed, as is customary in the southern states, the attic temperature is often assumed as the average between the indoor and outdoor temperatures.

For a shorter, approximate method of calculating heat losses through attics, the combined ceiling and roof coefficient may be used, as described in Chapter 9.

Table 4 .... Approximate Temperature Differentials Between Breathing Level and Ceiling, Applicable to Certain Types of Heating Systems[a]

Ceiling Height Ft	Breathing Level Temperature (5 ft Above Floor)									
	60	65	70	72	74	76	78	80	85	90
10	3.0	3.3	3.5	3.6	3.7	3.8	3.9	4.0	4.3	4.5
11	3.6	3.9	4.2	4.3	4.4	4.6	4.7	4.8	5.1	5.4
12	4.2	4.6	4.9	5.0	5.2	5.3	5.5	5.6	6.0	6.3
13	4.8	5.2	5.6	5.8	5.9	6.1	6.2	6.4	6.8	7.2
14	5.4	5.9	6.3	6.5	6.7	6.8	7.0	7.2	7.7	8.1
15	6.0	6.5	7.0	7.2	7.4	7.6	7.8	8.0	8.5	9.0
16	6.1	6.6	7.1	7.3	7.5	7.7	7.9	8.1	8.6	9.1
17	6.2	6.7	7.2	7.4	7.6	7.8	8.0	8.2	8.7	9.2
18	6.3	6.8	7.3	7.5	7.7	7.9	8.1	8.3	8.8	9.3
19	6.4	6.9	7.4	7.6	7.8	8.0	8.2	8.4	8.9	9.4
20	6.5	7.0	7.5	7.7	7.9	8.1	8.3	8.5	9.0	9.5
25	7.0	7.5	8.0	8.2	8.4	8.6	8.8	9.0	9.5	10.0
30	7.5	8.0	8.5	8.7	8.9	9.1	9.3	9.5	10.0	10.5
35	8.0	8.5	9.0	9.2	9.4	9.6	9.8	10.0	10.5	11.0
40	8.5	9.0	9.5	9.7	9.9	10.1	10.3	10.5	11.0	11.5
45	9.0	9.5	10.0	10.2	10.4	10.6	10.8	11.0	11.5	12.0
50	9.5	10.0	10.5	10.7	10.9	11.1	11.3	11.5	12.0	12.5

[a] The figures in this table are based on an increase of 1 percent per foot of height above the breathing level (5 ft) up to 15 ft and $\frac{1}{16}$ of one degree for each foot above 15 ft. This table is generally applicable to forced air types of heating systems. For direct radiation or gravity warm air, increase values 50 percent to 100 percent.

TEMPERATURES IN UNHEATED SPACES

The heat loss from heated rooms into unheated rooms or spaces must be based on the estimated or assumed temperature in such unheated spaces. This temperature will lie in the range between the indoor and outdoor temperatures, depending on the relative areas of the surfaces adjacent to the heated room and those exposed to the outside. If the respective surface areas adjacent to the heated room and exposed to the outdoors are approximately the same, and if the coefficients of transmission are approximately equal, the temperature in the unheated space may be assumed to be the mean of the indoor and outdoor design temperatures. If, however, the surface areas and coefficients are unequal, the temperature in the unheated space should be estimated by means of Equation 2.

$$t_u = \frac{t_i(A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.}) + t_o(A_aU_a + A_bU_b + A_cU_c + \text{etc.})}{A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.} + A_aU_a + A_bU_b + A_cU_c + \text{etc.}} \qquad (2)$$

where

t_u = temperature in unheated space, Fahrenheit.
t_i = indoor design temperature of heated room, Fahrenheit.
t_o = outdoor design temperature, Fahrenheit.
A_1, A_2, A_3, etc. = areas of surface of unheated space adjacent to heated space, square feet.
A_a, A_b, A_c, etc. = areas of surface of unheated space exposed to outdoors, square feet.
U_1, U_2, U_3, etc. = coefficients of transmission of surfaces of A_1, A_2, A_3, etc.
U_a, U_b, U_c, etc. = coefficients of transmission of surfaces A_a, A_b, A_c, etc.

Example 2: Calculate the temperature in an unheated space adjacent to a heated room having surface areas (A_1, A_2, and A_3) in contact therewith of 100, 120, and 140 sq ft and coefficients (U_1, U_2, and U_3) of 0.15, 0.20, and 0.25, respectively. The surface areas of the unheated space exposed to the outdoors (A_a and A_b) are respectively 100 and 140 sq ft, and the corresponding coefficients are 0.10 and 0.30. The sixth surface is on the ground and is neglected in this example. Assume $t_i = 70$ and $t_o = -10$.

Solution: Substituting in Equation 2:

$$t_u = \frac{70[(100 \times 0.15) + (120 \times 0.20) + (140 \times 0.25)] + -10[(100 \times 0.10) + (140 \times 0.30)]}{(100 \times 0.15) + (120 \times 0.20) + (140 \times 0.25) + (100 \times 0.10) + (140 \times 0.30)}$$

$$t_u = \frac{4660}{126} = 37 \text{ F.}$$

The temperatures in unheated spaces having large glass areas and having two or more surfaces exposed to the outdoors (such as sleeping porches and sun parlors), generally are assumed to be the same as outdoors.

GROUND TEMPERATURES

Ground temperatures to be assumed for estimating basement heat losses usually will differ in the case of basement walls and floors, the temperatures under the floors generally being higher that those adjacent to walls. Factors affecting these temperatures will be discussed.

Temperatures Under Basement Floors

The temperature of the ground under basement floors[11] is affected by heat sources within the basement and is not influenced by atmospheric conditions. In computing losses

Table 5 .... Below Grade Heat Losses for Basement Walls and Floors

Ground Water Temperature[a]	Basement Floor Loss[b] Btu/Sq Ft	Below Grade Wall Loss[b] Btu/Sq Ft
40	3.0	6.0
50	2.0	4.0
60	1.0	2.0

[a] See Fig. 4, Chapter 41.
[b] Based on basement temperature of 70 F and U of 0.10

through basement floors, the ground temperatures may be assumed to be the same as water temperatures at depths of 30 to 60 ft given in Fig. 4, Chapter 41. Test observations indicate that heat losses through basement floors frequently are over-estimated.[12]

Temperatures Adjacent to Basement Walls

Ground temperatures near the surface and under open spaces vary with the climate, the season of the year, and the depth below the surface. The nearer the surface (during the cold weather) the lower will be the ground temperature. Frost will penetrate to a depth of over 4 ft in some localities if not protected by snow. A thick blanket of snow will result in a higher ground temperature near the surface. Therefore, in localities where the ground is covered with a heavy blanket of snow throughout the winter, the ground temperatures near the surface will be higher than when little or no snow is present.

Complete data on ground temperatures adjacent to buildings are not available, but since the recommended transmission coefficient for basement walls in contact with the soil is only 0.10, any reasonable, assumed ground temperature will not materially affect the calculated heat loss.

BASEMENT TEMPERATURES AND HEAT LOSS

The allowance to be made for basement heat loss depends on whether the basement is to be heated or not.

If the basement is *heated* to a specified temperature, the heat loss should be calculated in the usual manner, based on the proper wall and floor coefficients (see Chapter 9) and the outdoor air and ground temperatures. Heat loss through windows and walls above grade should be based on outdoor temperatures and the proper air-to-air coefficients. Heat loss through basement walls below grade should be based on the floor and wall coefficients for surfaces in contact with the soil, and on the proper ground temperature.

The heat loss values for below-grade basement walls and floors given in Table 5 are sufficiently precise for general practice.

If a basement is completely below grade and is *not heated*, the temperature in the basement normally will range between that in the rooms above and the ground temperature. Basement windows will, of course, lower the basement temperature when it is cold outdoors, and heat given off by the heating plant will increase the basement temperature. In any case, the exact basement temperature is indeterminate if the basement is not heated. In general, it is found that the transient heat from the heating plant warms the air near the basement ceiling sufficiently to make it unnecessary to make an allowance for floor heat loss from rooms located over the basement.

The temperature in crawl spaces below floors will vary widely depending on the number and size of wall vents, the amount of warm piping present and type of piping insulation. It is necessary, therefore, to evaluate the conditions and to select an appropriate temperature by judgment.

HEAT LOSSES FROM FLOOR SLABS

Two types of concrete floors used in basementless houses are (*a*) the unheated floor, relying for warmth on heat delivered above floor level by the heating system, and (*b*) the heated floor containing heated pipes or ducts that constitute a radiant slab or portion thereof for complete or partial heating of the house.

For type (*a*) the floor heat loss, economically considered, is of minor importance since it comprises generally about 10 percent of the total heat loss of the house. From the comfort standpoint, however, it may be most important, since houses with cold floors are not successfully heated. In this connection, it should be remembered that a well insulated floor does not assure comfort if downdrafts from windows or exposed walls create pools of chilly air over considerable areas of the floor. For this reason a floor of type (*a*) should not be used in a severe climate except with a heating system that delivers enough heat near the floor to counteract the downdrafts of the exterior walls and the heat transmission through the floor.

The results of some experiments[12, 13] with type (*a*) unheated floor slabs indicate that the heat loss from a concrete slab floor on grade is more nearly proportional to the perimeter than to the area of the floor, and that the heat loss can be estimated by means of the equation:

$$H_F = FP\,(t_i - t_o) \qquad (3)$$

where

H_F = heat loss of the floor, Btu per hour.
P = perimeter or exposed edge of the floor, linear feet.

Table 6 .... Heat Loss of Concrete Floors at or Near Grade Level per Foot of Exposed Edge

Outdoor Design Temperature F	Heat Loss per Foot of Exposed Edge, Btu/hr: Recommended 2-in. Edge Insulation	Heat Loss per Foot of Exposed Edge, Btu/hr: 1-in. Edge Insulation
−20 to −30	50	55
−10 to −20	45	50
0 to −10	40	45
Outdoor Design Temperature F	**1-in. Edge Insulation**	**No Edge Insulation[a]**
−20 to −30	60	75
−10 to −20	55	65
0 to −10	50	60

[a] This construction not recommended; shown for comparison only.

F = heat loss coefficient, Btu per (hour) (linear foot of exposed edge) (degree difference in temperature between the indoor air and the outdoor air). (F ranges between 0.81 for a floor with no edge insulation to 0.55 for a floor with edge insulation.)
t_i = indoor air temperature, Fahrenheit.
t_o = outdoor air temperature, Fahrenheit.

In most instances the values given in Table 6 for edge loss are of sufficient precision for use.[14] The insulation shown extending under the floor horizontally for 2 ft can also be located along the foundation wall with equal effectiveness if the insulation extends 24 in. below the floor level.

Example 3: Calculate the heat loss from the floor of a 12 ft x 15 ft room with two exposures. The floor is an unheated concrete slab which is insulated at the edge with 2 in. of insulation extending horizontally for a distance of 2 ft from the edge, and the house is located in an area with an outdoor design temperature of −15 F.

Solution: From Table 6 the heat loss per foot of exposed edge is 45 Btu per hr. The length of exposed edge is 12 ft + 15 ft = 27 ft, and the total edge loss 27 x 45 = 1215 Btu per hr.

Floors of type (*b*) containing heating pipes or ducts, are now in common use. The heat loss downward into the ground and outward through the edges of the floor slab is called the reverse loss.

The results[15] of an investigation in which a warm air perimeter duct was embedded in four types of concrete floor-slab and foundation constructions has verified the indication that Equation 3 can be used to calculate the reverse loss when warm air perimeter heating ducts are used. To make the results of this application more usable, values corresponding to those shown in Table 6 for unheated floors are given in Table 7 for concrete floors with a warm air perimeter duct.

The desirability of edge insulation is apparent. One inch of water-resistant material is the minimum thickness of edge insulation that should be used, but a 2-in. thickness is recommended.[14, 16, 17] The values of edge loss in Table 7 indicate that the reverse heat loss of heated slabs is likely to be about 20 percent of the total heat loss of many types of present day houses, and may exceed 20 percent if only one inch of insulation is used at the edge of the floor.

The concrete floor slab is usually placed on a gravel fill 4 in. thick or more, both to insulate the floor from the earth and to retard the rise of ground water by capillarity. A waterproof membrane should be installed over the gravel fill. Obviously, it is important that such floors be laid several inches above grade, and that effective subsoil drainage be provided to avoid slabs soaked by rain or melting snow, and consequent excessive heat loss.

TRANSMISSION HEAT LOSS

The basic formula for the loss of heat by transmission through any surface is given in Equation 4:

$$H_t = AU\,(t_i - t_o) \qquad (4)$$

where

H_t = heat loss transmitted through the wall, roof, ceiling, floor, or glass, Btu per hour.
A = area of wall, glass, roof, ceiling, floor, or other exposed surface, square feet.
U = coefficient of transmission, air-to-air, Btu per (hour) (square foot) (Fahrenheit degree temperature difference).

Table 7 .... Floor Heat Loss to be Used When Warm Air Perimeter Heating Ducts Are Embedded in Slabs[a]
Btu per (hour) (linear foot of heated edge)

Outdoor Design Temperature, F	Edge Insulation: 1-in. Vertical Extending Down 18 in. Below Floor Surface	1-in. L-Type Extending at Least 12 in. Deep and 12 in. Under	2-in. L-Type Extending at Least 12 in. Down and 12 in. Under
−20	105	100	85
−10	95	90	75
0	85	80	65
10	75	70	55
20	62	57	45

[a] Factors include loss downward through inner area of slab.

t_i = indoor temperature near surface involved (this may not necessarily be the so-called breathing-line temperature), Fahrenheit degrees.
t_o = outdoor temperature, or temperature of adjacent unheated space or of the ground, Fahrenheit degrees.

Example 4: Calculate the transmission loss through an 8-in. brick wall having an area of 150 sq ft, if the indoor temperature t_i is 70 F and the outdoor temperature t_o is −10 F.

Solution: The coefficient of transmission U of a plain 8-in. brick wall is 0.41 (Chapter 9, Table 6). The area A is 150 sq ft. Substituting in Equation 4:

$$H_t = 150 \times 0.41 \times [70 - (-10)] = 4{,}920 \text{ Btu per hour.}$$

Transmission Loss Through Ceilings and Roofs

The transmission heat loss through top floor ceilings, attics, and roofs may be estimated by either of two methods:

1. By substituting in Equation 4 the ceiling area A, the indoor-outdoor temperature difference $(t_i - t_o)$ and the proper value of U:
   a. *Flat roofs.* Select the coefficient of transmission of the ceiling and roof from Tables 11 to 14, Chapter 9, or use appropriate coefficients in Equation 1 if side walls extend appreciably above the ceiling of the floor below.
   b. *Pitched roofs.* Select the combined roof and ceiling coefficient from Table 15, Chapter 9 or calculate the combined roof and ceiling coefficient by means of Equations 4 and 5, Chapter 9, where these formulas are applicable as explained in Chapter 9.
2. By estimating the attic temperature (based on the indoor and outdoor design temperatures) by means of Equation 1, and substituting for t_o in Equation 4, the value of t_o thus obtained, together with the ceiling area A and the ceiling coefficient U. This applies to *pitched roofs.* In the case of *flat roofs* it is not necessary to calculate the attic temperatures, as the ceiling-roof heat loss can be determined as suggested in preceding paragraph 1a.

INFILTRATION HEAT LOSS

The infiltration heat loss includes (1) the *sensible heat loss* or the heat required to warm the outdoor air entering by infiltration, and (2) the *latent heat loss* or the heat equivalent of any moisture which must be added.

Sensible Heat Loss

The formula for the heat required to warm the outdoor air which enters a room by infiltration to the temperature

of the room, is given in Equation 5:

$$H_s = 0.240\ Q_\rho\ (t_i - t_o) \qquad (5)$$

where

H_s = heat required to raise temperature of air leaking into building from t_o to t_i, Btu per hour.
0.240 = specific heat of air.
Q = volume of outdoor air entering building, cubic feet per hour (see Chapter 11).
ρ = density of air at temperature t_o, pounds per cubic foot.

It is sufficiently accurate to use $\rho = 0.075$ in which case Equation 5 reduces to

$$H_s = 0.018\ Q\ (t_i - t_o) \qquad (5a)$$

The volume Q of outdoor air entering per hour depends on the wind speed and direction, the width of crack or size of openings, the type of openings, and other factors, as explained in Chapter 11. Where the crack method is used for estimating leakage, it is more convenient to express the air leakage heat loss in terms of the crack length:

$$H_s = B\ L\ (t_i - t_o) \qquad (5b)$$

where

B = air leakage per (hour) (foot of crack) (Chapter 11) for the wind velocity and type of windows or door crack involved, multiplied by 0.018.
L = length of window or door crack to be taken into consideration, feet.

Example 5: What is the infiltration heat loss per hour through the crack of a 3 x 5 ft average, double-hung, non-weather-stripped, wood window, based on a wind speed of 15 mph? Assume indoor and outdoor temperatures to be 70 F and zero, respectively.

Solution: According to Table 2, Chapter 11, the air leakage through a window of this type (based on 1/16 in. crack and 3/64 in. clearance) is 39 cu ft per (ft of crack) (hour). Therefore, $B = 39 \times 0.018 = 0.70$. The length of crack L is $(2 \times 5) + (3 \times 3)$, or 19 ft; $t_i = 70$ and $t_o = 0$. Substituting in Equation 5b,

$$H_s = 0.70 \times 19 \times (70 - 0) = 931 \text{ Btu per hour.}$$

Crack Length to be Used for Computations

For designers who prefer to use the crack method, the basis of calculation is as follows: The amount of crack used for computing the infiltration heat loss should be not less that half of the total length of crack in the outside walls of the room. For a building having no partitions, air entering through the cracks on the windward side must leave through the cracks on the leeward side. Therefore, take one-half the total crack for computing each side and end of the building. In a room with one exposed wall, take all the crack; with two exposed walls, take the wall having the most crack; and with three or four exposed walls, take the wall having the most crack; but in no case take less than half the total crack.

In small residences the total infiltration loss of the house is generally considered to be equal to the sum of the infiltration losses of the various rooms. However, this is not necessarily accurate as at any given time infiltration will take place only on the windward side or sides and not on the leeward side. Therefore, for determining the total heat requirements of larger buildings it is more accurate to base the total infiltration loss on the wall having the most total crack, but in no case on less than half of the total crack in the building.

Number of Air Changes to be Used for Computations

Since a certain amount of judgment is required regarding quality of construction, weather conditions, use of room, and other factors in estimating infiltration by any method, some designers base infiltration upon an estimated number of air changes rather than upon the length of window cracks. Table 4 of Chapter 11 indicates air changes commonly used, but should be taken only as a guide.

When calculating infiltration losses by the air change method, Equation 5a may be used by substituting for Q the volume of the room multiplied by the number of air changes obtained from Table 4, Chapter 11. For further discussion of the method see section on Air Change Method in Chapter 11.

Latent Heat Loss

When it is intended to add moisture to air leaking into a room in order to maintain proper winter comfort conditions, it is necessary to determine the heat required to evaporate the water vapor added. This heat may be calculated by the equation

$$H_l = Q_\rho\ (W_i - W_o)\ h_{fg} \qquad (6)$$

where

H_l = heat required to increase moisture content of air leaking into building from W_o to W_i, Btu per hour.
Q = volume of outdoor air entering building, cubic feet per hour.
ρ = density of air at temperature t_i, pounds per cubic foot.
W_i = humidity ratio of indoor air, pounds per pound of dry air.
W_o = humidity ratio of outdoor air, pounds per pound of dry air.
h_{fg} = latent heat of vapor at W_i, Btu per pound.

If the latent heat of vapor h_{fg} is assumed to be 1060 Btu per lb, Equation 6 reduces to:

$$H_l = 79.5\ Q\ (W_i - W_o) \qquad (6a)$$

Equations 5a, 5b, and 6a may also be used for determining the sensible and latent heat gains due to infiltration in cooling load computations.

SELECTION OF WIND SPEEDS

The effect of wind on the heating requirements of any building should be given consideration for two reasons:

1. Wind movement increases the heat transmission of walls, glass, and roof, affecting poor walls to a much greater extent than good walls.

2. Wind increases materially the infiltration of cold air through the cracks around doors and windows, and even through the building materials themselves (see Tables 1 and 2, Chapter 11).

Theoretically, as a basis for design, the most unfavorable combination of temperature and wind speed should be chosen. It is entirely possible that a building might require more heat on a windy day with a moderately low outdoor temperature, than on a quiet day with a much lower outdoor temperature. However, the combination of wind and temperature, which is the worst, would differ with different buildings, because wind speed has a greater effect on buildings which have relatively high infiltration losses. It would be possible to compute the heating load for a building for several different combinations of temperature and wind speed which records show to have occurred, and to select the worst combination, but designers generally do not feel that such a degree of refinement is justified.

A complete correlation between the design temperatures in Column 6 of Table 1, and the simultaneous maximum wind speed has not been made at the present time. If a designer prefers the air change method for computing infiltration load, such correlation is not too important. Designers who use the crack method may use a leakage rate at 15 mph wind speed unless local experience has established that other speeds are more appropriate. Abnormally high wind speed may have significant effect on the transmission coefficient, U. (See Table 20, Chapter 9.)

Exposure Factors

Many designers use empirical *exposure* factors to increase the calculated heat loss of rooms or spaces on the side or sides of the building exposed to the prevailing winds. However, the use of exposure factors is unnecessary when THE GUIDE method of calculating heat losses is used. Therefore, exposure factors may be regarded as *factors of safety* for the rooms or spaces exposed to the prevailing winds, to allow for additional capacity for these rooms or spaces, or to *balance the radiation*, particularly in the case of multi-story buildings. Tall buildings may have severe infiltration heat losses, induced by their stack effect (see Chapter 11), that will require special consideration. Although the exposure allowance frequently is assumed to be 15 percent, the actual allowance to be made, if any, must to a large extent be a matter of experience and judgment of the designer, since there are at present no authentic test data available from which rules could be developed for the many conditions encountered in practice.

AUXILIARY HEAT SOURCES

The heat supplied by persons, lights, motors, and machinery always should be ascertained in the case of theaters, assembly halls, and industrial plants, but allowances for such heat sources must be made only after careful consideration of all local conditions. In many cases, these heat sources should not affect the size of the heating plant at all, although they may have a marked effect on the operation and control of the system. In general, where audiences are present, the heating system must have sufficient capacity to bring the building to the stipulated indoor temperature before the audience arrives. In industrial plants, quite a different condition exists, and heat sources, if always available during occupancy, may be substituted for a portion of the heating requirements. In no case should the actual heating installation (exclusive of heat sources) be reduced below that required to maintain at least 40 F in the building.

Electric Motors and Machinery

Motors and the machinery which they drive, if both are located in the room, convert all of the electrical energy supplied into heat. This heat is retained in the room if the product manufactured is not removed until its temperature is the same as the room temperature.

If power is transmitted to the machinery from the outside, then only the heat equivalent of the brake horsepower supplied is used. In some mills this is the chief source of heating, and it is frequently sufficient to overheat the building even in zero weather, thus requiring cooling by ventilation the year round. Table 8 shows the heat output equivalent of various sources of heat in a factory. For information concerning the heat supplied by persons, refer to data given in Chapter 6, and also Table 27, Chapter 13. For appliances see Table 28, Chapter 13.

INTERMITTENTLY HEATED BUILDINGS

In the case of intermittently heated buildings additional heat is required for raising the temperature of the air, the building materials, and the material contents of the building to the specified indoor temperature. The rate at which this additional heat must be supplied depends upon the heat capacity of the structure and its material contents, and upon the time in which these are to be heated.[18]

This additional heat may be computed and allowed for as conditions require, but inasmuch as the heating system proportioned for taking care of the heat losses will usually have a capacity about 100 percent greater than that required for average winter weather, and inasmuch as most buildings may either be continuously heated or have more time allowed for heating up during the few minimum temperature days, no allowance usually is made, except in the size of boilers or furnaces. For churches, auditoriums, and other intermittently heated buildings, additional capacity should be provided.

Table 8 .... Heat Equivalents of Various Sources[a]

Machinery (Motor in room)	= Motor Hp/efficiency x 2544 Btuh
Machinery (Motor outside room)	= Motor Hp x 2544 Btuh
Electric Lights	= Kilowatts x 3413 Btuh
Gas (Producer = 150) (Manufactured = 535)	(Natural = 1000) Btu/cu ft

[a] Additional values are given in Chapter 13, Table 28.

RESIDENCE HEAT LOSS PROBLEMS

The following *Examples 6* and *7* will illustrate the procedure for calculating the heat loss of a residence, uninsulated and insulated, in accordance with the recommendations given in this chapter.

Example 6: Calculate the heat loss of the residence shown in Fig. 1 located in the vicinity of Chicago. From Table 1, design outdoor conditions are − 10 F and 12 mph wind speed. Indoor temperature from Table 3 is assumed to be 70 F. The attic is unheated. Assume ground temperature to be 50 F (see Fig. 4, Chapter 41) under basement and garage floors and 32 F adjoining basement walls. Estimate infiltration losses by the air change method. No wall, ceiling, or roof insulation is to be considered in this problem, but all first and second floor windows, except in the garage, are to have storm sash. The building is constructed as follows (heat transmission coefficients U are in parentheses):

Walls: Brick veneer, building paper, wood sheathing, studding, metal lath, and plaster (0.29). Walls of dormer over garage, same except wood siding in place of brick veneer (0.26).

Attic Walls: Brick veneer, building paper, wood sheathing on studding (0.42).

Basement Walls: 10 in. concrete (0.10).

Roof: Asphalt shingles on wood sheathing on rafters (0.44).

Ceiling (Second Floor): Metal lath and plaster (0.74).

Windows: Double-hung wood windows averaging 70 percent glass (0.45; from Chapter 9, Table 18, Section D, the U value for wood windows with storm sash is 0.53 × application factor; by interpolation this factor is 0.85). Steel casement sash in ga-

Notes for Table 9... Heat Loss Calculation for Uninsulated Residence (Fig. 1)

[a] The indoor-outdoor temperature difference is 70− (−10) or 80 F except where otherwise noted.
[b] Volume of infiltration, cfh = (no. air changes) x (floor or ceiling area) x (ceiling height).
[c] From Equation 5a.
[d] The ceiling heat losses are calculated by estimating the attic temperature and then calculating the loss through the ceiling using the proper temperature difference. This unheated attic is not ventilated during winter months. The attic temperature is estimated from Equation 1 to be 30.2 F when the outdoor temperature is −10 F and room temperature is 70 F. The temperature difference is then 70—30.2 or 39.8 deg. For the insulated residence, attic temperature becomes 4.6 F and temperature difference 70—4.6 = 65.4 deg.
[e] Temperature in garage assumed to be 35 F.
[f] Coefficient for wall adjoining garage calculated on basis of metal lath and plaster on both sides of studs (U = 0.39).
[g] One-half of value from Table 4, Chapter 11, for storm windows or weatherstripping.
[h] Exposed on two sides, weatherstripped windows offset by fireplace. Use 1½.
[i] Window on one side weatherstripped but double-doors are hard to close tightly. Hence, conservative value of 1½.
[j] Assuming kitchen vent, door to vestibule usually open, allow full table value of 1½.
[k] One-half value in Table 4, Chapter 11, increased to 1½ by nearby outside door in vestibule.
[l] Full value in Table 4, Chapter 11, to allow for frequent opening of outside door.
[m] Two sides exposed, large doors but large volume. Use value 1½ as given in Table 4, Chapter 11.
[n] Two small unweatherstripped windows in protected location, but fireplace, indicate 1 change.
[p] Heat losses from these rooms into garage are heat gains for garage.
[q] Neglect heat loss to basement, as losses from boiler, piping, etc., will probably keep basement near, if not above, 70 F.
[r] Upstairs hall ceiling figures with downstairs. Heat should be provided downstairs for both.
[s] Linear feet of exposed edge.

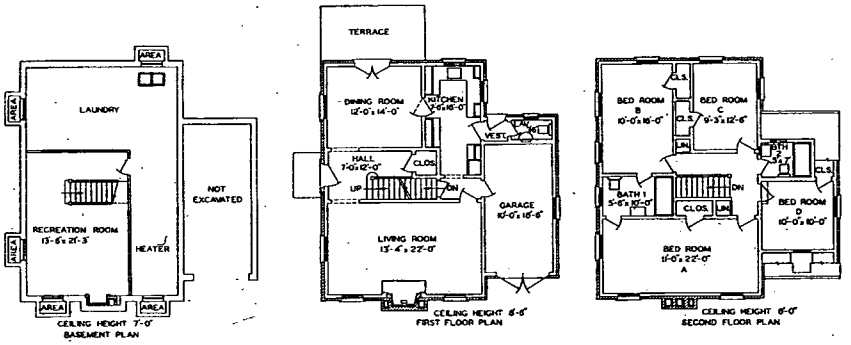

Fig. 1 . . . . Floor Plans of Residence

rage and basement (1.13; from Chapter 9, Table 18, U is 1.13 for all glass and the application factor is 1.00). French doors in dining room 50 percent glass, no storm doors (0.85; from Chapter 9, Table 18, U is 1.13 for all glass; by interpolation the application factor is 0.75).

Floor (Bedroom D): Maple finish flooring on yellow pine subflooring; metal lath and plaster ceiling below (0.26).

Floor (Basement and Garage): 4 in. stone concrete on 3 in. cinder concrete (0.10).

Solution: The calculations for this problem are given in Table 9, and a summary of the results in Table 10. The values in column F of Table 9 were obtained by multiplying together the figures in columns C, D, and E. The heat losses are calculated to the nearest 10 Btu. See reference notes for Table 8 for further explanation of data.

Attention is called to the summary of heat losses (Table 10) for the uninsulated residence. As storm windows are used in this instance the *glass* and *door* transmission heat losses of 19.8 percent are relatively small. The infiltration losses of 14.0 percent are also comparatively small because the storm windows are equivalent to weatherstripping. In this problem, the wall, ceiling, and floor transmission losses comprise 66.2 percent of the total.

Example 7: Calculate the heat loss of residence shown in Fig. 1 based on the same conditions as in *Example 6* but having construction improved or insulated to obtain coefficients as follows:

Walls, 0.13; *Walls of Dormer over Garage*, 0.12; *Attic Walls*, 0.28; *Walls Adjoining Garage*, 0.18; *Basement Walls (Recreation Room)*, 0.10.

Roof, 0.53.

Ceiling (Second Floor), 0.15.

Windows (Same as in *Example 6*).

Floor (Bedroom D), 0.18.

Solution: The procedure for calculating the heat losses is similar to that for *Example 6*. A summary of the results is given in Table 11.

Table 10 .... Summary of Heat Losses of Uninsulated Residence (Btu Per Hour)

CHAPTER 13

COOLING LOAD

Cooling Load Calculations; Design Conditions; Instantaneous Heat Load; Solar Radiation; Periodic Heat Flow; Tables for Calculating Solar Heat Gain Through Walls, Roofs, and Glass; Instantaneous Heat Gain vs. Cooling Loads; Load from Interior Partitions, Ceiling, and Floors; Load from Outdoor Air, Ventilation and Infiltration; Effect of Outdoor Air on Load; Heat Sources Within Conditioned Space; Moisture Transfer Heat Load; Miscellaneous Heat Loads; Apparatus Dew Point and Required Air Quantity Through Conditioning Equipment; Minimum Entering Air Temperature; Example Cooling Load Calculation

THE variables affecting cooling load calculations are numerous, often difficult to define precisely, and always intricately interrelated. Most of the components of the cooling load vary in magnitude over a wide range during a 24-hour period, and as the cyclic changes in load components are not usually in phase with each other, careful analysis is required to establish the resultant maximum cooling load for a building or zone. A zoned system must often handle peak loads in different zones at different hours.

Economic considerations must be of particular influence in the selection of equipment for cooling season operation in comfort air conditioning, and this fact, coupled with present inadequacies in available data and knowledge of the air-conditioning art, places a premium on the experienced judgment essential to successful design or practice. Variations in the weather, building occupancy, and other factors affecting load, necessitate carefully coordinated controls to regulate simultaneously the components and the equipment in order to maintain the desired room conditions.

The calculation procedures presented in this chapter deal with the various instantaneous rates of heat gain, both sensible and latent, in a conditioned space. There may be an appreciable difference between the *net instantaneous rate of heat gain* and the *total cooling load* at any instant. This difference is caused by the storage and subsequent release of heat by the structure and its contents. This thermal-storage effect may be quite important in determining an economical cooling equipment capacity. The lack of any adequate means of treating this storage quantitatively in its entirety for a complete structure, must be recognized in judging the procedures and data presented for calculating individual components of the net rate of instantaneous heat gain.

Solar heating calculations involve the same principles as cooling load calculations. Many of the data on solar radiation given in this chapter can be used in calculations for solar heating.

COOLING LOAD CALCULATIONS

Summer cooling load calculations, whether for industrial or comfort applications, require consideration of the following factors:

A. Design Conditions: (1) indoor conditions; (2) outdoor conditions; (3) ventilation rate.

B. Instantaneous Heat Load, Sensible and Latent: (1) load from solar radiation, sky radiation, and from outdoor-indoor temperature differential for glass areas and exterior walls and roofs, modified by periodic heat flow or lag factors depending on the type of structure; (2) load due to heat gain through interior partitions, ceilings, and floors; (3) load due to ventilation, either natural or mechanical; (4) load due to heat sources within the conditioned space such as people, lights, power equipment, and appliances; (5) load due to moisture transfer through permeable building materials; and (6) miscellaneous heat sources.

C. Determination of Air Quantity and Apparatus Dew Point.

These factors will be discussed in turn. The material presented leads to an illustrative procedure for a cooling load calculation, and a numerical example is given to demonstrate the calculations involved.

DESIGN CONDITIONS

Indoor Conditions

Indoor air conditions for human health and comfort have been and continue to be the subject of much discussion and research.

The effective temperature index, explained in Chapter 6, is probably the best available source of design criteria for comfort air-conditioning systems for buildings or enclosures in which the air and inside surface temperatures remain substantially equal; a condition that can safely be assumed for most ordinary comfort air-conditioning installations. Other sources of design specifications are to be found in the requirements of codes and ordinances, and in the varied long-term experiences of manufacturers, contractors, and engineering specialists.

Past experience, cumulative over many years, indicates that indoor design conditions, for which summer air-conditioning equipment is selected, should not exceed a temperature of 80 F or a relative humidity of 50 percent for the average job in the United States. If these conditions are exceeded, complaints of discomfort may be expected, especially with continuous occupancy. For very brief occupancy only, a slightly higher peak-load design temperature may be employed. In regard to the lower limit of humidity, complaints are not encountered for store installations operated down to 35 percent relative humidity or, for office jobs, somewhat lower. These observations apply to normal commercial practice in this country only. For extremes, such as tropical or very hot regions, it is regarded as more practicable to design for a peak-load outdoor-indoor temperature difference of about 15 to 20 F deg.

Table 1 offers typical design conditions for average requirements encountered. The values in line 1 would also apply in general for localities having a summer outdoor design tem-

Table 1 .... Design Room Conditions Usually Specified for Summer Average Peak Load in Comfort Air Conditioning[a]

Type of Installation	Dry-Bulb Temp	Wet-Bulb Temp[b]	Relative Humidity Percent	Grains Per Lb[b]	Effective Temp[c]
1. Ample capacity	78	65	50	72.7	72.2
2. Practical application	80	67	51	78.5	74.0
3. Occupancy—15 to 40 min	82	68	49	80.0	75.3

[a] Values in Table 1 are for *peak load* conditions. It is general practice to operate a system at approximately 75 F and 50 percent relative humidity at other than peak load.

[b] Psychrometric data for standard barometric pressure.

[c] Fig. 10, Chapter 6, air movement 15 to 25 fpm.

perature of 90 F or less; and the *15 to 40 min* occupancy values, or even somewhat higher dry-bulb temperatures, would indicate acceptable conditions for very hot localities. Table 1 *is to be used with good judgment*, for there is no universal rule that may be applied to indoor design conditions.

Guarantees of conditions to be maintained for summer operation are based upon a definite set of load conditions. At other than the guarantee load, the conditions produced by a system are determined by the balance of imposed load and equipment capacity, and by the method adopted for regulating the system operation. Complete specifications of indoor design conditions would include part-load and overload operation, particularly from the viewpoint of economy.

In the field of *industrial air conditioning*, indoor design conditions are established by the requirements of goods and processes, in addition to the comfort and efficiency of the workers. Many typical indoor design conditions for products in industrial air conditioning are given in Chapter 50.

The load calculations for either comfort or industrial air conditioning are usually made in accordance with a guarantee. In comfort applications, for example, this is frequently 80 F and 51 percent relative humidity or 78 F and 50 percent relative humidity. The system is *normally operated* at 75 or 76 F and approximately 50 percent relative humidity at all times as long as the equipment has capacity to maintain these conditions. During very hot weather, the room temperature will rise above the control point and the equipment will operate continuously. Normally, industrial jobs are operated at design conditions at all times if the optimum conditions are selected for the benefit of the product.

The indoor design conditions suggested have had reference to conditions to be maintained at the level of occupancy. For extremely high ceilings in public or industrial buildings, only the zone from 10 to 15 ft above the floor may be cooled to the full extent. The air temperature at the ceiling would be much higher, and this should be kept in mind when calculating the convective portion of the roof heat gain. A reduction of outdoor-to-indoor air temperature differential may be assumed in such instances but radiation from the inner roof surface is not diminished.

Outdoor Conditions

Summer climatic conditions and suggested design wet-bulb and dry-bulb temperatures are given in Table 2 for various locations in the United States. The highest temperature ever recorded is for the period of record shown. In some cases it should be noted that this period of record is comparatively short, and higher temperatures may be expected. In making comparisons for localities other than those shown in Table 2, due consideration must be given to elevation.

Column 6 of Table 2 indicates the design dry-bulb temperature suggested by the ASHAE Technical Advisory Committee on Weather Design Conditions. This temperature is the maximum hourly outdoor temperature which has been equalled or exceeded 2½ percent of the total hours of June, July, August, and September for the period of record, in this case the 5-year period 1935–1939, and should not be confused with the period of record given in Column 4 which applies only to highest temperature ever recorded. Since all of these data (Column 4) are based on airport records, they are not necessarily applicable to cities.

The data given in Columns 7 and 8 were obtained from local ASHAE Chapter Secretaries, and represent the design temperatures in local use. Where such information was not available, it was taken from a publication of the ARI[1] and from various other sources.

The Technical Advisory Committee on Weather Design Conditions has suggested that wet-bulb design temperature be taken as that wet-bulb temperature which has been equalled or exceeded in 5 percent of the hours during months of the period of record. While not available for this edition of THE GUIDE, due to the tremendous task of compiling these data, it is hoped that they will be available for some stations for future editions.

The wind velocity to be used in design should be that wind velocity which accompanies the design temperatures in each instance, but since these data are not available, the average summer wind velocities for the period of record were taken from U. S. Weather Bureau records revised to 1948. It is pointed out that this is not necessarily the velocity which coincides with the design temperatures, but it may serve as a guide to the designer.

Other weather data, such as *daily range of temperature*, are useful particularly when making cooling load calculations for an early morning peak on an east exposure. Daily range of temperature is the difference between the average of the daily maximum dry-bulb temperatures and the average of the daily minimum temperatures. This range is highest in semi-arid or desert regions and at high elevations, and lowest near the oceans or very large lakes. The daily range of temperature (Fahrenheit degrees) in July for the principal areas of the United States can be approximated from the following tabulation:

East Sea Shore	12 to 18
East of Mississippi River	19 to 24
Gulf Sea Shore	12 to 18
Great Lakes Shore	18 to 21
Mississippi River to Rocky Mountains	24 to 33
Rocky Mountain Area	33 to 42
West Coastal States	20 to 35
West Sea Shore	15 to 20

Ventilation Rate

The introduction of outdoor air is necessary for the ventilation of conditioned spaces. Chapter 6 suggests *minimum* outdoor air requirements for representative applications; but it is to be emphasized that minimum requirements are not necessarily *adequate* requirements for all psychological attitudes and physiological responses. Where maximum economy in space and load are essential, as in submarines or other restricted spaces, as little as 1 cfm of outdoor air per person has been found to be sufficient provided that satisfactory

ventilation is simultaneously obtained by an adequate decontamination of recirculated air.[2]

Local codes and ordinances frequently specify ventilation requirements for public places and for industrial installations. For operating rooms, minimum requirements for safe practice are given in a National Board of Fire Underwriters' pamphlet.[3] This pamphlet does not require 100 percent outdoor air in operating rooms, although 100 percent outdoor air is normally used and recommended.

Recommended and minimum ventilation rates for the most common applications are summarized in Table 3. For further general applications, a basis of estimating the cfm per person may be taken as:

1. People not smoking	7½	*Recommended*	5 *Minimum*
2. People smoking	40	*Recommended*	25 *Minimum*

The cooling load due to the introduction of outdoor air for ventilation is determined once the indoor and outdoor design conditions are fixed. Calculations will be discussed subsequently.

INSTANTANEOUS HEAT LOAD

The total cooling load is frequently divided for convenience into two components, *sensible heat* and *latent heat*. While this subdivision is not imperative, past practice has found it convenient.

A gain of *sensible heat* is considered to occur when there is a direct addition of heat to the enclosure by any one or all of the mechanisms of conduction, convection, and radiation. A gain of *latent heat* is considered to occur when there is an addition of water vapor to the air of the enclosure. For example, when the humidity in an enclosure is increased by water vapor emitted by human occupants, or by water vapor resulting from a process such as cooking, the heat required to vaporize the water does *not* come from the air. Maintenance of a constant humidity ratio in a sealed enclosure requires the condensation of water vapor in the cooling apparatus at a rate equal to its rate of addition within the enclosure. The rate of heat removal from this condensing vapor would be substantially equal to the product of the rate of condensation and the latent heat of condensation; this product, expressed in Btu per hour, would be called a *latent heat* load.

As a further example, the infiltration of outdoor air with a high dry-bulb temperature and a high humidity ratio, and the corresponding escape of room air at a lower dry-bulb temperature and a lower humidity ratio, would increase both the *sensible heat* load and the *latent heat* load.

SOLAR RADIATION

Magnitude of Solar Radiation

If a plane surface were set perpendicular to the sun's rays (i.e., for *normal incidence*) outside the earth's atmosphere, it would receive solar radiation of about 420 Btu per (hr) (sq ft). A similarly oriented surface, at the surface of the earth, would receive considerably less solar energy because a large part of the radiation is scattered in passing through the air; moisture, smoke, and dust which comprise the earth's atmosphere, and also, because some of the atmospheric constituents, notably water vapor, ozone, and carbon dioxide, absorb solar radiation. The intensity of solar radiation varies with wavelength, reaching a peak at about 0.5 microns (a micron equals 1/1000 of a millimeter) and, for practical purposes, is confined to the radiation spectrum between 0.3 and 2.3 microns. The effects of scattering and absorption vary with the wavelength, but to make an exact analysis of these phenomena is impracticable in air-conditioning estimates. The important principle to remember is that the total radiation I_t, received by a surface at the earth, is the sum of I_D and I_d, where

$I_D = KI_{Dn}$ = the *direct* or *beamed* solar radiation, Btu per (hour) (square foot of receiving surface).

I_{Dn} = the direct solar radiation on a plane normal to the sun's rays, Btu per (hour) (square foot of receiving surface).

I_d = the *sky* or *diffuse* solar radiation, Btu per (hour) (square foot of receiving surface). This comes principally from the atmosphere itself as a consequence of scattering. Vertical surfaces also receive solar radiation by reflection of direct and diffuse radiation from the ground and other objects. Such radiation is usually diffuse. The diffuse radiation strikes at *all* angles.

I_t = total incident solar radiation, Btu per (hour) (square foot of receiving surface).

K = cosine of the angle of incidence, θ. For a vertical surface, θ is defined in Fig. 1.

Standardized, practical-purpose values of the *direct* solar radiation I_{Dn} incident upon a plane *perpendicular* to the sun's rays at the earth's surface, have been proposed by Moon.[4] Table 4 gives these values. They are representative of a *clear* summer day at sea level elevation, and are nearly identical with values derived from suggested design sol-air temperatures for Lincoln, Nebraska.[5] Values typical of a humid industrial area derived from sol-air data for New York City[6] are also given in Table 4. Day-to-day changes in the amount of dust and water vapor in the atmosphere cause large differences in solar intensity values observed on cloudless days at a given locality. For example, it has been observed in Cleveland that values of the order of those given for industrial atmospheres are usually associated with dry-bulb and wet-bulb temperatures near the design values of 95 F and 75 F (67 F dew point). On the other hand, values approaching or exceeding those for a clear atmosphere are often encountered during Cleveland summers, but with dew-point and maximum dry-bulb temperatures 10 to 15 deg lower. Considerable judgment, therefore, is required in selecting solar intensity values for design purposes.

Data regarding the irradiation of vertical and horizontal surfaces by diffuse or sky radiation are few. Suggested design values for a 40-deg latitude on August 1 (18-deg declination,

(*Continued on p. 176*)

Notes for Table 2

[a] Data compiled from U. S. Weather Bureau Data and various other sources.

[b] Column 2. The station designation AP or CO indicates airport or city office station, respectively.

[c] Column 3. The elevations marked c are ground elevations of the station. All other elevations given are the actual elevations of the thermometer bulb above mean sea level, corrected to 1948.

[d] The periods of record indicated apply only to the highest temperature ever recorded shown in Column 5, and do not necessarily include all of the summer months of the first year indicated. The last year indicated includes July or August, except those marked d which terminate prior to July of that year.

[e] It should be noted that Column 6 in the United States section of the table applies only to airports, as these data for city stations are not available at this time. The temperature shown is the maximum hourly outdoor temperature which has been equalled or exceeded 2½ percent of the total hours of June, July, August, and September for the 8-year period 1935–1939 inclusive. It is pointed out that in most cases the airport stations are outside of the city, and that these data would apply primarily to rural areas.

[f] Columns 7 and 8 in the United States section and Columns 9 and 10 in the Canadian section of the table record wet- and dry-bulb temperatures in use by ASHAE members as reported by Chapter secretaries for various stations. Where such values were not available, the design temperatures published by API or obtained from various other sources have been inserted.

[g] The average wind velocities in Column 9 in the United States section were furnished by the U. S. Weather Bureau, corrected to 1948. In general these velocities are averages for the months of June through September.

[h] The bulletin published by the ASHAE for the annual weather data of Detroit indicates 73 F as the design wet-bulb temperature which has been equalled or exceeded 5 percent of the hours for period 1935–39.

[i] Blank spaces indicate data not available.

[j] The data for Canada were compiled by D. W. Boyd and Morley Thomas from the records of the Meteorological Division, National Research Council of Canada.

[k] The highest temperature ever recorded in the Canadian section of the table is for the 30-year period, 1921–1950, where available. In some cases the stations have been relocated and in a few instances, some years are missing.

[l] In the Canadian section of the table, the summer design dry-bulb temperatures for the basis of *1*, 2½, *5*, and *10* percent are the Fahrenheit temperature values at or above which these percentages of all the July hourly outdoor temperatures occur, for the years 1941–1950 inclusive.

[m] Most of the wind speeds are based on the periods ending in 1947 which are somewhat shorter than the periods for the highest temperatures. The three months June, July, and August were used.

(*Continued from p. 169*)

north) are given in Table 4 for the two types of atmospheres. These are based upon observations made on cloudless days in Cleveland over a period of several summers. Since less extensive data were available for industrial atmospheres, there is more uncertainty regarding these values. In both instances, the values include an unknown amount of ground reflection, which may be expected to vary with location. It should be noted that clouds which do not obscure the sun tend to *increase* diffuse radiation values. Nearby buildings may *reduce* diffuse irradiation by partial shading.

Calculation Tables

The irradiation of a surface by the sun is the product of I_{Dn}, the direct normal radiation (see Table 4), and the cosine K of the incident angle θ. For horizontal surfaces, the cosine K equals the sine of the solar altitude. For vertical walls, K is a function of the solar altitude β and the wall solar azimuth γ, thus

$$K = \cos\theta = \cos\beta\cos\gamma \qquad (1)$$

These three angles are defined in Fig. 1. Values of K are given in Table 5 and values of β and γ are given in Table 6 for 18-deg north declination (August 1).

To compute K values for orientations other than those given in Table 5, third angle ϕ, the solar azimuth, is required. In this discussion, ϕ will be measured east from south in the morning, and west from south in the afternoon. Hence, ϕ values are equal to 90 deg minus the γ values for an east or west facing wall, except when Table 6 shows the south walls to be in the shade. In this case ϕ equals $90 + \gamma$, that is, ϕ is greater than 90 deg.

The wall azimuth ψ is the angle, measured east from south to the perpendicular to the wall for walls which have an easterly component, and west from south for those having a westerly component. For example, ψ for a wall facing northeast is 135 deg.

The wall solar azimuth γ may be found according to the following schedule:

For walls facing east of south:	For walls facing west of south:
$\gamma = \phi - \psi$ a.m.	$\gamma = \phi + \psi$ a.m.
$\gamma = \phi + \psi$ p.m.	$\gamma = \phi - \psi$ p.m.

Treat negative values of γ as if they were positive. If γ is greater than 90 deg, the wall is in the shade.

Values of K for other seasons and latitudes may be found in the literature,[7] or may be computed from data given in *Hydrographic Office Bulletin* No. 214, *Tables of Computed Altitude and Azimuth*[8] and the Ephemeris of the Sun.[9] Table 7 shows the variation of solar declination during the months ordinarily requiring cooling.

Example 1: Find the solar azimuth ϕ at 6:30 p.m. at 40-deg north latitude on August 1.

Solution: From Table 6 in the column of γ for a wall facing west ϕ for 6:00 p.m. is $90 + 14 = 104$ deg, and at 7:00 p.m. is $90 + 24 = 114$ deg. By interpolation, ϕ for 6:30 p.m. is 109 deg west of south (at 5:30 a.m. ϕ would be 109 deg east of south).

Example 2: Find K for a wall facing 18 deg east of south at 10:00 a.m. on August 1 at 50-deg north latitude.

Solution: The wall azimuth is 18 deg. The solar azimuth is 48 deg east (Table 6). The wall solar azimuth is $48 - 18$ or 30 deg. From Table 6, β is 50 deg. Then

$$K = \cos\beta\cos\gamma = \cos 50 \times \cos 30 = 0.643 \times 0.866 = 0.557.$$

Example 3: Find K for the wall in *Example 2* at 3:00 p.m.

Solution: The solar azimuth is 65 deg west. The wall solar azimuth is therefore $65 + 18 = 83$ deg. The angle β is 42 deg.

$$K = \cos 42 \times \cos 83 = 0.743 \times 0.122 = 0.091.$$

Example 4: Find the total solar irradiation for the wall for the conditions of *Example 2*.

Solution: Use clear atmosphere solar intensities. At 50-deg altitude, the direct normal radiation is 273 Btu per (hr) (sq ft). Then,

$$I_D = K \times I_{Dn} = 0.557 \times 273 = 152.0 \text{ Btu per (hr) (sq ft).}$$

By linear interpolation, the diffuse irradiation is

$$I_d = 25 + \tfrac{15}{60}(33 - 25) = 26.6 \text{ Btu per (hr) (sq ft)}.$$

The total solar irradiation is

$$I_t = 152.0 + 26.6 = 178.6 \text{ Btu per (hr) (sq ft)}.$$

PERIODIC HEAT FLOW THROUGH WALLS AND ROOFS

The calculation of heat flow, through a structural section of a building exposed to the weather, requires consideration of the diurnal cycles of solar irradiation and air temperature. These cycles and other factors lead to a periodic variation in the instantaneous rate of heat flow into the weather surface, and a related periodic variation in the rate of heat flow into the air-conditioned space. Because of heat capacity and other factors, these heat-flow cycles are, in general, out of time phase and unequal in amplitude.

In order to calculate the rate of heat entry into the weather surface of a building, it is necessary to know:

1. The intensity of direct solar radiation striking the surface.
2. The absorptivity (or reflectivity) of the surface for direct solar radiation.
3. The intensity of diffuse or sky solar radiation striking the surface.
4. The absorptivity (or reflectivity) of the surface for diffuse or sky solar radiation.
5. The rate at which the surface emits radiation to the sky and other surroundings.
6. The rate at which the surface absorbs the low temperature radiation emitted by the sky and other surroundings by virtue of their temperatures and radiating characteristics.
7. The temperature of the surrounding air.
8. The temperature of the outer building surface.
9. The unit convective conductance for heat transfer between the air and the building surface.

The Sol-Air Temperature

The complex interrelationship of the above factors can be considerably simplified through the use of the sol-air temperature concept. The sol-air temperature t_e is the temperature of the outdoor air, which, in the absence of all radiation exchanges, would give the same rate of heat entry into the surface as would exist with the actual combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with the outdoor air.

* α = surface absorptivity, dimensionless, roof = 0.9; dark walls = 0.9, and light walls = 0.5. f_o = unit convective conductance = 4.0 Btu per (hr) (F deg).
[b] Values in this column are magnitudes of t_o, the outdoor air temperature.

The sol-air temperature data[4, 9, 10] as developed by Mackey and Wright for an industrial atmosphere were used as a basis for preparing Table 8 showing summer design sol-air temperatures. Sol-air temperatures may also be estimated from experimental observation of surface temperatures of walls and roofs which appear in the literature.[11, 13] Both analytical and experimental studies have been made on the problem[10] of heat flow through walls and roofs. Those concerned with a further study of the details of cooling load estimates in particular relation to periodic heat flow will find much of value and interest in the reports of experimental studies of these problems.[10, 11, 12, 13, 14, 15] The reader may also refer to the Cooling Load chapter of THE GUIDE 1952 for the theory of heat flow through walls and roofs.

PRACTICAL TABLES FOR CALCULATING SOLAR HEAT GAIN THROUGH WALLS AND ROOFS

The analytical[10] method reported by Mackey and Wright was used by Stewart[16] to obtain temperature differentials based on Table 8 and shown in Tables 9 and 10. These analytical procedures, as well as those using Tables 9 and 10, presented here, yield generally higher rates of heat gain than reported for Pittsburgh in early ASHAE experimental studies. Current authoritative opinion indicates a preference for analytical calculations. Thermal and physical properties of materials used in these tables are given in a paper.[16] The rate of heat flow is obtained by multiplying the overall heat transmission coefficient of the structure by the equivalent temperature differential obtained from the tables.

Tables 9 and 10 were developed by using an outside surface conductance of 4.0 and an inside film conductance of 1.65 Btu (hr) (sq ft) (F deg). A reduction was made in the temperature differentials for roofs amounting to some 20 percent of solar radiation as explained by Stewart.[16] This was to compensate for several factors, one of which is the radiant heat lost to the sky which is not included in the Mackey and Wright method. Experimental work by Parmelee[17] and previous work by Brunt[18] give data showing the magnitude of this radiant heat loss from a roof or wall to the sky. Temperature differentials for roofs probably would be reduced below those shown in Table 9 whenever the radiant heat lost to the sky is included in calculation of sol-air temperature. The *temperature differentials* for roofs were based on an inside surface conductance of 1.65 because the charts prepared by Mackey and Wright[10] used this value, and it was not practicable to repeat their work using a different film coefficient. An examination of the values given in their paper indicates that the *temperature differential* would be changed very little even if a value 1.20 were used instead of 1.65. To obtain the heat-flow rates through roofs, more accurate

Notes for Table 9

Explanation: {Total heat transmission from solar radiation and temperature difference between outdoor and room air. Btu per (hr) (sq ft) of roof area} = {Equivalent temperature differential from above table} × {Heat transmission coefficient for summer Btu per (hr) (sq ft) (F deg)}

1. *Source.* Calculated by Mackey and Wright method (see reference list) and adjusted after studying ASHAE original test data. Estimated for about August 1 in 40 deg north latitude. (For sol-air temperatures used in calculations see Table 8.) For typical design day where the maximum outdoor temperature is 95 F and minimum temperature at night is approximately 75 F (daily range of temperature, 20 F) mean 24 hr temperature 84 F for a room temperature of 80 F. All roofs have been assumed a dark color which absorbs 90 percent of solar radiation, and reflects only 10 percent.

2. *Application.* These values may be used for all normal air conditioning estimates; usually without correction, in latitude 0 deg to 50 deg north or south when the load is calculated for the hottest weather. Note 5 explains how to adjust the temperature differential for other room and outdoor temperatures.

3. *Peaked Roofs.* If the roof is peaked and the heat gain is primarily due to solar radiation, use for the area of the roof, the area projected on a horizontal plane.

4. *Attics.* If the ceiling is insulated and if a fan is used in the attic for positive ventilation, the total temperature differential for a roof exposed to the sun may be decreased 25 percent.

5. *Corrections. For temperature difference when outdoor maximum design temperature minus room is different from 15 deg.* If the outdoor design temperature minus room temperature is different from the base of 15 deg, correct as follows: When the difference is greater (or less) than 15 deg add the excess to (or subtract the deficiency from) the above differentials.

For outdoor daily range of temperature other than 20 deg. If the daily range of temperature is less than 20 deg, add 1 deg for every 2 deg lower daily range; if the daily range is greater than 20 deg, subtract 1 deg for every 2 deg higher daily range. For example, the daily range in Miami, Florida is 12 deg or 8 deg less than 20 deg, therefore, the correction is +4 deg at all hours of the day.

Notes for Table 9.... Total Equivalent Temperature Differentials for Calculating Heat Gain Through Sunlit and Shaded Roofs (Concluded)

Light Colors. Credit should not be taken for light colored roofs except where the permanence of the light color is established by experience, as in rural areas or where there is little smoke. When the exterior surface of roof exposed to the sun is a light color, such as white or aluminum (which absorb approximately 50 percent and reflect 50 percent of the solar radiation) add to the temperature differential for roof in shade 55 percent of the difference between the roof in sun and roof in shade. When the roof exposed to the sun is a medium color such as light grey, blue or green, or bright red, add 80 percent of this difference.

For solar transmission in latitudes other than 40 deg north, and in other months. The table values of temperature differentials will be approximately correct for a roof in the following months:

North Latitude		South Latitude	
Latitude (deg)	Months	Latitude (deg)	Months
0	All months	0	All months
10	All months	10	All months
20	All months except Nov, Dec, Jan	20	All months except May, June, July
30	Mar, Apr, May, June, July, Aug, Sept	30	Sept, Oct, Nov, Dec, Jan, Feb, Mar
40	April, May, June, July, Aug	40	Oct, Nov, Dec, Jan, Feb
50	May, June, July	50	Nov, Dec, Jan

For other months, the total temperature differential (t_d) may be approximated by the use of the following formula:

$$t_d = t_s + \frac{I_s}{I_y}(t_e - t_s)$$

where

t_s = temperature differential for the same roof in shade for desired time of day; obtained from Table 9.

I_y = maximum solar transmission through glass, Btu per (hr) (sq ft) for flat skylight in Aug., 40 deg north latitude (*Note:* this is maximum value irrespective of time).

I_s = same as I_y except use the maximum value for flat skylight, for month, and latitude desired for t_e.

t_e = temperature differential for particular roof exposed to sun for the desired time of day from Table 9.

(*Note that this makes adjustment only for solar radiation and that there may be additional correction for outdoor temperature.*)

values will be obtained if the *overall heat transmission coefficient is calculated using* 1.2 as the inside film conductance for summer.

The roof coefficients of transmission for summer shown in Table 11 are based on surface conductances f_{so} of 4.0 for an outside roof surface and 1.20 for an inside ceiling surface. The outside conductance 4.0 is used for summer because it corresponds to a wind velocity of approximately 7.5 mph averaged for rough and smooth surfaces, and is more representative of summer wind velocities. Also, the lower wind velocity should be used in order to be on the safe side in determining the sol-air temperature. The inside conductance 1.20 is used because the convective portion of the film conductance for downward heat flow from a horizontal surface is appreciably less than the winter conductance for heat flowing upward.

Since there is little difference in *wall transmission coefficients* for summer, based on the conductances of 4.0 and 1.65, and the winter coefficients, based on 6.0 and 1.65, it is recommended that the overall coefficient *U, for walls*, be taken directly from the tables in Chapter 9 in which they are based on an outside film conductance of 6.0, corresponding to a 15 mph wind velocity.

Advantages of Equivalent Temperature Differential Method

The advantages of the *equivalent* temperature differential method of determining the total heat transmission are given in following paragraphs, and are apparent from *Examples 5* to 7.

1. The total sensible heat flow is obtained by multiplying the overall heat transmission coefficient U, and the equivalent temperature differential indicated in Tables 9 and 10.

2. The temperature differentials listed for a few representative types of construction may be used on all classes of walls and roofs, even though the overall heat transmission coefficient is different, provided the structure has thermal and physical properties similar to one of those listed in Tables 9 and 10.

3. Adjustments can be made, according to instructions given in the footnotes, for room and outdoor conditions different from those on which the tables are based.

Examples of Use of Equivalent Temperature Tables

Example 5: Given: A roof is constructed of 6 in. of stone concrete with 2 in. of insulating board and tar felt roofing ⅜ in. thick, and is exposed to the sun. The location is the central part of the United States. Find the rate of heat flow into building at 2:00 p.m. during July for an outdoor design temperature 95 F, and an indoor temperature 80 F.

Solution: From Table 9 in 2 p.m. column for 6-in. concrete plus 2-in. insulation find the total equivalent temperature differential 34 deg. The overall heat transmission coefficient for summer is taken from Table 11 and is found to be 0.13. The heat-flow rate equals 34 × 0.13 = 4.42 Btu per (hr) (sq ft).

Example 6: For the conditions of *Example 5*, find the rate of heat flow into building at 2:00 p.m. during July for design temperatures of 105 F (outdoor) and 78 F (indoor). Daily range of temperature 30 deg, i.e., outdoor temperature minimum of 75 F which occurs at 4:00 or 5:00 a.m.; this being 30 deg less than the maximum.

Solution: Make correction in equivalent temperature differential in accordance with Note 5 in Table 9 as follows:

The correction for 27-deg design temperature difference is (27 − 15) = +12.

The correction for 30-deg daily range is $\left(-\frac{30-20}{2}\right) = -5$.

Net total correction is +12 − 5 = +7.

The heat-flow rate at 2:00 p.m. is (34 + 7) × 0.13 = 5.32 Btu per (hr) (sq ft).

A method of determining *heat-flow rates*, when structure is not given in Tables 9 or 10, is illustrated in *Example 7*.

Example 7: A 4-in. stone concrete roof covered with an average depth of 4 in. of cinder concrete ($k = 4.9$), on which is placed a ⅜-in. thick felt roof with ½-in. pitch and slag

Notes for Table 10

Explanation: {Total heat transmission from solar radiation and temperature difference between outside and room air, Btu per (hr) (sq ft wall area)} = {Equivalent temperature differential from above table} × {Heat transmission coefficient for wall, Btu per (hr) (sq ft) (F deg)}

1. *Source.* Same as Table 9. A north wall has been assumed to be a wall in the shade; this is practically true. Dark colors on exterior surface of walls have been assumed to absorb 90 percent of solar radiation and reflect 10 percent; white colors absorb 50 percent and reflect 50 percent. This includes some allowance for dust and dirt since clean, fresh white paint normally absorbs only 40 percent of solar radiation.

2. *Application.* These values may be used for all normal air conditioning estimates, usually without corrections, when the load is calculated for the hottest weather. Correction for latitude (Note 3) is necessary only where extreme accuracy is required. There may be jobs where the indoor room temperature is considerably above or below 80 F, or where the outdoor design temperature is considerably above 95 F, in which case it may be desirable to make correction to the temperature differentials shown. The solar intensity on all walls other than east and west varies considerably with time of year.

3. *Corrections. Outdoor minus room temperature.* If the outdoor maximum design temperature minus room temperature is different from the base of 15 deg, correct as follows: When the difference is greater (or less) than 15 deg, add the excess to (or subtract the deficiency from) the above differentials.

Outdoor daily range temperature. If the daily range of temperature is less than 20 deg, add 1 deg to every 2 deg lower daily range; if the daily range is greater than 20 deg, subtract 1 deg for every 2 deg higher daily range. For example, the daily range in Miami, Florida is 12 deg, or 8 deg less than 20 deg; therefore, the correction is +4 deg.

Color of exterior surface of wall. Use temperature differentials for light walls only where the permanence of the light wall is established by experience. For cream colors use the values for light walls. For medium colors interpolate half way between the dark and light values. Medium colors are medium blue, medium green, bright red, light brown, unpainted wood, natural color concrete, etc. Dark blue, red, brown, green, etc., are considered dark colors.

For latitudes other than 40 deg north; and in other months. These table values will be approximately correct for the east or west wall in any latitude (0 deg to 80 deg North or South) during the hottest weather. In the lower latitudes when the maximum solar altitude is approximately 80 deg to 90 deg (the maximum occurs at noon) the temperature differential for either a south or north wall will be approximately the same as a north, or shade wall. The temperature differential (t_s) for any wall facing, and for any latitude for any month may be approximated as follows:

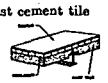
$$t_s = t_g + \frac{I_2}{I_1} \times (t_w - t_g)$$

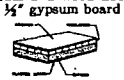
where

t_g = temperature differential for the same wall in shade for desired time of day; obtained from Table 10.

I_1 = maximum solar radiation intensity transmitted through glass, Btu per (hr) (sq ft) for particular wall facing, in July, 40 deg north latitude (*note:* this is maximum value irrespective of time).

I_2 = same as I_1 except use the maximum value for wall facing, for month, and latitude desired for t_g.





t_w = temperature differential for particular wall facing, for the desired time of day from above table.

(*Note that this makes adjustment only for solar radiation, and that there may be additional correction for outdoor temperature.*)

4. *For insulated walls* use same temperature differentials as used for uninsulated walls.

[a] The summer coefficients are considered temporary, and have been calculated with an outdoor wind velocity of 8 mph. For summer an inside surface conductance of 1.2 has been used instead of the regular 1.65 value. In all of these roofs a 4 ply felt roof has been assumed ⅜ in. thick, thermal conductivity = 1.33. Pitch and slag have been assumed as an additional thickness of ½ in. which has been assigned thermal conductivity = 1.0. In both cases thermal conductivity refers to one inch thickness.

[b] 87½ percent gypsum, 12½ percent wood fiber. Thickness indicated includes ½ in. gypsum board. This is a poured roof.

[c] Nominal thickness of wood is specified, but actual thickness was used in calculations.

[d] If corkboard insulation is used, the coefficient *U* may be decreased 10 percent.

surface, is exposed to the sun. The location is the central part of the United States. Design temperatures are: outdoor 95 F; daily range 20 deg; indoor temperature 80 F. Find the heat-flow rate at 2:00 p.m. for a day in July.

Solution: For the purpose of selecting the *equivalent temperature differential*, this construction is assumed to be equal approximately to an uninsulated 6-in. concrete roof, for which the equivalent temperature is found to be 38 deg in the 2:00 p.m. column of Table 9. Calculate the overall heat transmission coefficient *U* (see Equation 3 of Chapter 9) of the roof as follows:

$$U = \frac{1}{\frac{1}{1.2} + \frac{4}{12} + \frac{4}{4.9} + \frac{0.375}{1.33} + \frac{0.50}{1.00} + \frac{1}{4.0}} = 0.33$$

The heat-flow rate is then 38 × 0.33 equals 12.5 Btu per (hr) (sq ft).

TABLES FOR CALCULATING SOLAR HEAT GAIN THROUGH GLASS AREAS

Basic Principles

In order to set forth the principles involved in calculating heat flow through glass areas, the general instantaneous heat balance relation will be presented. It will be shown schematically in Fig. 2. The net heat gain for the indoor space is the result of several contributing factors.

The following observations concerning the behavior of

glass with respect to radiant energy will lead to a better understanding of the heat balance relation.

1. Glass transmits, in varying degrees, radiation having wavelengths between 0.29 and 4.75 microns. The percentage of each wavelength transmitted is dependent upon the chemical and physical characteristics of the glass, and upon the angle of incidence of the radiant energy. Of the energy not transmitted, part is absorbed and part reflected.

2. Glass is opaque to radiant energy emitted from sources below 450 F.

3. Because of the above principles, it is convenient to group radiant energy into two classifications, solar radiant energy and low temperature radiant energy.

The complete heat balance for a glass section can be expressed for a unit time interval as follows:

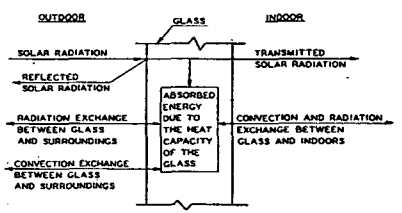

Fig. 2 .... Instantaneous Heat Balance for a Glass or Glass Block Section

$$\begin{bmatrix}\text{Total heat flow,}\\ \text{through glass section}\end{bmatrix} = \begin{bmatrix}\text{Transmitted,}\\ \text{solar radiation}\end{bmatrix} \pm \begin{bmatrix}\text{Heat flow by convective}\\ \text{and radiative exchanges at}\\ \text{the indoor surface}\end{bmatrix} \quad (2a)$$

The second term of the right side of Equation 2a can also be expressed by a heat balance equation as follows:

$$\begin{bmatrix}\text{Heat flow by convective}\\ \text{and radiative exchanges}\\ \text{at the indoor surface}\end{bmatrix} = \begin{bmatrix}\text{Absorbed}\\ \text{solar}\\ \text{radiation}\end{bmatrix} \pm \begin{bmatrix}\text{Radiative exchanges be}\\ \text{-tween outer surface of glass}\\ \text{and outdoor surroundings}\end{bmatrix} \quad (2b)$$

$$\pm \begin{bmatrix}\text{Convective exchanges}\\ \text{between outer surface of}\\ \text{glass and outdoor air}\end{bmatrix} \pm \begin{bmatrix}\text{Heat storage}\\ \text{within the}\\ \text{glass section}\end{bmatrix}$$

Equations 2a and 2b can be combined and expressed in symbolic terms by Equation 2c. Tabular values of the two bracketed terms of Equation 2a are presented later in this section for various types of glass for specific design conditions.

$$(q/A) = [\tau_D I_D + \tau_d I_d] + [\alpha_D I_D + \alpha_d I_d + \epsilon_{go} R_s - \epsilon_{go} R_{go} - f_{co}(t_{go} - t_o) - S] \quad (2c)$$

where

(q/A) = instantaneous rate of heat flow, Btu per (hour) (square foot).

τ_D, τ_d = transmittance of glass for direct and diffuse solar radiation, respectively.

I_D, I_d = incident direct and diffuse solar radiation, respectively, Btu per (hour) (square foot).

α_D, α_d = absorptance of glass for direct and diffuse solar radiation, respectively.

ϵ_{go} = emissivity of glass at temperature t_{go}.

R_s = low temperature radiant energy falling on glass from outdoor surroundings, Btu per (hour) (square foot).

R_{go} = low temperature radiant energy emitted by a surface with emissivity equal to 1.0 at temperature t_{go}.

f_{co} = outdoor convective conductance, Btu per (hour) (square foot) (Fahrenheit degree).

t_{go} = temperature of outdoor surface of glass, Fahrenheit.

t_o = temperature of outdoor air, Fahrenheit.

S = rate at which glass stores energy, Btu per (hour) (square foot).

Transmissivity and absorptivity vary with both wavelength of the incident radiation and incident angle. Normal incidence transmittance values for some commonly used types and combination are given in Table 14. Some variation in these values can be expected in practice due to variations in manufacture and in solar energy distribution. However, a change in transmissivity causes a compensating change in absorptivity. Generally, the *total heat flow* is not greatly altered. Transmittance data for a number of types of glass and various patterns of 8-in. glass block are given in ASHAE research papers.[19, 20, 21, 22, 23, 24]

As stated earlier in this chapter, present data as to the value of R_s are inadequate, so for the present it is suggested that f_{co} be increased to include radiation, and the term $\epsilon_{go}R_s - \epsilon_{go}R_{go}$ be disregarded. It is not practicable to give values of S in this chapter. However, for ordinary glass, the value of S is small.

Fig. 3 is a graphical solution, for single glass, of Equation 2b. Only absorbed solar radiation is considered, although low temperature radiation exchange and heat storage can be added algebraically to $\alpha_i I_i$ if such data are available. The small thermal resistance of the glass has been neglected. The heat-flow rates are for 80 F indoor temperature, an in-

Table 14 .... Application Factors to Apply to Tables 12, 13 and 15 to Obtain Instantaneous Rates of Heat Gain for Various Types of Single Flat Glass and Combinations of Two Sheets of Flat Glass Spaced at ¼ In.

Glass[a]	Normal Incidence Transmittance	Factor to Apply to Table 12	Factor to Apply to Table 13
Single common window	0.87	1.00	$1.0(X)^c + 0.0(Y)^d$
Single regular plate	0.77	0.87	$1.0(X) + 0.25(Y)$
Single heat absorbing plate	0.41	0.46[b]	$1.0(X) + 1.00(Y)$
Double common window	0.76	0.85	$0.6(X) + 0.10(Y)$
Double regular plate	0.60	0.66[b]	$0.6(X) + 0.55(Y)$
Heat absorbing plate outdoors, Regular plate indoors	0.35	0.37[b]	$0.6(X) + 0.75(Y)$

[a] Common window glass ⅛ in. thick. Plate glass ¼ in. thick.

[b] For better precision, increase factors 10 percent when glass is in the shade.

[c] X values are Table 13 values.

[d] Y values are Table 15 values.

side surface conductance for convection f_{ci} as given by Equation 3, and an equivalent surface conductance for radiation f_{ri} as given by Equation 4. Inside surfaces *seen* by the glass are assumed to radiate as a black body at room air temperature.

$$f_{ci} = 0.27\ (t_{gi} - t_i)^{0.25} \qquad (3)$$

$$f_{ri} = 0.162\left[\left(\frac{t_{gi} + 460}{100}\right)^4 - \left(\frac{t_i + 460}{100}\right)^4\right] \Big/ (t_{gi} - t_i) \qquad (4)$$

where

t_{gi} = temperature of inside surface of glass, Fahrenheit.

t_i = temperature of indoor air, Fahrenheit.

A more complete treatment of the problem is given in an ASHAE research paper.[22]

Design Tables for Flat Glass

Tables 12 and 13 give design values of instantaneous rates of heat gain for *single unshaded common window glass* for a solar declination of 18 deg. This corresponds to a nominal August 1 day. The tables are based upon the solar intensity values for a clear atmosphere as given in Table 4. Table 12 values represent the first bracketed term of Equation 2a; therefore, the values are dependent only upon values of I and τ. Table 13 values represent the second term of Equation 2a, and are based upon a 80 F indoor temperature and a dry-bulb temperature cycle, with a 95 F maximum as tabulated. *The total heat gain is the sum* of the Table 12 and Table 13 values. In preparing Table 13, convection and radiation heat exchange were combined, and a combined surface conductance of 4.0 used. Corrections to be applied for other design temperatures are given in Table 24 in a later section Effect of Deviation from Design Conditions.

Tables 12 and 13 may be used for other types of glass with good accuracy, by using the factors given in Table 14. Table 12 values are multiplied by the appropriate factor given in Table 14 to obtain heat gain due to transmitted solar radiation. For glasses having a transmittance for normally incident radiation differing from the table values, factors may be found by linear interpolation. To obtain instantaneous rates of heat gain by convection and radiation, two steps are required. *First*, Table 13 values are multiplied by the appropriate coefficient of X listed in Table 14. *Second*, Table 15 values are multiplied by the appropriate coefficient of Y listed in Table 14, and added to the first value. All convection and radiation gain values for double glass were computed for a ¼-in. air space. No great error is involved in cooling load estimates if these are used for double glass with other air spaces.

Example 8: Find the total instantaneous heat gain through a single sheet of regular plate glass in a southwest wall at 2 p.m. sun time and 40-deg north latitude on August 1. The maximum dry-bulb temperature for design is 98 F; the atmosphere is clear. The indoor temperature is 80 F.

Solution: From Table 12 the heat gain due to transmitted radiation is 148 Btu per (hr) (sq ft) for common window glass; from Table 14, the factor for regular plate glass is 0.87. The coefficient of X in Table 14 is 1.0, while X is found from Table 13 for common window glass for the same hour, orientation and latitude. The coefficient of Y in Table 14 is 0.25, while the Y value is found from Table 15 for a southwest wall at 2:00 p.m. and 40-deg north latitude. The correction for design dry-bulb temperature is found from Table 24 to be 1.0 Btu per (hr) (sq ft) per degree difference from 95 F design temperature. The total instantaneous heat gain is, from Equation 2a,

$$q = 0.87 \times 148 + 1.0 \times 19 + 0.25 \times 27 + 1.0\ (98 - 95)$$
$$= 157.5 \text{ Btu per (hr) (sq ft)}.$$

Design Tables for Rolled Figured Glass

Tables 16 and 17 give design values of instantaneous rates of heat gain for a number of common patterns of single vertical sheets of rolled figured glass. The tables are for a solar declination of 18 deg, which corresponds to a nominal August 1 day, and are based upon the solar intensity values for a clear atmosphere as given in Table 4. The values are given in terms of corrections to apply to Tables 12 and 13. The heat gain due to transmitted solar radiation is found by multiplying the Table 12 values by the approximate percentages given in Table 17. To obtain instantaneous rates of heat gain by convection and radiation, Table 15 values are multiplied by the appropriate value of Y from Table 16 and then added to the corresponding Table 13 values. The total instantaneous heat gain is the sum of the gain due to transmitted solar radiation and the gain by convection and radiation.

The values given in Tables 16 and 17 are based upon an ASHAE research paper[23] to which the reader is directed for additional data. The values in Tables 16 and 17 may be used with fair precision for other patterns of similar transmittance and surface characteristics. For example, the data for hammered glass may be used for glass having shallow, closely spaced ribs or for glass having small, closely spaced circular indentations. Because some patterns have distinct orienta-

tion properties, no attempt has been made to give values for nonvertical glass.

Design Tables for Glass Block Walls

Table 18 describes the glass block patterns discussed in following text. Table 19 gives design values for instantaneous heat gain due to *transmitted direct and diffuse solar radiation* for 8-in. hollow glass block of Type I pattern. For glass blocks of Types II to V the corresponding instantaneous heat gain is found by multiplying the value found for Type I block from Table 19 by the appropriate factor from Table 20.

The instantaneous rate of heat gain due to *convection and radiation* for unshaded 8-in. hollow glass blocks of Types I to V are given in Table 21. The *convection and radiation* gain values for all blocks are so nearly the same that a single table suffices. Note, however, that corrections must be made for certain hours for east and west facing walls of some patterns.

Tables 22 and 23 give instantaneous heat gain values for two types of glass block design for use in skylights. The Type VI block is 10⅝ x 10⅝ in. and the Type VII block 12 x 12 in.

It should be noted that the data for Type VI glass block in Tables 22 and 23 are for panels as assembled. Since the manner of mounting this type of block is standard the ratio of glass area to *opaque* area is virtually constant from one skylight to another. The Type VII glass block may be mounted on a wide range of center-to-center distances. The *opaque* portion of the assembly should be given separate consideration independent of the glass block. See Reference 24 for more complete information.

These tables are based upon the solar intensity values for a clear atmosphere as given in Table 4. For solar energy transmittance data refer to References 21 and 24.

The values of convection and radiation gain are based on values of 80 F for indoor air temperature, a maximum outdoor air temperature of 95 F and upon experimentally determined values of solar energy and temperature difference between the two faces. Indoor and outdoor convection and radiation heat-transfer values are the same as those used for common

Table 16 . . . . Application Factors to Apply to Tables 13 and 15 to Obtain Instantaneous Rates of Heat Gain for Vertical Single Sheets of Rolled Figured Glass Having Normal Incidence Transmittances and Listed Thicknesses (Smooth Side Indoor, Figured Side Outdoor)

(See Table 17 for Factors to Apply to Table 12 Values)

Glass Pattern	Normal Incidence Transmittance	Thickness, Inches	Factor to Apply to Table 13
Hammered	0.75	7/32	1.0(X)[a] + 0.50(Y)[b, e]
Hammered, etched both sides	0.67	7/32	1.0(X) + 0.65(Y)[d]
Deep ribs on ⅛ in. centers	0.77 approx.	7/32	1.0(X) + 0.50(Y)[e]
Hammered heat absorbing	0.21	¼	1.0(X) + 1.15(Y)[f]
Hammered heat absorbing, etched both sides	0.14	¼	1.0(X) + 1.40(Y)

Type VII—Light-diffusing (skylight)
A: Smooth surface
B, C: Stippled surface
D: Narrow-ribbed surface
E: Green-tinted glass fiber screen

window glass. Table 24 gives corrections to be applied for other design temperatures.

Example 9: Find the total instantaneous heat gain through an east wall of 8-in. hollow glass block of Type V pattern at 8 a.m. and 50-deg north latitude. The design temperatures are 80 F indoors and 95 F maximum outdoor dry-bulb, with a clear atmosphere.

Solution: The gain due to transmitted solar radiation is found from Table 19 for Type I pattern. The factor for Type V is found from Table 20. The convection and radiation gain is found from Table 21 (note the footnote).

The total instantaneous heat gain is, from Equation 2a,

$$q = 86 \times 0.65 + 26 \times 1.4 = 92.3 \text{ Btu per (hr) (sq ft)}.$$

Effect of Deviations from Design Conditions

If the indoor temperature differs from 80 F, or the design outdoor dry-bulb temperature differs from 95 F, corrections can be made to the convection and radiation gain values for flat glass, rolled figured glass, and glass block according to the schedule in Table 24.

The effect of the humid industrial-type atmosphere is to cause a considerable reduction in heat gain, if all factors except solar intensity remain the same. Reference 22 gives heat gain values for four orientations at 40-deg north latitude on August 1 for several types of flat glass and glass block, and solar intensities typical of humid industrial atmospheres. These data show that the following approximate reductions, based on total gain for the day, can be expected: 20 percent for all types of glass and glass block in east or west facing walls; 10 percent for south facing flat glass; 5 percent for south facing glass block walls.

Shading of Glass Areas—Shade Factors

The shade factor is defined as the total gain from a shade-glass combination minus the convection and radiation gain from single unshaded common window glass divided by the total incident solar radiation transmitted by single unshaded common window glass. In equation form,

$$\text{Shade factor} = \frac{\left(\begin{matrix}\text{Total Gain from}\\ \text{Shade Glass}\\ \text{Combination}\end{matrix}\right) - \left(\begin{matrix}\text{Convection \& Radiation}\\ \text{Gain from Single}\\ \text{Unshaded Common Glass}\end{matrix}\right)}{\begin{matrix}\text{Total Solar Energy Transmitted by}\\ \text{Single Unshaded Common Glass}\end{matrix}}$$

Design shade factors for a number of combinations are listed in Table 25. The total gain for a shaded window is found by multiplying the values of Table 12 by the appropriate shade factor and adding to these values the corresponding values from Table 13.

The values for sunlit windows are average values based upon calculations for several orientations. Actually the shade factor varies somewhat with orientation and time of day, because the proportion of direct to diffuse incident solar radiation as well as the profile angle varies. Generally these variations may be neglected.

There are a number of variables affecting these ratios such as color, fit, solar altitude, and angle of incidence of the solar radiation. These values, therefore, must be considered as approximate, only, and will have to be used with considerable judgment. An inside shade is effective to the extent of its reflectivity, since the portion of the solar radiation directly transmitted by the glass that is absorbed by the shade is transferred by convection to the room air, and by radiation to the solid room surfaces.

A more complete analysis of shade factors may be found in Reference 25.

Roof Overhang, Canopies, and Other Horizontal Projections

In some cases, a considerable reduction in heat transfer through windows can be attained by the use of a suitable horizontal projection. This is particularly true for S, SE, and SW orientations. In Table 26 are tabulated the required projections to produce a shadow height of 10 ft on a window or wall. The projection necessary for other shadow heights can be found by direct ratio. For example, a shadow height of 5 ft would require one-half the projection needed for a shadow height of 10 ft. Note that the table is for the period from April 11 through September 1.

The choice of projection should not necessarily be based on providing complete shading during all daylight hours. Reference should be made to Tables 12 through 15 to determine during which hours of the day the solar gain is sufficiently large to indicate the desirability of shading. This and the architectural practicability of the required projection should be deciding factors.

INSTANTANEOUS HEAT GAINS VS. INSTANTANEOUS COOLING LOADS

The difference between instantaneous heat gain and instantaneous cooling load has been mentioned previously; its practical importance is sufficient to warrant further consideration. Fig. 4 offers a simplified schematic illustration showing how the *radiative* part of the instantaneous heat gain is first absorbed by solid objects, and is not encountered by the conditioning equipment as a cooling load until some later time, when it finally appears in the air stream entering the equipment. While it is true that some lag also is inherent in convective heat transfer and the time required to change the air in the conditioned space, this is usually of the order of a few minutes to perhaps half an hour. Heat storage in the interior furnishings and structure increases according to the proportion of the instantaneous heat gain which is in the form of radiation, and also increases as the thermal capacitance of the objects and materials involved is increased.

The radiation absorbed by the interior furnishings and structure reaches the conditioning equipment after a considerable delay in time.

Fig. 4 .... Origin of the Difference Between the Magnitudes of the Instantaneous Heat Gain and Instantaneous Cooling Load

Constituents of the total instantaneous heat gain which have appreciable radiation components include those due to glass areas, exposed walls and roofs, lighting, appliances, and people.

A large difference in the time-incidence of the peaks between various spaces or parts of the same space indicates the necessity for zoning. In a building having an east and west exposure, where solar heat gains form a fair share of the cooling load, the times of individual zone peaks are apt to be some hours apart, and the peak load of one plus the off-peak load of the other will be substantially less than their combined peak loads. Proper zoning will permit operation to take full advantage of this condition or of similar conditions of nonsimultaneous peaks, and will result in a lower total load and in savings in equipment.

A factor similar in effect and closely related to the non-

simultaneous occurrence of peak loads, is diversity. Typical of this is the case of a large department store where the air-handling equipment serving a certain space must be sufficient to handle the load created by the throngs of people attending sales in that space. Under such a condition the number of people in other spaces is usually normal or below. While this means that the air-handling equipment for certain departments must be large enough to cope with the situation, the refrigeration equipment need be only large enough to handle the average maximum. If a system employing zone recirculating fans and a single central fan and dehumidifier were used, the saving would be reflected in the capacity of the central fan and dehumidifier. Another example of this diversity is found in an office building having restaurants and stores of certain types in the first story and basement.

[b] For N, NE, E, W and NW use 40 deg North Latitude values.

At noon, when the restaurants and stores are crowded, the offices are below normal occupancy.

Heat lag should be carefully considered in the cooling load calculations. In certain types of buildings the effect of solar radiation is still apparent several hours after the sun has shifted from that exposure. In other types having a much lighter construction, the heat gain due to solar radiation decreases markedly with the passing of the sun. Some walls, warmed by the sun, may radiate heat long after the passing of the sun, thus requiring lower indoor temperatures to offset the radiant energy.

Buildings have considerable heat storage capacity which can often be utilized to great advantage, and which has provided an unexpected safety factor in many installations. If a space is kept below the design indoor temperature for some time, the interior walls, floors, furniture, and fixtures begin to assume the temperature of the space. Where the time is sufficient the entire mass, rather than merely its surface, may reach the room temperature. Thus, when a space has been precooled below the design maximum temperature for a period of time prior to the advent of the peak load, and the heat gain begins to increase to peak conditions, some of the increase is used in raising the temperature of the furniture, fixtures, etc., to the design conditions and the cooling load can be reduced accordingly. However, unless very accurate data with regard to the mass, surface, specific heat, etc., of the items within the space are available, due caution must be used in discounting the cooling load for this storage effect. In the absence of reliable data this allowance is often a matter of experience rather than calculation.

Table 24 .... Approximate Corrections to Tables 13 and 21 for Deviations from Indoor and Outdoor Design Temperatures

For each degree the design room temperature exceeds 80 F, subtract correction.[a] For each degree the design outdoor dry-bulb temperature exceeds 95 F, add correction.[b] Apply these corrections to each value in Table 13 or Table 21.

Glass Type	Correction Btu per (hr) (sq ft)
Single flat or rolled figured glass	1.0
Double flat glass and glass block	0.5

[a] If temperature is less than 80 F, add correction.
[b] If temperature is less than 95 F, subtract correction.

Where air-conditioning supply and return ducts pass through unconditioned spaces, there will be a transfer of heat from these spaces to the air in the ducts, even though these ducts are well insulated. An allowance should be made for this heat gain and included in the heat estimate so that air can be supplied at a temperature low enough to offset the rise caused by this heat gain (see Chapter 21). There will also be some heat gain to the air in ducts passing through conditioned spaces, but since a cooling effect is produced in *the space through which the duct passes, this is not a loss* and usually can be compensated for by adjustment of air quantities between the various spaces.

No comprehensive data are presently available for use in design load estimates to evaluate the interior load-lag effect, but several investigators[12, 14, 26, 27, 28] have made a study of the problem and have presented many useful data. Tables 9, 10, 12, 13, 17, 19, 20, 21, 22, and 23 are all based on instantaneous rates of heat transfer. Hence, practical judgment and experience offer the only basis of procedure. Until the needed data become available, it is recommended that the noncontinuous load be averaged over two or three hours during the time of maximum load, when determining the total instantaneous cooling load where a large portion of the heat gain is radiant. This suggestion applies only to conditions near the time of maximum heat gain, as the heat stored within the structure would necessarily appear in the cooling load eventually; but if it appears at a time when the gain from outdoors is relatively low, the equipment will be able to maintain satisfactory conditions within the range of maximum capacity.

LOAD FROM INTERIOR PARTITIONS, CEILINGS, AND FLOORS

Whenever a conditioned space is adjacent to another space in which a different temperature prevails, the transfer of heat through the separating structural section must be considered. Calculations are made according to the relation:

$$q = U_i A_i (t_b - t_i) \text{ Btu per hour.} \quad (6)$$

where

U_i = coefficient of overall heat transfer between the adjacent and the conditioned space, Btu per (hour) (square foot) (Fahrenheit degree).

Table 25 .... Shade Factors for Various Types of Shading

Type of Shading	Finish on Side Exposed to Sun	Shade Factor
Canvas awning sides open	Dark or medium	0.25

[a] Projection greater than 20 ft required.

A_i = area of separating section concerned, square feet.

t_b = air temperature in adjacent space, Fahrenheit.

t_i = air temperature in conditioned space, Fahrenheit.

Magnitudes of U_i may be obtained from Chapter 9. The temperature t_b may have any value over a considerable range, according to conditions in the adjacent space. The temperature in a kitchen or boiler room may be as much as 15 to 50 deg above the outdoor air temperature. It is recommended that actual temperatures be measured in adjoining spaces wherever practicable. Where nothing is known, except that the adjacent space is of conventional construction and contains no heat sources, it is recommended that the difference $(t_b - t_i)$ be taken as the difference between the outdoor air and conditioned-space design dry-bulb temperatures *minus* 5 deg. In some cases it may be that the air temperature in the adjacent space will correspond closely to the outdoor air temperature at all times. Under these latter conditions, the heat gain through the partition will be periodic in nature, and the value of a shaded wall should be used from Table 10.

For floors directly in contact with the ground, or over an underground basement that is neither ventilated nor warmed, the heat transfer may be neglected for cooling-load estimates.

LOAD FROM OUTDOOR AIR, VENTILATION, AND INFILTRATION

Ventilation. Data for determining the necessary ventilation rate have been presented previously in this chapter. Ventilation required is primarily dependent upon the number of occupants and upon the materials and apparatus within the space which may give off odors. For spaces having ceiling heights 10 ft or less, the total requirement should be checked against the volume, and in no case should the ventilation air rate be less than one air change per hour. In spaces having ceilings higher than 10 ft where the occupant load is low, a check calculation can be made against the volume of the space below an assumed 10-ft ceiling.

Infiltration must never be counted upon to provide ventilation, because on still days there will be little or no infiltration.

Infiltration. The principles of infiltration calculations have been discussed in Chapters 11 and 12, with emphasis on the heating season. For the cooling season, infiltration calculations are usually limited to doors and windows.

To compute cooling-load infiltration for windows by the crack method, use the data of Table 2, Chapter 11, for a wind velocity of 10 mph. Note that for double-hung windows the length of crack is three times the width plus twice the height; while for metal-sash windows the crack length is the total perimeter of the movable or ventilating sections. In calculating window infiltration for an entire structure, it is not necessary to consider the total crack length on all sides of the building, for the wind would not act simultaneously on all sides at once. In no case, however, should less than half of the total crack length be figured. A knowledge of the prevailing wind direction will aid judgment in this consideration.

Cooling-load infiltration for doors[28] may be obtained from Table 3, Chapter 11. For conditions other than those covered, the notes appended to the table will provide a basis for estimates. The tabulated data may also be used as the basis of estimates for interior doors between an air-conditioned and a non-air-conditioned space.

Infiltration load must be included whenever the new air introduced through the system is not sufficient to maintain sufficient pressure within the enclosure to prevent the infiltration. Whenever economically feasible, it is desirable to introduce sufficient outdoor air through the air-conditioning equipment to maintain a constant outward escape of air, and thus eliminate the infiltration portion of the load. The pressure maintained must be sufficient to overcome wind pressure through cracks and door openings. When this condition prevails it is not necessary to include any infiltration load. When the quantity of new air introduced through the cooling equipment is not sufficient to build up the required pressure to offset infiltration, the entire infiltration load should be included in the cooling load calculations.

Total Outdoor Air Load. Many cooling coil manufacturers publish tables giving psychrometric data based on the *average* conditions of the leaving air for various coil temperatures, air velocities, and entering dry-bulb and wet-bulb conditions. When these tables are used, it is necessary to calculate the mixed-air condition entering the coil, and determine from the tables what coil and air velocity will produce the desired leaving-air conditions as required for the space to be conditioned. When cooling coils are listed as 80 to 95 percent efficient, the manufacturer indicates that 20 to 5 percent of the air passes through the coil without being cooled. If data of this nature are used, the uncooled portion of the air must be added to the space load before determining the effective air quantity. See later section on Apparatus Dew Point.

To determine the design cooling load caused by the introduction of outdoor air, the maximum rate of outdoor-air entry is first established. In some applications the use of special exhausters from the conditioned space may add to the outdoor-air requirements in determining the maximum rate. When this design quantity is established, and the design indoor- and outdoor-air states are known, the cooling load may be computed. There are several methods in use, the more accurate of which require rather detailed calculations. Refer to Chapter 3, and also section on Apparatus Dew Point in this chapter. The following equations are considered to be of sufficient precision for use at usual design conditions, as their accuracy is within 1 percent.

Sensible Load $q_s = Q \times 60 \times 0.244 \times 0.075 \left(\frac{1 - 0.00923}{0.62}\right) (t_o - t_i)$

$$= Q \times 1.08\ (t_o - t_i), \text{ Btu per hour} \quad (7)$$

Latent Load $q_s = Q \times 60 \times 0.075 \times 1076\ (W_o - W_i)$

$$= Q \times 4840\ (W_o - W_i), \text{ Btu per hour} \quad (8)$$

Total Load $q_t = q_s + q_s$ (9)

where

Q = rate of entry of outdoor air, cubic feet per minute.

t_o = outdoor dry-bulb temperature, Fahrenheit.

t_i = indoor dry-bulb temperature, Fahrenheit.

W_o = outdoor humidity ratio, pounds moisture per pound of dry air.

W_i = indoor humidity ratio, pounds moisture per pound of dry air.

0.075 = standard air density, pounds per cubic foot.

0.244 = a constant approximating the specific heat of dry air corrected for moisture, Btu per (pound) (Fahrenheit degree).

1076 = a factor approximating the average Btu released in condensing one pound of water vapor from air.

As explained later in the section on Apparatus Dew Point, some methods of load calculations break down the ventilation air into two parts: one portion which does not contact the coil surfaces (i.e., bypasses the coil) in passing through the coil and thus becomes a part of the room load; and a second portion, the remainder of the air which contacts the coil surfaces and is cooled down to the apparatus dew point. This detailed method explained in the literature by Ashley,[29] is believed to be very easy and accurate to use. Similar equations, therefore, can be written:

Space Sensible Ventilation Load,

$$q_{si} = Q \times 1.08\ (t_o - t_i) \times b \quad (10)$$

Space Latent Ventilation Load,

$$q_{si} = Q \times 4840\ (W_o - W_i) \times b \quad (11)$$

Remaining Sensible Ventilation Load,

$$q_{ss} = Q \times 1.08\ (t_o - t_i)\ (1 - b) \quad (12)$$

Remaining Latent Ventilation Load,

$$q_{ss} = Q \times 4840\ (W_o - W_i)\ (1 - b) \quad (13)$$

$$q_t = q_{si} + q_{ss} + q_{si} + q_{ss} \quad (14)$$

where

b = fraction of air passing through coil which does not contact surfaces, coil bypass factor.

Standard air weight (0.075 lb per cu ft) is recommended for use in all calculations, as this is the basis for rating fans and its consistent use keeps all parts of the calculations in conformity.

HOW OUTDOOR AIR LOAD AFFECTS ROOM LOAD

Actually, the outdoor air used for ventilation would pass through the conditioning equipment, and be cooled and dehumidified to a lower temperature and humidity ratio than room conditions before entering the room; but for heat-balance purposes the cooling load chargeable to the outdoor air is that corresponding to the difference between the outdoor and indoor air conditions.

One important purpose of the cooling-load estimate is to determine the conditions and quantity of air supplied to the space. All the various sensible and latent heat loads within the space must be included. Infiltration must be included in the space load since this air enters the doors and windows, and its heat and moisture load must be offset by the introduction of cooler, dryer air to the space. However, since outdoor air is taken through the conditioning equipment and cooled, this portion does not become a part of the space load, except a small portion which passes through the coil untreated. To determine the total load on the refrigeration machine, the remaining outdoor-air load must be included in the grand total load.

Example 10: For outdoor design conditions of 95 F dry-bulb and 75 F wet-bulb, and indoor design conditions of 80 F dry-bulb and 67 F wet-bulb, and for the supply of outdoor air at the rate of 1000 cfm and the exhaust of room air at the corresponding rate, calculate the total, sensible, and latent heat gains.

Solution: Substituting in Equation 7:

$$q_s = 1000 \times 1.08\ (95 - 80) = 16{,}200 \text{ Btu per hr.}$$

From psychrometric data $W_o = 0.01413$, $W_i = 0.01122$. Substituting in Equations 8 and 9:

$$q_s = 1000 \times 4840\ (0.01413 - 0.01122) = 14{,}100 \text{ Btu per hr.}$$

$$q_t = q_s + q_s = 30{,}300 \text{ Btu per hr.}$$

HEAT SOURCES WITHIN THE CONDITIONED SPACE

People. The rates at which heat and moisture are given off by human beings under different states of activity are given in Table 27. In many applications these sensible and latent heat gains become a large fraction of the total load. Appreciable variations in heat-emission rates must be recognized according to the age and sex of the individual, state of activity, environmental influences, and duration of occupancy (since for short occupancy the extra heat and moisture brought in by people may be a significant factor).

While Chapter 6 should be referred to for detailed information, Table 27 in this chapter summarizes practical data representing conditions commonly encountered.

Lighting. In general, the instantaneous rate of heat gain from electric lighting[21] may be calculated from the following relation:

$$q_{sl} = \begin{Bmatrix}\text{total light}\\ \text{wattage}\end{Bmatrix} \times \begin{Bmatrix}\text{use}\\ \text{factor}\end{Bmatrix} \times \begin{Bmatrix}\text{special allow-}\\ \text{ance factor}\end{Bmatrix} \times 3.41, \text{ Btu per hr.} \quad (15)$$

The *total light wattage* is obtained from the ratings of all fixtures installed, both for general illumination and for display use.

The *use factor* is the ratio of the wattage in use, for the conditions under which the load estimate is being made, to the total installed wattage. For commercial applications such as stores, the use factor would be unity.

The *special allowance factor* is introduced to care for fluorescent fixtures, and for fixtures which are either ventilated or installed so that only part of their heat goes to the conditioned space. For *fluorescent fixtures*, the special allowance factor is recommended to be taken as 1.20 in order to allow for power consumed in the *ballast*. For *ventilated fixtures, recessed fixtures*, and the like, manufacturers' or other data[21] must be sought to establish the fraction of the total wattage which may be expected to enter the conditioned space.

Power. When equipment of any sort is operated within the conditioned space by electric motors, the heat equivalent of this operation must be considered in the cooling load. The general equation for calculating this load is:

$$q_m = \left(\frac{\text{Horsepower Rating}}{\text{Motor Efficiency}}\right) \times \begin{Bmatrix}\text{Load}\\ \text{Factor}\end{Bmatrix} \times 2544, \text{ Btuh} \quad (16)$$

It is assumed that both the motor and the driven equipment are within the conditioned space. If the motor is outside the space, then *do not divide* by the motor efficiency in Equation 16. The *load factor* is merely the fraction of the rated load which is being delivered under the conditions of the cooling-load estimate. *Motor efficiencies* may be approximated as follows: about 50 to 60 percent at ½ hp rating, increasing to 80 percent at 1 hp, and to 88 percent at 10 hp and above.

Appliances. Care must be taken in a cooling-load estimate to take into account the heat gain from all appliances, electrical, gas, or steam. Table 28 presents recommended data.[21] Note that the *maintaining rate* in Table 28 is the heat input required to maintain the appliance at the normal operating temperature even though it is not being used, i.e., no coffee is being made, no toast is being made, no food is being cooked in the fry kettle, etc. The maintaining rate is useful in setting

Table 27 .... Rates of Heat Gain from Occupants of Conditioned Spaces[a]

Degree of Activity	Typical Application	Total Heat Adults, Male Btu/Hr	Total Heat Adjusted[b] Btu/Hr	Sensible Heat Btu/Hr	Latent Heat Btu/Hr
Seated at rest	Theater—Matinee	390	330	180	150
	Theater—Evening	390	350	195	155
Seated, very light work	Offices, hotels, apartments	450	400	195	205
Moderately active office work	Offices, hotels, apartments	475	450	200	250
Standing, light work; or walking slowly	Department store, retail store, dime store	550	450	200	250
Walking; seated Standing; walking slowly	Drugstore, Bank	550	500	200	300
Sedentary work	Restaurant[c]	490	550	220	330
Light bench work	Factory	800	750	220	530
Moderate dancing	Dance hall	900	850	245	605
Walking 3 mph; moderately heavy work	Factory	1000	1000	300	700
Bowling[d] Heavy work	Bowling alley Factory	1500	1450	465	985

[a] *Note:* Tabulated values are based on 80 F room dry-bulb temperature. For 78 F room dry-bulb, the total heat remains the same, but the sensible heat values should be increased by approximately 10 percent, and the latent heat values decreased accordingly.

[b] *Adjusted total heat gain* is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is 85 percent of that for an adult male, and that the gain from a child is 75 percent of that for an adult male.

[c] *Adjusted total heat value for sedentary work, restaurant,* includes 60 Btu per hour for food per individual (30 Btu sensible and 30 Btu latent).

[d] For *bowling* figure one person per alley actually bowling, and all others as sitting (400 Btu per hour) or standing (550 Btu per hour).

up a lower limit to the heat gain to a room from the appliance when in operation.

Experienced judgment must be used in the application of data given in Table 28. Consideration must be given to the heat contributed by appliances which are in use at the time of peak load. The quantity of heat will depend upon whether products of combustion are vented to a flue, whether they escape into the space to be conditioned, or whether appliances are hooded to allow part of the heat to escape through a stack. There are no generally accepted data available on the effects of venting and shielding heating appliances, but it is believed that when they are properly hooded with a positive fan-exhaust system through the hood, 50 percent of the heat will be carried away and 50 percent dissipated in the space to be conditioned. In the case of gas-burning appliances where the heat of combustion adds considerably to the total heat output, it is believed that a well-designed hood will remove more than 50 percent of the heat generated at the appliance. The same effectiveness of the hood should be figured for both latent and sensible heat.

For each meal served the heat transferred to the dining space is approximately 50 Btu per hr, of which 75 percent is sensible and 25 percent latent.

Heat gains from cooking appliances, motors, lights, and people are not considered in cooling load calculations if the appliances are located in a separate kitchen that is not part of the conditioned area.

LOAD FROM MOISTURE TRANSFER THROUGH PERMEABLE BUILDING MATERIALS

The diffusion of moisture through all common building materials is a natural phenomenon which is always present to a greater or lesser degree.

The permeability and permeance values for various building materials are given in Table 2 of Chapter 10, together with an explanation of moisture transmission through these materials.

In the usual comfort air-conditioning application, it is common practice to neglect moisture transfer through walls, because the actual rate is quite small and the corresponding latent-heat load is hardly significant. *Vapor barriers* are frequently employed in modern construction for the purpose of keeping moisture transfer to a minimum, and reducing the deteriorating and insulation-destroying effects of moisture.

Industrial jobs, on the other hand, frequently call for a low moisture content to be maintained in a conditioned space. Here the matter of moisture transfer cannot be neglected; indeed, it is quite possible to have the latent-heat load accompanying this transfer be of greater magnitude than any other latent-heat load. The equation for computing this load is:

$$\left(\frac{q_m}{A}\right) = \frac{M}{7000} \times \left(\begin{matrix}\text{Vapor-Pressure}\\ \text{Difference, In. Hg}\end{matrix}\right) \times 1076, \text{ Btuh/sq ft} \quad (17)$$

where

M = permeance of the specimen in perms, or grains per (square foot) (hour) (inch of mercury vapor-pressure *difference*).

7000 = grains per pound.

The factor 1076 is defined in list of symbols at Equation 9. (Sensible cooling of the water vapor is included in the factor 1076.)

The only means of preventing moisture transfer is to use a vapor proof wall, or to apply a special lining, which is vapor proof. All openings in moisture proof construction must be equipped with special gaskets to prevent entrance of moisture.

When moisture transfer contributes an appreciable part of the latent-heat load, it is recommended that estimates should be made intentionally liberal in order to avoid later difficulties with insufficient dehumidifying capacity. Storage spaces, for example, would require sufficient dehumidifying capacity to handle the moisture brought in with goods to be stored, in addition to moisture leaking in subsequently.

MISCELLANEOUS HEAT LOADS

This designation is intended to cover the various small heat gains from exposed piping, ducts, work done by circulating fan, and unforeseen contingencies. Where sufficient data are available, these various heat gains may be estimated individually. In the majority of cases, however, common practice is to lump these factors together and combine them with a *safety factor* according to the experience and judgment of the estimator. On this basis, a small safety factor is added to the calculated cooling load to compensate for miscellaneous effects. *No rules* can be given for this procedure, as experience in air conditioning is indispensable for application of suitable safety factors.

APPARATUS DEW POINT AND REQUIRED AIR QUANTITY THROUGH CONDITIONING EQUIPMENT

In ordinary practice, with commercial apparatus, complete saturation of the air is seldom obtained. Four-row finned cooling coils contact approximately 80 percent of the air, whereas six-row finned coils contact approximately 95 percent of the air. In spray-type dehumidifiers of good design the air leaves the dehumidifier at 1 to 2 deg higher wet-bulb temperature than the spray water leaving the dehumidifier, and the difference between the dry-bulb and wet-bulb temperatures leaving the dehumidifier may be as low as 1 deg. A spray-type dehumidifier having sufficient length of spray chamber and density of spray, together with proper arrangement of nozzles, may approach saturation very closely.

As explained in Chapter 3, and shown in Fig. 5, the slope of the line on the psychrometric chart connecting the room condition with the apparatus dew point on the saturation line, determines the ratio of sensible heat absorbing capacity to the moisture absorbing capacity of the supply air. Therefore the room condition can be maintained as long as the supply-air temperature lies on this line, but a greater volume of supply air must be used to satisfy the room load if the cooling coil does not contact 100 percent of the air. For a given room load, the same apparatus dew point will be required whether the cooling appliance contacts all the air or only part of the air.

From the point of view of satisfying the given cooling load requirements, the air passing through the apparatus without being cooled below the dew-point temperature produces two effects:

1. The air quantity which must be passed through the dehumidifier must be increased. Thus, if 20 percent of the air passing is not contacted, then $(20 \div 80) \times 100 = 25$ percent more air must be used than would be necessary if all of it were contacted.

2. Passing untreated air may change the room cooling load, which in turn may change the enthalpy-humidity difference ratio (sometimes called the sensible-heat factor). If return air only is passed through the dehumidifier or if room air only is bypassed, the room load will not change, but if some outdoor air is passed through, the room sensible-heat gain and room latent heat gain will be changed due to the addition of untreated outdoor air which changes the enthalpy-humidity difference ratio. When a load calculation is made, it is necessary to know the percentage of air treated in the dehumidifier, and calculation must be made accordingly.

If the ventilation air is drawn through the dehumidifier before it goes into the room, only that portion of the air not saturated must be included in the room load for the purpose of determining the apparatus dew point and supply-air quantity. It should be noted when evaluating the load added by untreated outdoor air that the temperature difference between room air and outdoor air, and the moisture content difference between room air and outdoor air, should be used, rather than the difference between outdoor air and apparatus dew point, since the rise from the apparatus dew point to room condition is charged against the dehumidifier as the cooling and dehumidifying load.

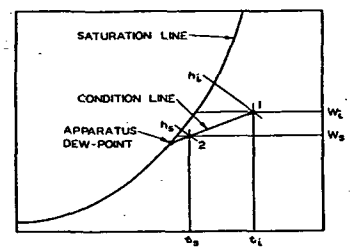

Fig. 5 .... Apparatus Dew-Point Shown on ASHAE PSYCHROMETRIC CHART

The procedure for determining the required air quantity is based upon the thermodynamic principles of Chapter 3 and the use of the ASHAE PSYCHROMETRIC CHART. Readers are advised to review these principles, paying particular attention to the illustrative examples.

Calculation of the cooling load for a conditioned space is equivalent to making, for the space, a heat balance in which all heat, moisture, and infiltration are treated as directly entering the space. As explained in the section, Load from Outdoor Air, Ventilation, and Infiltration, the outdoor-air load normally does not become a part of the space load, because heat and moisture are removed in the air conditioner before this air gets into the conditioned space. The desired conditions are maintained by considering a certain quantity of air to be withdrawn from the space, passed through the conditioning equipment, and returned to the space with such a temperature and humidity ratio that its net effect will be to counterbalance or remove the given entering amounts of heat and water vapor. This quantity of *indoor air*, which is considered to be circulated in this manner, is called the *required air quantity* and its determination is normally part of every cooling-load estimate. The procedure is as follows:

1. Determine the total sensible and latent heat loads in Btu per hour for the space.

2. Compute the quantity called the enthalpy-humidity difference ratio (also referred to as heat-moisture ratio) of

[a] For restaurant appliances, miscellaneous electrical and miscellaneous gas burning appliances.
[b] When these appliances are hooded and provided with adequate exhaust, use 50 percent of recommended rate of heat gain from unhooded appliances.

the room load, $\frac{h_i - h_s}{W_i - W_s}$. Use the equation

$$\frac{h_i - h_s}{W_i - W_s} = \frac{\text{(Space sensible load + space latent load)}}{\text{Space latent load/1076}} \quad (18)$$

where

h_s = enthalpy of moist air supplied to the space, Btu per pound of dry air.

h_i = enthalpy of moist air at room design conditions, Btu per pound of dry air.

W_s = humidity ratio of moist air supplied to the space, pounds of vapor per pound of dry air.

W_i = humidity ratio of moist air at room design conditions, pounds of vapor per pount of dry air.

Note that the ratio (space latent load/1076) is the equivalent of the required rate of water vapor removal in pounds per hour. If the rate of water removed is known, it may be used directly in Equation 18.

3. Draw a line through the reference point on the ASHAE PSYCHROMETRIC CHART and the value of $(h_i - h_s)/(W_i - W_s)$ determined above. Draw a second line through the state point of the room air (design wet-bulb and dry-bulb temperatures) parallel to this line. This is the *condition line* for the process.

4. Read the temperature where the condition line from step 3 intersects the saturation line. This is called the *apparatus dew point*.

See Fig. 5. Note that instead of using this graphical method the left hand side of Equation 18 may be solved by trial and error by substituting values of h_s and W_s corresponding to assumed apparatus dew-point temperatures.

5. Compute the *required air quantity* from the relation

$$Q_{ra} = \text{Space sensible load} \Big/ \left\{1.08 \left[\begin{pmatrix}\text{Space}\\ \text{dry-bulb}\end{pmatrix} - \begin{pmatrix}\text{Apparatus}\\ \text{dew-point}\end{pmatrix}\right] \times \left(1 - \begin{matrix}\text{Coil}\\ \text{bypass}\\ \text{factor}\end{matrix}\right)\right\} \quad (19)$$

The magnitude of Q_{ra} is substantially the quantity, cfm, of cooled and dehumidified air for which the distribution system must be designed.

The numerical factor 1.08 is derived from the product 1 cfm × 60 min × 0.244 × 0.075$\left(1 - \frac{0.00923}{0.62}\right)$ = 1.08, assuming an average supply air dew point of 55 F. Since standard air density (0.075) includes the weight of the water vapor, it is desirable to reduce it to the basis of dry air by the last factor where 0.00923 = humidity ratio of air at 55 F dew point, and 0.62 = ratio of density of water vapor to dry air at same temperature and pressure. Refer to Chapter 23 for coil selection.

Note that the product [(space dry-bulb) − (apparatus dew point)] × (1 − coil bypass factor) is equal to the dry-bulb range through which the conditioned air is cooled. Hence, in rare instances when the *condition line* of the process may not intersect the saturation line, any other convenient reference temperature on the *condition line* may be used instead, provided that the coil bypass factor is specified accordingly on the proper basis.

MINIMUM ENTERING AIR TEMPERATURE

Due consideration must be given to the temperature of the air entering the conditioned space in order to prevent objectionable drafts. With ceiling-type diffusers or wall grilles with a high aspect ratio (see Chapter 20), many engineers consider 20 deg as the maximum difference for good design under average conditions. This difference can only be exceeded with extremely high ceiling outlets or wall grilles. Thus, if 80 F dry-bulb is to be maintained in a space with average ceiling height, the minimum delivered air temperature would be limited to about 60 F dry-bulb temperature. If the latent heat load is relatively high, it is often necessary to circulate more air with a higher delivered dry-bulb temperature in order to produce a thermodynamic balance. If the dry-bulb temperature of the air supplied to the space is known, the required air quantity can be calculated from the formula,

$$Q_{ra} = \frac{q_s}{1.08\ (t_i - t_s)} \quad (20)$$

or the supply temperature t_s can be determined as follows,

$$t_s = t_i - \frac{q_s}{1.08 \times Q_{ra}} \quad (21)$$

EXAMPLE—COOLING-LOAD CALCULATION

Example 11: A one-story office building Fig. 6 is located in an eastern state near 40 deg latitude. The adjoining buildings on the north and west are not conditioned, and the air temperature within them is known to be substantially equal to the outdoor air temperature at any time of the day.

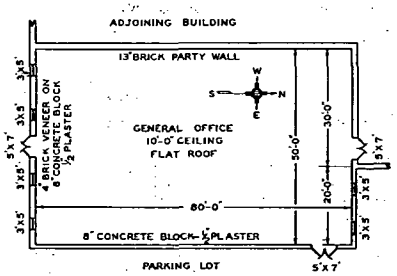

Fig. 6 .... Plan of One-Story Office Building

South wall construction: 8-in. concrete block, 4-in. brick veneer. (Table 7, Chapter 9, U = 0.41.)

East wall and outside north wall construction: 8-in. concrete block, no plaster on walls. (Table 6, Chapter 9, U = 0.52.)

West wall and adjoining north party wall construction: 13-in. solid brick, no plaster:

$$\frac{1}{U} = \frac{1}{1.65} + \frac{13}{5} + \frac{1}{1.65} \quad \text{or,} \quad U = 0.263. \quad \text{Use } U = 0.26.$$

Roof construction: 2½-in. flat roof deck of 2-in. gypsum slab on ¼-in. asbestos cement board surfaced with built-up roofing. (Table 13B, U = 0.34 *for summer*.)

Floor construction: 4-in. concrete on ground.

Window: 3 ft x 5 ft, nonopening type, with medium colored Venetian blinds for windows on south wall. Approximately 4-in. reveal on all windows.

Front doors: Two 2 ft-6 in. x 7 ft (glass panels).

Side doors: Two 2 ft-6 in. x 7 ft (½ glass panels).

Rear doors: Two 2 ft-6 in. x 7 ft (wood panels).

Outdoor design conditions: Maximum dry-bulb 95 F, wet-bulb 78 F; W_o = 0.0168 lbs vapor per lb dry air; h_o = 41.38 Btu per lb dry air.

Indoor design conditions: Dry-bulb 80 F, wet-bulb 65 F; W_i = 0.0098 lb vapor per lb dry air; h_i = 29.95 Btu per lb dry air.

Occupancy: 85 office workers.

Lights: 12,000 watts, fluorescent; 4000 watts, tungsten.

Fan motor: 7½ hp.

Assume that cooling coil has a bypass factor of 0.15, i.e., that 15 percent of the air passes through the coil without contacting the coil surface.

Conditioning equipment to be located in adjoining structure to north.

Find: Total, sensible, and latent maximum cooling loads and required air quantity through conditioning equipment.

Solution: From Table 3, the recommended ventilation rate is 15 cfm per person. Total necessary = 85 × 15 = 1275 cfm or 76,500 cu ft per hr.

As the room volume is 40,000 cu ft, the air changes per hour will be 76,500/40,000 = 1.91 which is more than one air change.

Estimated Time of Maximum Cooling Load:

For this job, judgment indicates that the roof will make the greatest single contribution to the cooling load. Hence, the time of maximum cooling load probably will be the time of maximum heat gain through the roof. From Table 9 the maximum temperature differential for a 2-in. gypsum roof of medium weight construction is 54 deg at 4:00 p.m., and 53 deg at 3:00 p.m. Examination of Table 12 (40 deg N Latitude) shows that solar heat gain through glass on the south wall is 18 Btu per (hr) (sq ft) at 4:00 p.m.; and 42 Btu at 3:00 p.m. This indicates that the maximum cooling load occurs at approximately 3:00 p.m. Therefore make load calculations at 3:00 p.m. sun time. (This may be slightly different from 3:00 p.m. local time.) In some cases, there would be no clear-cut evidence of this nature, and consequently, it would be necessary to estimate the load for several successive times, and then to select the maximum.

Heat Gain Through Outer Wall and Roof Areas:

From Table 10 the temperature differential for the south wall (8-in. concrete block with 4-in. brick veneer) may be about the same as a 12-in. brick which is 6 deg at 3:00 p.m. for a dark colored wall. From the same table, the temperature differential for the east wall (8-in. concrete block with plaster) will be 11 deg at 3:00 p.m. for a *light colored wall* (interpolating between 2:00 and 4:00 p.m.). Likewise, the temperature differential for the north exposed wall (8-in. concrete block plus plaster) will be 3 deg at 3:00 p.m. (by interpolation) for a light wall.

The party wall of 13-in. brick on the west side and part of the north side may be treated as if it were an outside wall in the shade which has a temperature differential (from Table 10) of 2 deg.

For the door in north wall, estimate U = 0.59 from Chapter 9. The outdoor temperature at 3:00 p.m. is 95 F. Neglect time lag and any decrement factor. The temperature differential is $(t_o - t_i)$ = 95 − 80 = 15 deg. The tabulation of the preceding values at 3:00 p.m. is given in the following table:

Section	Net Area Sq Ft	Temperature Differential F Deg	Heat Transmission Coefficient U	Heat Flow Rate per Hour Btu
Roof	4000	53	0.34	72,000
South wall	405[a]	6	0.41	995
East wall	765[a]	11	0.52	4,380
North exposed wall	170[a]	3	0.52	265
West & north party wall	1065[a]	2	0.26	550
Door in north wall	35	15	0.59	310
Total				78,500

[a] Calculated from gross wall area, less windows and doors.

Heat Gain Through Glass Areas:

In computing the load for 3:00 p.m., only the south windows and doors will be exposed to direct sunlight. Tables 12 and 13 will give the total heat gain from the glass areas. The window reveals will shade the south windows; the fraction of the window area receiving direct radiation is obtained from Equation 5 by substituting values as follows:

$r_1 = s/l = 4/60$; $r_2 = 4/36$; β = 45.5 deg, tan β = 1.02

γ = 74 deg, tan γ = 3.487, cos γ = 0.276

$$G_f = 1 - \frac{4}{60}\left(\frac{1.02}{0.276}\right) - \frac{4}{36}(3.487) + \left(\frac{4}{60}\right)\left(\frac{4}{36}\right)\frac{(1.02)(3.487)}{0.276} = 0.462.$$

The south doors will be considered entirely sunlit. The outdoor air temperature is 95 F at 3:00 p.m. From Table 25 the inside Venetian blind factor is 0.65. The instantaneous heat gains due to transmitted direct and diffuse solar radiation, and from convection and radiation gain, are found in Tables 12 and 13 as listed below for the south-facing doors and windows, the north-facing windows and the ½ glass doors in the east wall. The gain through the solid portion of the east doors may be approximated by use of Fig. 3, since the wood panels have little heat capacity. From Table 4 the diffuse radiation value is taken as 18 Btu per (hr) (sq ft) from which $t_o + \alpha_o I_o / f_{co}$ is found to be 98.2 for α = 0.7 and f_{co} = 4.0. From Fig. 3, q = 22.0 Btu per (hr) (sq ft). These heat gains are itemized in the following table.

Location	Area Sq Ft	Fraction Sunlit	Trans Solar Gain Btu/(hr) (sq ft)	Conv and Rad Gain Btu/(hr) (sq ft)	Total Gain Btu/(hr) (sq ft)	Total Gain Btu/hr
South windows*	60	0.462	13	19	32	1920
South doors	35	1.00	42	19	61	2135
East doors						
Glass	18	—	14	17	31	560
Wood	18	—	—	22	22	395
North windows	30	—	15	17	32	960
Total						5970

* Shade factor = 0.65.

In some jobs it would be desirable to increase (or decrease) the instantaneous radiation heat gain by a load-lag factor. The reason for not doing so in this case is that the solar gain is of a low magnitude, and reference to the table indicates that 0.8 of the previous hour would not affect the results materially.

Heat Gain from Ventilation and Infiltration:

Since the desired outdoor air rate 1275 cfm is greater than one air change per hour, it will be satisfactory for determining the ventilation component of the heat gain.

Window infiltration can be taken as negligible since the windows do not open.

Door infiltration requires some judgment. Assume that for each person passing through the double doors, the infiltration will be 100 cu ft of outdoor air, *see* Chapter 10, Table 3. Assume that the outside doors will be used at the rate of 10 persons per hour and the inside doors at the rate of 30 persons per hour. Total infiltration will then be 40 × 100 = 4000 cfh or 67 cfm.

The design rate of entry of outdoor air is then:

$$Q = 1275 + 67 = 1342 \text{ cfm.}$$

The sensible, latent, and total loads are determined from Equations 7, 8, and 9, respectively, at 3:00 p.m. (t_o = 95, t_i = 80, W_o = 0.0168, W_i = 0.0098). All the air entering the room as infiltration becomes a part of the space load.

Infiltration (see Equations 7, 8, and 9):

$q_s = 67 \times 1.08\ (95 - 80) = 1085$ Btuh, sensible.

$q_s = 67 \times 4840\ (0.0168 - 0.0098) = 2270$ Btuh, latent.

$q_t = q_s + q_s = 1085 + 2300 = 3385$ Btuh, total.

Ventilation Air Taken through Cooling Unit Which Becomes a Part of the Space Load (see Equations 10 and 11):

q_{si} = 1275 × 1.08 (95–80) (0.15) = 3,100 Btuh, sensible.

q_{ei} = 1275 × 4840 (0.0168–0.0098) (0.15) = 6,480 Btuh, latent.

Ventilation Air Taken through Cooling Unit Which Does Not Become a Part of the Space Load (see Equations 12 and 13):

q_{ss} = 1275 × 1.08 (95–80) (1–0.15) = 17,600 Btuh, sensible.

q_{es} = 1275 × 4840 (0.0168–0.0098) (1–0.15)
= 36,715 Btuh, latent.

$q_t = q_{si} + q_{ss} + q_{ei} + q_{es}$ = 3100 + 17,600 + 6480 + 36,715
= 63,895 Btuh total.

Heat Gain from Sources within the Conditioned Space:

For the occupants, use the data of Table 27 for moderately active office work.

Sensible heat gain = 85 × 200 = 17,000 Btu per hr.
Latent heat gain = 85 × 250 = 21,250 Btu per hr.
Total = 38,250 Btu per hr.

For the gain from *lighting*, use Equation 15 with a use factor of unity, and a special allowance factor of 1.20 for the fluorescents and of unity for the tungsten globes.

q_{el} = (12,000 × 1.20 + 4000) × 3.41 = 62,700 Btu per hr.

For the *fan motor*, use Equation 16 with a load factor of unity, and omit term *Motor Efficiency* because the motor is not within the space.

q_{em} = 7.5 × 2544 = 19,100 Btu per hr.

Moisture Permeation, Miscellaneous Allowance, and the Load-Lag Estimate:

Moisture permeation will be negligible, since this is a comfort job with a good building construction.

There would be some heat gain in the ductwork, but this would not be great because of the short run involved. Practical judgment for this job would suggest that no adjustment for load lag need be made to the load as computed. (Refer to Fig. 4). While it is true that inside radiation forms an important part of the total heat gain, it is advisable to be conservative in recognizing the effect of the large, flat, hot roof on the *comfort sensations of the occupants*. Radiation from the relatively low ceiling, augmented by heat absorption from the lighting fixtures, would produce a sensation of warmth in excess of the nominal effective temperature (see Chapter 6) established by the wet-bulb and dry-bulb temperatures. Hence, it is not desirable to take advantage of every small decrease possible in the peak design load, especially since the peak occurs in mid-afternoon when everything would be rather well warmed.

Total Loads and Required Air Quantity through Conditioning Equipment:

The total loads are summarized in the following table:

SUMMARY OF TOTAL LOADS—EXAMPLE 11

LOAD COMPONENT	SENSIBLE BTU/HR	LATENT BTU/HR
All walls, roof and doors	78,500	....
Glass areas	5,970	....
Infiltration 67 cfm	1,085	2,270
Ventilation air (1275 cfm × 0.15)	3,100	6,480
Occupants	17,000	21,250
Lighting	62,700	....
Motor, fan	19,100	....
Space load	187,455	30,000
Ventilation 1275 cfm × (1–0.15)	17,600	36,715
Totals	205,055	66,715
Grand total sensible and latent		271,770

Compute the enthalpy difference ratio from Equation 18.

$$\frac{h_i - h_s}{W_i - W_s} = \frac{(187{,}455 + 30{,}120)}{30{,}120} \times 1076 = 7770.$$

From the ASHAE PSYCHROMETRIC CHART, Chapter 3, determine that the apparatus dew point is 53.9 F.

Compute the effective air quantity (Equation 19). Then,

$$Q_{es} = \frac{187{,}455}{1.08(80 - 53.9) \times 0.85} = 7830 \text{ cfm.}$$

(Refer to Chapter 23 for coil selection.)

From note under Equation 19 the dry-bulb range will be (80 − 53.9) × 0.85 = 22.2 deg, and the dry-bulb temperature of air leaving the coil will be 80 − 22.2 = 57.8 F. The dry-bulb temperature leaving the fan (including the heat supplied by the fan motor) or, delivered into the room, will be (from Equation 21):

$$t_s = 80 - \frac{187{,}455 - 19{,}100}{1.08 \times 7830} = 80 - 19.9 = 60.1 \text{ F.}$$

With good distribution and diffusion, this temperature should not produce objectionable drafts.

The various calculations for the sensible, latent, and total heat loads for Example 11 may be summarized as follows:

EXAMPLE 11: SUMMARY

OUTDOOR CONDITIONS	95 DB	78 WB	0.0168 HUMIDITY RATIO
SPACE CONDITIONS	80 DB	65 WB	0.0098 HUMIDITY RATIO
DIFFERENCE	15		0.0070

	Btu/Hr.

Latent 1275 cfm × 4840 × 0.0071 × (1–0.15) =		36,715
GRAND TOTAL LOAD		271,770

LETTER SYMBOLS USED IN CHAPTER 13

α = fraction of incident solar radiation absorbed, dimensionless; subscripts D, d, and t refer to direct, diffuse, and total, respectively.

β = solar altitude, degrees.

γ = wall solar azimuth, degrees.

ϵ = emissivity, dimensionless.

θ = incident angle, degrees.

τ = fraction of incident solar radiation transmitted, dimensionless.

Subscripts D, d, and t refer to direct, diffuse, and total, respectively.

ϕ = solar azimuth, degrees.

ψ = wall azimuth, degrees.

A = area across which heat is being transferred, square feet.

b = fraction of air passing through coil which does not contact surfaces, coil bypass factor.

f = unit surface conductance, Btu per (hour) (square foot) (Fahrenheit degree).

Subscripts c, r, o, and i refer to convection, radiation, outdoor, and indoor, respectively.

G_f = fraction of total window area receiving direct solar radiation when shaded by window reveal, dimensionless.

h = enthalpy of air per pound of dry air, Btu per pound. Subscripts i, o, and s refer to indoor, outdoor, and supply air, respectively.

I = incident solar radiation, Btu per (hour) (square foot). Subscripts D, d, Dn, and t refer to direct, diffuse, direct normal, and total solar radiation, respectively.

K = cosine of angle of incidence for direct solar radiation striking a surface, dimensionless.

k = thermal conductivity of building material, Btu per (square foot) (hour) (Fahrenheit degree per inch).

l = height of window, feet.

M = the permeance of the specimen in *perms* or grains per (square foot) (hour) (inch of mercury vapor pressure difference).

Q = rate of entry of outdoor air, cubic feet per minute.

Q_{es} = required air quantity through conditioning equipment, cubic feet per minute.

q = instantaneous rate of heat transfer, Btu per hour.

q_e = instantaneous latent heat load, Btu per hour.

q_{ei} = instantaneous space latent ventilation load, Btu per hour.

q_{es} = instantaneous latent ventilation load which does not become a part of space load, Btu.

q_m = latent heat load due to moisture transmission through materials, Btu per (hour) (square foot).

q_s = instantaneous sensible heat load, Btu per hour.

q_{si} = instantaneous space sensible ventilation load, Btu per hour.

q_{ss} = instantaneous sensible ventilation load which does not become a part of space load, Btu per hour.

q_t = $q_s + q_e$, also $q_{ei} + q_{es} + q_{si} + q_{ss}$, Btu per hour.

R_r = low temperature radiant energy received from outdoor surroundings (does not include solar radiation), Btu per (hour) (square foot of receiving surface).

R = radiant energy emitted by a black body, Btu per (hour) (square foot). Subscripts go and L refer to outdoor surfaces of glass and building, respectively.

S = rate of heat storage within a glass section, Btu per (hour) (square foot).

t_e = sol-air temperature, Fahrenheit.

t_{gi} = temperature of indoor glass surface, Fahrenheit.

t_{go} = temperature of outdoor glass surface, Fahrenheit.

t_i = indoor air temperature, Fahrenheit.

t_m = 24-hr cyclic average sol-air temperature, Fahrenheit.

t_o = outdoor air temperature, Fahrenheit.

t_s = room supply air dry-bulb temperature, Fahrenheit.

U = overall coefficient of heat transfer of a structural section, Btu per (square foot) (hour) (Fahrenheit degree).

v_o = volume of outdoor air per pound of dry air, cubic feet.

w = width of window, feet.

W = humidity ratio, pounds moisture per pound of dry air. Subscripts i, o, and s refer to indoor, outdoor, and supply air, respectively.

CHAPTER 14

RADIATORS, CONVECTORS, BASEBOARD AND FINNED-TUBE UNITS

Definitions, Heat Emission, Radiators, Convectors, Baseboard, Finned-Tube, Ratings, Corrections for Non-Standard Conditions, Enclosed Radiators

RADIATORS, convectors, baseboard, and finned-tube are the types of heat-distributing units used in steam and hot water heating systems to supply heat to a room by radiation and convection. The function of these devices is the maintenance of the desired mean radiant and air temperatures in the area. Since heat losses through the various parts of the structure constantly tend to lower these temperatures, heat distributing units should be so placed and regulated that their output will replace the losses when and where they occur. If 80 percent of the room heat loss occurs through a cold wall or window area, then 80 percent of the input should be introduced in or directed toward that area.

The term *radiator* is generally confined to sectional cast-iron radiation. Cast-iron radiator types may be column, large-tube, small-tube, or wall.

The term *convector* refers to a heat-distributing unit that operates with gravity-recirculated room air, is surrounded on all sides by an enclosure having an air-inlet opening below the heating element, and an air-outlet opening above the heating element.

The terms *baseboard* and *baseboard radiation* refer to steam or water heat-distributing units designed for installation along the bottom of the walls replacing the conventional baseboard. They operate with gravity-recirculated room air, and have a substantial portion of their frontal face surface directly exposed to the room.

The term *finned-tube* refers to steam or water heat-distributing units fabricated from metallic tubing with metallic fins bonded to the tube. They operate with gravity-recirculated room air and are designed for installation without enclosure, or with open-type grilles or covers, or with enclosures having top, front, or inclined outlets.

HEAT EMISSION

Steam or water heat-distributing units emit heat by radiation and convection. These heat-transfer processes and the factors that affect them are discussed in detail in Chapter 5. In general, those units having a large portion of their heated surface exposed emit a larger portion of heat by radiation than do units having their heating surfaces completely or partly concealed from view.

The output of a heat-distributing unit is expressed in units of Btu per hr (Btuh), 1000 Btu per hr (Mbh), or in square feet equivalent direct radiation (EDR) (e.g., 240 Btuh for steam = 1 sq ft EDR).

RADIATORS

Column and large-tube radiators are no longer manufactured, but since many of these units are still in use, Tables 1 and 2 are included to provide principal dimensions and average ratings.

The *small-tube type radiators*, with a spacing of 1¾ in. per section, occupy less space than the older column and large-tube radiators, and are particularly suited for installation in recesses.

After a study of the demand for various sizes of radiators, the Institute of Boiler and Radiator Manufacturers, in cooperation with the Division of Simplified Practice, National Bureau of Standards, established *Simplified Practice Recommendation* R174-47, *Cast Iron Radiators*, for small-tube cast-iron radiators. Table 3 shows the size and dimensions now being manufactured.

Wall radiators are hung from wall brackets and are well adapted to use in factory buildings. Tests have shown that the heat emitted from a wall-type radiator may be reduced from 5 to 10 percent if the radiator is placed near the ceiling with the bars horizontal and in an air temperature exceeding 70 F. Installation of wall radiators at the ceiling is not recommended because the resulting large temperature gradients between floor and ceiling make it difficult to heat the living zone satisfactorily. Dimensions and heat emission rates of wall radiators for normal wall installations are given in Table 4.

Pipe Coils

Pipe coils are sometimes used in factory buildings and are usually placed under windows or along heavily-exposed walls. The heat emission of such pipe coils may be obtained from Table 5.

CONVECTORS

Convectors are made in a wide variety of depths, sizes, lengths, and enclosure or cabinet types. The basic sizes and types are listed in *Simplified Practice Recommendation* 238-50, *Convectors*. The heating elements are available in fabricated ferrous and non-ferrous metals as well as cast iron. The air enters the enclosure below the heating element, is heated in passing through the element, and leaves the enclosure through the outlet grille located above the heating element. Factory-assembled units comprised of a heating element and enclosure are widely used. These may be free standing, wall hung, or recessed, (Fig. 1) and may have outlet grilles and arched inlets or inlet grilles as desired.

In cases where cabinets or enclosures are to be used but are not furnished by the manufacturer, it is important that the proportions of the cabinets or enclosures and the grilles be so designed that they will not impair the performance of the assembled convector. It is desirable that the cabinet or

45	10	2400				

[a] These ratings are based on steam at 215 F and air at 70 F. They apply only to installed radiators exposed in a normal manner; not to radiators installed behind enclosures, grilles, or under shelves. For Btu per hour ratings at other temperatures, divide table values by factors found in Table 7.

enclosure for the convector fit as snugly as possible so that the air passing through cannot bypass the heating element.

BASEBOARD UNITS

Baseboard heat-distributing units are divided into three types: (1) radiant, (2) radiant-convector, and (3) finned-tube.[1]

Radiant-type baseboard is made of cast iron or steel. This type of unit emits a large portion of its heat output by radiation. Units are sometimes suspended from the ceiling in rooms having little or no available wall space for floor mounted units. As the convected heat obtained from these units when mounted at the ceiling is less than when they are mounted at floor level additional length must be added as recommended by the manufacturer to allow for the reduction.

Radiant-convector type baseboard also is made of cast iron or steel. The units are provided with air openings at the top and bottom to permit circulation of room air over the wall side of the unit. The wall side of the unit has extended surface to provide increased heat output. A large portion of the heat emitted is transferred by convection. This type of baseboard having a greater output per linear foot than the radiant type is particularly adaptable where wall space is at a premium or the heat loss of the room is high.

Finned-tube type of baseboard has a finned-tube heating element that is concealed by a long low sheet-metal enclosure or cover. A major portion of the heat is transferred to the room by convection. The output varies over a wide range depending on the physical dimensions and the materials used. When selecting this type of baseboard the designer should avoid using a unit with too high an output per linear foot. Baseboard performs best when units are so selected that they are installed along as much of the exposed wall as possible.

The basic advantage of the baseboard heat-distributing unit is that its normal placement is along the cold walls and under areas where the greatest heat loss occurs. Other advantages claimed for the baseboard heat-distributing unit are: it is inconspicuous; it offers a minimum of interference with furniture placement; and it distributes the heat near the floor. This last characteristic reduces the floor-to-ceiling temperature gradient to about 2 to 4 F deg, and tends to produce uniform temperatures throughout the room. It also makes baseboard heat-distributing units adaptable to basementless homes, where cold floors are prevalent.[2]

Table 2 . . . . Large-Tube Cast-Iron Radiators

Sectional, cast-iron, tubular-type radiators of the large-tube pattern, that is, having tubes approximately 1⅝ in. in diameter, 2½ in. on centers.

Number of Tubes per Section	Catalog Rating per Section[a]		Height	Width	Section Center Spacing[b]	Leg Height[c] to Tapping

Eight	651	796	907
Ten	732	907	1020
Twelve	812	1005	1135

Heat loss calculations for baseboard heating systems are the same as those used for other types of heat-distributing units. The procedure for designing baseboard heating systems is given in *I = B = R Installation Guide* No. 5.[1] Ratings for baseboard heat-distributing units are expressed in Btuh per linear foot.

FINNED-TUBE UNITS

A finned-tube heat-distributing unit is a room-air heater composed of a finned-tube element fabricated from metallic tube to which metallic fins have been bonded. It does not include a fin-tube type baseboard element provided with an enclosure for replacement of the conventional baseboard.

The finned-tube unit can be used with either steam or hot water systems. It has advantages for installation where it is desired to distribute the heat along the entire outside wall and thereby prevent down drafts along the walls in buildings such as schools, churches, hospitals, and factories.

Normal placement of finned tube is along the walls where the heat loss is greatest. If necessary, the units can be installed in two or three tiers along available wall space to meet the heating requirements. For hot water system installations where two or three tiers are required, a sinuous water flow through the heaters is recommended because a header connection with parallel flow may permit the water to short circuit along the path of least resistance.

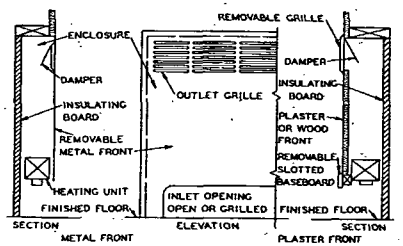

Fig. 1 . . . . Typical Recessed Convector

Protection of the heating element may be provided by open-type grilles fabricated of expanded metal or perforated materials covering the top and front of the finned-tube element. Covers and enclosures are also available to enhance the appearance and to increase heating efficiency.

A *cover* is a fabricated shield having at least a portion of the front skirt made of solid material. It can be mounted on the finned-tube element so that there is clearance between the wall and the cover, and the rear of the finned-tube element is not completely enclosed. A cover may have a top, front, or inclined outlet.

An *enclosure* is a shield of solid material installed so that the finned-tube element is completely enclosed at both front and rear. An enclosure may have an integral back or may be installed tightly against the wall so that the wall itself forms the back. An enclosure may have a top, front, or inclined outlet.

Finned-tube units are available in four tube sizes from 1 in. to 2 in. IPS with various fin arrangements. The resistance to the flow of water or steam is rather low so that a

separate system of distribution piping is generally not required.

The heating capacity of finned tube varies over a wide range depending on tube size, fin size and thickness, spacing of fins, and the materials used. A major portion of the heat transferred to the room to be heated is by convection.

The heating capacity of finned-tube heat-distributing units is determined by test. The Institute of Boiler and Radiator Manufacturers has developed a testing and rating code for finned-tube type of radiation.[4]

Heat loss calculations for finned-tube heating systems are the same as those used for other types of radiation. Ratings are expressed in Btuh per linear foot or square feet Equivalent Direct Radiation per linear foot for steam, and Btuh per linear foot for water.

RATINGS OF HEAT-DISTRIBUTING UNITS

Radiators

A standard method of testing radiators was adopted by the ASHAE in 1927.[4] This Code was withdrawn but the method is still used in industry. It provides for a standard test room, the temperature of which is to be maintained at 70 F, measured in the center of the room at an elevation of 5 ft above the floor. The steam temperature in the radiator is to be 215 F, which corresponds to 15.6 psia. The weight of condensate per hour, under these standard conditions, multiplied by the difference in the enthalpy of the steam entering the radiator and that of the condensate leaving the radiator, gives the radiator output in Btu per hour (Btuh).

If the rating in square feet Equivalent Direct Radiation is desired, divide this output by 240 (which by definition is the Btuh equivalent of 1 sq ft EDR). Correction of output from non-standard test conditions to output at 70 F room and 215 F steam may be made by multiplying the output under test by the ratio

$$\frac{(\text{Standard temperature difference, steam} - \text{air})^{1.3}}{(\text{Test temperature difference, steam} - \text{air})^{1.3}}$$

Convectors

The generally accepted method of testing and rating both ferrous and non-ferrous convectors, is given in *Commercial Standard* CS140-47, *Testing and Rating Convectors*,[5] which has been developed cooperatively by the Convector Manufacturers Association, the Institute of Boiler and Radiator Manufacturers, other members of the trade, and the National Bureau of Standards. This *Commercial Standard* contains details covering construction and instrumentation of the test booth or room and procedures for determining both steam and water ratings.

Steam ratings are expressed in square feet EDR and Btu per hour (Btuh). Water ratings are expressed in Btuh at specified water temperature drops and average water temperatures.

Under the provisions of *Commercial Standard* CS140-47 the rating of a top outlet convector is established at a value not in excess of the test capacity (which is the heat extracted from the steam or water in the convector under standard test conditions). For convectors with other types of enclosures or cabinets a percentage that varies up to a maximum of 15 percent depending on the height and type of enclosure or cabinet is added for heating effect.[6, 7] The additions made for heating effect must be shown in the manufacturer's literature.

Table 6 .... Factors to Convert I=B=R Finned-Tube Steam Ratings to Hot Water Ratings at Temperatures Indicated

Average Radiator Temperature	Factor	Average Radiator Temperature	Factor
150	0.45	190	0.78
155	0.49	195	0.82
160	0.53	200	0.86
165	0.57	205	0.91
170	0.61	210	0.95
175	0.65	215	1.00
180	0.69	220	1.05
185	0.73		

Baseboard

The generally accepted method of testing and rating baseboards is covered in the *I = B = R Testing and Rating Code for Baseboard Type of Radiation*.[8] This Code contains details covering construction and instrumentation of the test booth or room, procedures for determining steam ratings, and licensing provisions for the obtaining of approval of these ratings.

Baseboard ratings include an allowance for heating effect of 15 percent, added to the test capacity. The addition made for heating effect must be shown in the manufacturer's literature.

Steam ratings are expressed in Btuh per linear foot or square feet EDR per linear foot. Water ratings are determined from steam ratings and are expressed in Btuh per linear foot, at specified water flow rates and average water temperatures.

Finned-Tube

The generally accepted method of testing and rating finned-tube heat-distributing units is covered in the *I = B = R Testing and Rating Code for Finned-Tube Type of Radiation*.[9] This Code contains details covering construction and instrumentation of the test booth or room, procedures for determining steam and water ratings, and licensing provisions for the obtaining of these ratings. Steam ratings are expressed in Btuh per linear foot or square feet EDR per linear foot. Water ratings are determined from steam ratings and are expressed in Btuh per linear foot at specified water flow rates and average water temperatures.

The rating of a finned-tube unit in an enclosure having a top outlet is established at a value not in excess of the test capacity (which is the heat extracted from the steam or water in the unit under standard test conditions). For finned-tube with other types of enclosures or covers a percentage is added for heating effect which varies up to a maximum of 15 percent depending on the height and type of enclosure or cover. The additions made for heating effect must be shown in the manufacturer's literature.

Corrections for Non-Standard Conditions

The heat output of a radiator, convector, baseboard or finned-tube heat-distributing unit is an exponential function of the temperature difference between the air in the room and the heating medium in the room-heating unit, or, expressed as an equation

$$H = c(t_s - t_a)^n \qquad (1)$$

where

H = heat output, Btu per hour (Btuh).

c = a constant determined by test from Equation 1.

t_s = average temperature of heating medium, Fahrenheit. For hot water the arithmetical average of the entering and leaving water temperatures is used.

t_a = room air temperature, Fahrenheit. Air temperature 60 in. above the floor is generally used for radiators while the entering air temperature is used for all other types of heating units.

n = an exponent which equals 1.3 for cast-iron radiators, 1.4 for baseboard radiation, and 1.5 for convectors. For finned-tube units n varies with both air and heating medium temperatures. Correction factors to convert outputs at standard rating conditions to outputs at other conditions are given in Tables 6, 7, and 8.

Table 7 .... Correction Factors for Direct Cast-Iron Radiators and Convectors[a]

[a] To determine the size of a radiator or a convector for a given space, multiply the heat loss of the space in Btu per hour by the proper factor from the above table and select radiator or convector having an equivalent Btu per hour rating.

An alternate method is to divide the heat loss in Btu per hour by 240 and multiply the result by the proper factor from the above table and select radiator or convector having an equivalent square foot rating.

To determine the heating capacity of a radiator or a convector under conditions other than the basic ones with the heating medium at a temperature of 215 F, and the room temperature at 70 F in the case of a radiator, and the inlet air temperature at 65 F in the case of a convector, divide the heating capacity at the basic rating conditions by the proper factor from the above table.

[a] To determine the heating capacity under conditions other than the basic ones with the heating medium at a temperature of 215 F, and the inlet air temperature at 65 F, divide the heating capacity at the basic rating conditions by the proper factor from the above table.

Enclosure, Paint, Humidity Effect

The general effect of an enclosure placed about a direct radiator is to restrict the air flow, and diminish the proportion of output due to radiation. Enclosures of proper design may, however, improve the heat distribution within the room as compared to the heat distribution obtained with an unenclosed radiator.[4, 8]

For a radiator or cast-iron baseboard the finish coat of paint affects the heat output. Oil paints of any color will give about the same results as unpainted black or rusty surfaces, but an aluminum or a bronze paint will reduce the heat emitted by radiation. The net effect may be a reduction of 10 percent or more in the total heat output of the radiator.[10, 11, 12]

Some commercial enclosures and shields for use on direct radiators are equipped with water pans for the purpose of

adding moisture to the air in the room. Tests[28] show that an average evaporative rate of about 0.235 lb per (hr) (sq ft of water surface) may be obtained from such pans, when a radiator is steam heated and the relative humidity in the room is between 25 and 40 percent. This source of supply of moisture alone is not adequate to maintain a relative humidity above 25 percent on a zero day.

CHAPTER 15

UNIT VENTILATORS AND UNIT HEATERS

Unit Ventilators: Classification, Ratings, Capacity, Requirements, Application, Control, Location, Exhaust Vents, Window Downdraft Prevention, Mechanical Cooling; Unit Heaters: Classification, Application, Heating Medium, Type, Location, Sound Level, Ratings, Control, Piping, Maintenance.

UNIT ventilators and unit heaters are discussed in this chapter. The types, characteristics, method of rating, and procedures for selection and application of these products are described.

UNIT VENTILATORS

The term *unit ventilator* denotes an assembly, the principle functions of which are to heat, ventilate, and cool a space by the introduction of outdoor air in quantities up to 100 percent of its rated capacity. The heating medium may be steam, hot water, gas, or electricity. The essential elements of a unit ventilator are fans and motor, heating element, dampers, filters, and outlet grilles (or diffusers), all encased in a housing.

Unit ventilators are used primarily in schools, meeting rooms, offices and other areas where the density of occupancy indicates the need for controlled ventilation. The typical unit is equipped with a system of control that permits the heating, ventilating, and cooling effect to be varied while the fans are operating continuously. In normal operation, the discharge air temperature from a unit is varied in accordance with the room requirements. When heating is required, the air delivered is above room temperature. When the heat generated within the room by occupants, lights, sun, etc., is sufficient to cause overheating, the temperature of the air delivered is below that of the room. It is customary to equip unit ventilators with control devices that prevent the delivery of air at a temperature low enough to cause discomfort.

Classification

The various types of unit ventilators can be classified according to the three following methods:

1. *Heating Medium.* Four types of heating elements are used: (*a*) *steam*, (*b*) *hot water*, (*c*) *gas-fired*, and (*d*) *electric*.

2. *Type of Unit.* Under this classification there are three basic types to be considered: (*a*) *Floor-mounted* type, (*b*) *ceiling-mounted* type, and (*c*) *auditorium* type which are used in vertical, horizontal, or inverted positions. Figs. 1 and 2 show typical *floor-mounted* units. Fig. 3 shows a typical *ceiling-mounted* unit, while Fig. 4 shows a typical *auditorium-type* unit in horizontal position.

3. *Arrangement of Elements.* Unit ventilators may be of the (*a*) *draw-through*, or (*b*) *blow-through* arrangement. Fig. 1 shows a typical *draw-through* unit and Fig. 2 shows a typical *blow-through* unit.

Ratings of Unit Ventilators

Unit ventilators are customarily cataloged with two ratings: the *standard air rating* and the *anemometer air rating*. The *standard air rating* is obtained in accordance with the ASHAE *Standard Code for Testing and Rating Steam Unit Ventilators*.[1] This code requires 0 F entering air temperature, unit fan operating at rated speed with standard louver or grille on the outlet, and dry saturated steam at a temperature at the unit corresponding to a pressure of 16.7 psia (218.5 F). The *standard air rating* of the unit is the delivery in cubic feet per minute, converted to standard air at 70 F.

The *anemometer air rating* is peculiar to school ventilation. It originated as a convenient field measurement for checking air quantities, and is the basis of rating for ventilation requirements under some state and local building codes. The anemometer rating (air capacity) is obtained by averaging the air velocities obtained by an anemometer (propeller or averaging type) held over equal subdivisions of the outlet grille at a distance of 2 in. from the grille, and multiplying the average velocity by the gross area of the grille. The anemometer rating is based on the final temperature of the air leaving the grille while the unit is delivering outdoor air and recirculated air in the proper proportion and the heating element is supplying heat as specified. This

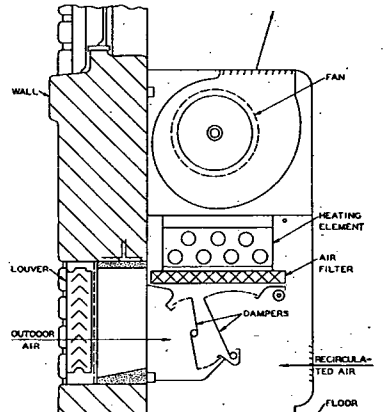

Fig. 1. . . . Typical Floor-Mounted Unit Ventilator—Draw-Through Type

method of rating is subject to error from differences in types and calibration of instruments, grille design, and the care with which the rating test is conducted. Because of this, the *standard air rating* is used by manufacturers to rate unit ventilators.

Table 1 shows the air delivery capacities by the two methods of rating and the approximate room heating equivalent in square feet of direct radiation (EDR) of an intermediate size of heating element. Heating elements are available for higher and lower capacities.

Heating Capacity Requirements for Unit Ventilators

Since a unit ventilator has the dual function of introducing outdoor air for ventilation and maintaining a specified room temperature, the heat required by the unit may be similarly divided into (1) *heat required for ventilation* H_v and (2) *surplus heat* H_s. The *surplus heat* is available for maintaining room temperature. If auxiliary radiation is installed, the *surplus heat* requirement may be reduced by a corresponding amount. The sum of H_v and H_s is the total heat H_t to be supplied by the unit ventilator.

These quantities of heat are related by the following equations:

$$H_v = 0.24\ W\ (t - t_o) \quad (1)$$

$$H_t = 0.24\ W\ (t_f - t_o) \quad (2)$$

$$H_s = H_t - H_v = 0.24\ W\ (t_f - t) \quad (3)$$

$$W = d\ 60\ Q \quad (4)$$

$$H_t = H_v + 0.24\ d\ 60\ Q\ (t - t_o) \quad (5)$$

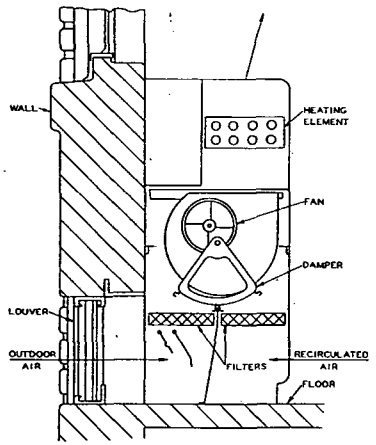

Fig. 2 .... Typical Floor-Mounted Unit Ventilator—Blow-Through Type

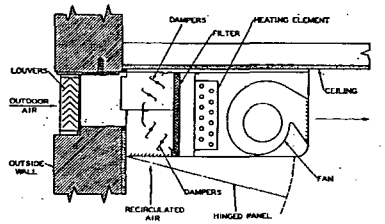

Fig. 3 .... Typical Ceiling-Mounted Unit Ventilator

where

d = density of air, pounds per cubic foot (0.075 lb per cu ft for Standard Air by definition).
H_s = surplus heat, Btu per hour.
H_v = heat required to warm air for ventilation, Btu per hour.
H_t = total heat requirements for both heating and ventilation, Btu per hour.
Q = volume of air handled by the ventilating equipment, cubic feet per minute.
t = temperature to be maintained in the room, Fahrenheit
t_o = outdoor temperature, Fahrenheit.
t_f = temperature of the air leaving the unit, Fahrenheit.
W = weight of air circulated, pounds per hour.
0.24 = specific heat of air at constant pressure (approximate value).

Example 1: The heat loss of a certain room is 24,000 Btu per hour, and the ventilating requirements are 1000 cfm. If the room temperature is to be 70 F and all air is taken from the outdoors at 0 F, what will be the total heat demand on the unit if it is required to provide for both the heating and ventilating requirements (combined system)?

Solution: Since the surplus heat is available to replace the heat loss of the room,

$$H_s = 24{,}000 \text{ Btu per hour.}$$

Substituting in Equation 5:

$$H_t = 24{,}000 + 0.24 \times 0.075 \times 60 \times 1000\ (70 - 0)$$

$$= 99{,}600 \text{ Btu per hour}$$

$$t_f = \frac{24{,}000}{0.24 \times 0.075 \times 60 \times 1000} + 70 = 92.2 \text{ F}$$

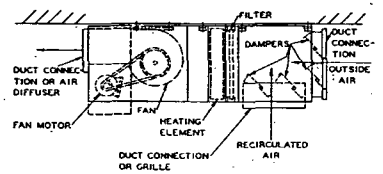

Fig. 4 .... Typical Auditorium Unit Ventilator in Horizontal Position

Table 1 .... Typical Capacities of Unit Ventilators for an Entering Air Temperature of 0 F

Cubic feet of air per minute		Total capacity in square feet, equivalent direct radiation	Capacity available for heating the room, square feet equivalent direct radiation	Final air temperature F
Anemometer rating	Standard air rating			
750	500	214	56	95
1000	750	320	84	95
1260	1000	427	112	95
1560	1250	534	141	95

If in *Example 1* a 1000 cfm (Standard Air) unit were required, but only 25 percent of the air introduced were outdoor air, the solution is:

$$H_t = 24{,}000 + 0.24 \times 0.075 \times 60 \times 0.25 \times 1000\ (70 - 0)$$

$$= 42{,}900$$

$$t_f = \frac{24{,}000}{0.24 \times 0.075 \times 60 \times 1000} + 70 = 92.2$$

The only difference from *Example 1* is that the ventilation load has been reduced.

Heating Capacity Ratings

Heating capacity ratings for *steam* unit ventilators are obtained in accordance with the ASHAE *Standard Code for Testing and Rating Steam Unit Ventilators*.[1] Under this code the capacities are established for varying air entering temperatures in addition to the standard rating. Capacity ratings include the *entering air temperature*, the *total heating capacity*, the *surplus* or *heating capacity*, and the *final air temperature*.

Hot water unit ventilators have heating capacity ratings based on various entering water temperatures, flow rates or temperature drops, and entering air temperatures.

Gas-fired unit ventilators have heating capacity ratings obtained in accordance with regulations established by the American Gas Association. Heating capacities include the *total heat input* and the *total heat output*, in Btu per hour, for various entering air temperatures.

Electric unit ventilators have heating capacity ratings based on the heat input to the electric heating element, in kilowatts or Btu per hour.

The air capacities of hot water, gas-fired, and electric unit ventilators are obtained in accordance with the ASHAE *Standard Code for Testing and Rating Steam Unit Ventilators*.[1]

Applications of Unit Ventilators

Items to be considered in the application of unit ventilators are: (1) unit air capacity, (2) percent minimum outdoor air, (3) heating capacity, (4) cycle of control, and (5) location of unit.

The primary considerations in the selection of the *unit air capacity* are the mild weather cooling capacity and the number of occupants in the space. Other factors to be considered are state and local code requirements, volume of the room, density of occupancy, and the usage of the room. A safe rule for determining unit air capacity is to allow a total air quantity of 30 cfm per person, or six to nine room air changes, per hour, whichever is greater. With this quantity of air handled, it is possible to obtain satisfactory cooling in mild weather. Table 2 gives recommended room volume circulation rates for different types of spaces served. For rooms facing East, South or West, higher values should be used.

The minimum amount of outdoor air for ventilation is determined after the total air capacity has been established. It may be governed by state or local codes or may be calculated by the engineer to meet the ventilating air needs of the particular application.

The *heating capacity* of a unit to meet the heating requirement can be determined from manufacturers tables. Selection of *heating capacity* should always be made after determining the basic size of unit by selecting the unit *air capacity*.

Automatic Control of Unit Ventilators

Many different *cycles of control* are available. The principle difference in the various cycles pertains to the amount of outdoor air delivered to the room during normal periods of occupancy. Usually a room thermostat controls both a valve to regulate the heat supply and a damper to regulate the supply of outdoor air. An air-stream thermostat in the unit prevents the discharge of air below the desired minimum temperature. Unit ventilator control cycles provide the proper sequence for the following stages:

Warm-up Stage. All control cycles function to provide rapid warm-up by having the units provide full heat with the outdoor damper closed. Thus 100 percent room air is recirculated and heated until the room temperature approaches the desired temperature level.

Heating and Ventilating Stage. As the room temperature rises into the operating range of the thermostat, ventilation is accomplished by the partial or complete opening of the outdoor air damper according to the cycle used. Auxiliary heating equipment is shut off. As the room temperature continues to rise the unit ventilator heat supply is throttled.

Cooling and Ventilating Stage. When the room temperature rises above the normal level, cool air is discharged into the room. The room thermostat accomplishes this by throttling the heat supply, finally shutting it off, and opening the outdoor air damper to prevent overheating of the room. The air stream thermostat frequently takes control during this stage to prevent the discharge temperature from falling below a set level.

The three basic *cycles of control* commonly used are as follows:

Cycle X. 100 percent of outdoor air is admitted at all times except during the *warm-up stage.*

Table 2 .... Recommended Outdoor Air Capacities for Mild Weather Cooling

For North Exposure

Type of space	Recommended outdoor air delivery—room volumes per hour
Classrooms	6–9
Laboratories, Forge Shops	6–8
Metal Working Shops	6–8
Offices	6–8
Card Rooms, Lodges	6–9
Private Offices	6–9
Cafeterias & Kitchens	4½–7

Cycle Y. A minimum amount of outdoor air (normally 25 to 50 percent) is admitted during the *heating and ventilating stage*. This percentage is gradually increased to 100 percent, if needed, during the *cooling and ventilating stage*.

Cycle Z. Except during the *warm-up stage* a variable amount of outdoor air is admitted as needed to maintain a fixed temperature of the air entering the heating element. This is controlled by the air-stream thermostat which is set low enough (often 55 F) to provide cooling when needed.

Night Control

For maximum economy it is general practice to maintain the building at reduced temperature at night and over weekends and vacations. Several control arrangements to accomplish this are in common use. One uses the unit as a convector at night. Another turns the fans on and off as in the case of a unit heater whenever the unit convective capacity is insufficient. Still another arrangement uses the convective capacity of the unit supplemented by the convective capacity of auxiliary equipment installed within the room. More elaborate arrangements are available, permitting operation at daytime temperatures in some spaces and lowered temperatures in others for maximum economy during night occupancy of part of the building. For general information on controls, see Chapter 43.

Location of Unit Ventilators

The location of the unit is important. Wherever possible it should be placed against the outside wall and near the centerline of the room. It is difficult to obtain proper air distribution if the unit is installed either on an inside wall or in the corner of the room. Standard unit models are set against the wall, or may be recessed into the wall; and discharge the air stream upward. Ceiling models discharge the air horizontally.

Air Exhaust Vents

The location and size of exhaust vents are not of particular importance on systems employing unit ventilators. However, many states have regulations which require vents in public buildings. When vents are used, it is important that they be sized and located properly. Vents should be fitted with manual dampers so that the exhaust can be regulated for proper air distribution. Back-draft dampers should be installed in the vent opening to prevent cold air from entering through the vent.

It has become common practice, where regulations permit, to exhaust into the corridor through louvers in the classroom door, with powered or gravity exhaust from the corridor to the outdoors. Thus, the slight pressurizing of the building by the unit ventilators provides the force to exhaust the entire building. It is common practice also to use the exhaust from the classroom as secondary ventilation by passing the exhaust air through wardrobes and lockers. Many state and local codes make this arrangement mandatory.

Window Downdraft Prevention

Increasing use of large window areas has presented a window downdraft problem caused by chilled air flowing down the windows and into the occupied areas of the room. Three basic means of combatting these downdrafts have been developed for use with unit ventilators. These are shown in Fig. 5 and operate as follows:

Window sill heating employs finned radiation of moderate capacity installed along the wall under the window area. Heated air rises by convection upward and counteracts the downdraft by tempering it and diverting it upward to eliminate the cold draft.

Window sill recirculation is obtained by placing the return air intake along the window sill. Room or return air to the unit includes the cold downdrafts, takes them out of the occupied area of the room and thus eliminates the problem.

Window sill discharge directs a portion of the unit ventilator discharge air into a delivery duct along the sill of the window. The unit discharge air, delivered vertically at the window sill, provides room-wide air distribution and combats downdraft by upwardly-directed streams of air.

Unit Ventilators For Mechanical Cooling

With increased use of school buildings during the summer months, some school building programs incorporate mechanical cooling or provisions for including it in the future. In either instance, the unit ventilators provide the same function during the heating season as the unit ventilators previously discussed in this chapter, using hot water as the heating medium. Chilled water is used to provide summer air conditioning. Units designed only for heating and ventilating are not suitable for use with chilled water. When provision for future mechanical cooling is made, the supply and return piping, piping insulation, unit ventilators and controls are usually installed initially as required for complete air conditioning. Water chillers, cooling towers, or evaporative condensers, and associated accessories are installed later when mechanical cooling is required.

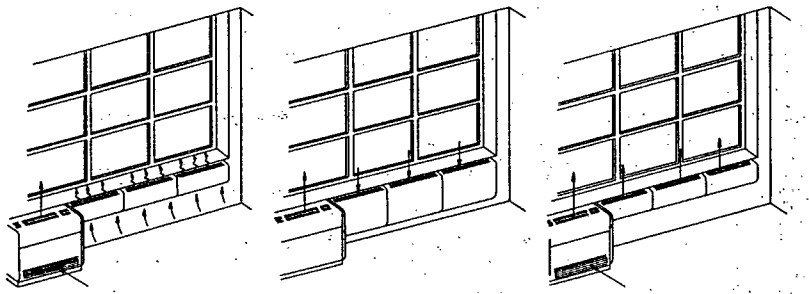

Fig. 5.... Three Methods of Preventing Window Downdraft

UNIT HEATERS

The term *unit heater* denotes an assembly of elements, the principal function of which is heating. The essential elements of a unit heater are a fan and motor, a heating element, an enclosure, and a directional outlet. Filters, dampers, duct collars, combustion chambers, and flues may also be included. Some types are shown in Figs. 6 to 13.

Classification

The various types of unit heaters in present use can usually be classified according to one or more of the following methods:

1. *By heating medium:* Under this classification there are five heating media to be considered: (*a*) steam, (*b*) hot water, (*c*) gas, (*d*) oil, (*e*) electric.

2. *By type of fan:* Under this classification there are two types of fans to be considered: (*a*) *propeller* and (*b*) *centrifugal*. Propeller fan units may be of the *horizontal-blow* or *down-blow* type. Centrifugal fan units may be of the smaller *cabinet* type, or larger *industrial* type. Either may be arranged for the delivery of air horizontally, or vertically up or down.

3. *By arrangement of elements:* Under this classification there are two types of units to be considered: (*a*) the *draw-through type*, in which the fan draws air through, and (*b*) the *blow-through type*, in which the fan blows air through the heating element. Direct-fired unit heaters are always of the blow-through type.

Application

Unit heaters have three principal characteristics, as distinguished from gravity heating units: (1) relatively large heating capacities in compact casings, (2) the ability to project heated air in a controlled manner over a considerable distance, and (3) a relatively low installed cost per Btu output. They are therefore usually employed in applications where the heating capacity requirements, or the physical volume of the heated space, or both, are larger than those that can be adequately or economically handled by gravity heating units.

Where the heating capacity requirement is large, the installation of a small number of unit heaters will usually prove more economical than will the use of a multiplicity of gravity heating units of the same total capacity. Where the volume of the space is large, and especially where ceilings are high, unit heaters can provide comfort through uniform heat distribution, and economy of operation by confining of the heat to the occupied zone and eliminating stratification in a manner which is difficult to attain with gravity radiation. Unit heaters located overhead permit 100 percent utilization of floor space. They may often be used to advantage in specialized applications requiring spot heating, or intermittent heating, such as the blanketing of outside doors in industrial plants, or in corridors and vestibules. Unit heaters are also employed where filtration of the heated air is required, and they may be modified to provide ventilation where the introduction of outdoor air is required.

Unit heaters are used principally for heating commercial and industrial structures such as garages, factories, warehouses, showrooms, stores and laboratories, and, for heating corridors, lobbies, vestibules, and similar auxiliary spaces in all types of buildings.

Unit heaters may be applied to a number of industrial processes, such as drying and curing, in which the use of heated air in rapid circulation with uniform distribution is of particular advantage. They may be used for moisture absorption, such as fog removal in dye houses, or for the prevention of condensation on ceilings or other cold surfaces of buildings in which process moisture is released. When such conditions are severe, it is necessary that the units be equipped to draw air from outdoors in sufficient volume to provide a rapid air change, and that they operate in conjunction with exhaust ventilators or fans for exhausting the moisture-laden air. (See discussion of condensation in Chapter 10.)

Factors Affecting Application

There are four major factors to be considered in the application of unit heaters: (1) the heating medium to be employed, (2) the type of unit, (3) the location of the unit for proper heat distribution and (4) the permissible sound level.

Heating Medium

The selection of the proper heating medium is usually determined on an economic basis, and requires an examination of the first cost, the operating cost, and the conditions of use. Steam and hot water unit heaters are relatively inexpensive, but require a boiler plant and piping system, the per-unit cost of which generally decreases as the number of units installed increases. Gas- and oil-fired units are more costly, but the fuel lines and vent flues required are comparatively inexpensive, and the overall installation cost will usually be lower where a small number of units is used. Electric units are relatively inexpensive to purchase and install, but are usually associated with a high operating cost per Btu output unless electric rates are very favorable.

Steam or hot water units are most frequently used in new installations in which the number of units is large enough to justify the expense of a new boiler and piping system, and in existing installations or additions in which the system is of sufficient capacity to handle the additional load. *High-pressure steam* or *high-temperature hot water* units are usually employed in larger installations or where a high temperature medium is also required for process work. Low-pressure steam and conventional hot water units are usually installed in smaller installations and in those primarily concerned with comfort heating.

Gas-fired and oil-fired unit heaters are usually preferred in installations in which the number of units required does not justify the expense of a new boiler and piping system, where the space or the time required to construct a new boiler plant is not available, or where individual metering of the fuel supply is required, as in a shopping center. Gas-fired units are usually of the horizontal propeller type or the industrial centrifugal type. Oil-fired units are largely of the industrial centrifugal type. Some codes limit the use of direct-fired unit heaters in certain applications.

Electric unit heaters are used where low cost electric power is available, or for isolated locations, intermittent use, supplementary heating or temporary service requirements. Typ-

ical applications are ticket booths, watchmen's offices, factory offices, locker rooms, and other isolated rooms scattered over large areas. Electric units are particularly useful in isolated and untended pumping stations or pits where they may be thermostatically controlled to prevent freezing temperatures.

Type of Unit

Propeller fan units are usually used in free-delivery applications where the heating capacity and distribution requirements can best be met by units of moderate output used singly or in multiples, and where filtration of the heated air is not required. *Horizontal-blow* units are usually associated with low to moderate ceiling heights. *Down-blow* units are employed in high-ceiling spaces, and where floor and wall space limitations dictate an out-of-the-way location for the heating equipment.

Industrial centrifugal fan units are applied where heating capacities and space volumes are large, or where filtration of the heated air, operation against static resistance, or the introduction of outdoor air are required. Down-blow or horizontal-blow units may be used, depending on the requirement.

Cabinet unit heaters are used for applications where a more attractive appearance is desired. They are suitable for free delivery or low static pressure duct applications, may be equipped with filters, and can be arranged to discharge either horizontally, or vertically up or down.

Location for Proper Heat Distribution

Location of the units for proper heat distribution is of utmost importance in the application of unit heaters. In general, the units must be selected, located, and arranged so as to provide complete heat coverage and at the same time maintain acceptable air motion and temperature in the working or occupied zone. Proper application depends on a number of factors: the size, number, type and direction of blow of the units, the mounting height, the outlet velocity, the outlet temperature, the air volume and the type of directional outlet employed. Many of these factors are interrelated, and manufacturers therefore publish data for specific units showing heat coverage and mounting heights for various outlet velocities and outlet arrangements. Such data should normally be consulted in selecting unit heaters for a particular application.

In general, however, *mounting height* and the area of heat coverage increase with increased air volume and outlet velocity, and decrease with increased final temperature. The mounting height may be governed by space limitations or by the presence of equipment such as display cases or machinery. Both noise and air velocity in the occupied zone generally increase with increased outlet velocities and must therefore be considered.

The blow is dependent to a marked degree on the *temperature of air leaving the heater* as well as upon its velocity and volume. Increased final temperature will reduce the area of heat coverage and the mounting height. Care must be exercised in the application of down-blow unit heaters. The higher the mounting height, the lower must be the outlet temperature of the air leaving the heater in order that the heated air will be forced down into the occupied zone.

Since the outlet temperature of air from a unit heater increases with the temperature of the heating medium, unit heaters for high-pressure steam or high-temperature hot water should be designed to produce approximately the same leaving air temperature as would be obtained from a lower temperature heating medium.

In order to obtain the desired air distribution and heat diffusion, unit heaters are commonly equipped with directional outlets, adjustable louvers, or fixed types of diffusers. For a given unit with a given discharge temperature and outlet velocity, the mounting height and heat coverage can vary widely with the type of directional outlet, adjustable louver, or diffuser employed.

Other factors which may influence the heat coverage must also be considered. Obstructions, such as columns, beams, partitions, or machinery, either in the discharge air stream or in the approach area to the unit, can reduce the heat coverage substantially. The presence of strong drafts or other air currents will also reduce the coverage. Exposures such as large glass areas, or outside doors, especially on the windward side of the building, require special attention, and units should be arranged so as to blanket such exposures with a curtain of heated air which will intercept the cold drafts.

For area heating, horizontal-blow unit heaters in exterior zones should be located so as to blow along the exposure or toward it at a slight angle. Where possible, multiple units should be arranged so that the discharge air streams support each other and create a general circulatory motion in the space. Interior zones under exposed roofs or skylights should be completely blanketed. Down-blow units should be arranged so that the heated areas from adjacent units overlap *slightly so as to provide complete coverage.*

For spot heating of individual spaces in larger unheated areas, single unit heaters may be employed, but allowance must be made for the inflow of unheated air from adjacent spaces and the consequent reduction in heat coverage. Isolation of such spaces by partitioning or enclosure is always desirable from a heating standpoint.

Horizontal unit heaters should have their discharge outlets located well above the head level, and both horizontal *and vertical units should be so applied that the heated air* stream will be delivered to the occupied zone at temperatures and velocities which are not objectionable. Where possible, units should be so located that the discharge air flow is into open spaces such as aisles and not directly on the occupants.

Manufacturers' catalogs usually give suggestions for the best arrangements of various unit heaters, recommended mounting heights, heat coverages for various outlet velocities, final temperatures, and directional outlets.

Sound Level

Consideration must be given to the problem of noise generated by unit heaters if they are applied in spaces having a requirement for low sound levels. All unit heaters generate some noise, and whether or not that noise will be acceptable depends upon the type of space in which it is applied. For example, units with noise levels acceptable in *a manufacturing plant might be too noisy for use in a* show-room. A unit heater for a particular application must therefore be selected for satisfactory sound level as well as for adequate heating capacity and proper heat distribution.

Ratings of Unit Heaters

It is standard practice to rate all types of unit heaters on the basis of the amount of heat delivered by the air in Btu per hour above an entering air temperature of 60 F.

Steam. Rating of steam unit heaters has been standard-

ized by a code[3] in which the following items are the basis of rating: dry saturated steam at 2 psig pressure at the heater coil; air at 60 F (29.92 in. Hg barometric pressure) entering the heater; and heater operating free of external resistance to air flow.

The capacity of a heater increases as the steam pressure increases, and decreases as the entering air temperature increases. The heating capacity for any condition of steam pressure and entering air temperature other than standard may also be determined by means of a standard procedure prescribed by this code.

Hot Water. A standard for the rating of hot water type unit heaters has also been established by code[4] in which the following items are the basis of rating: entering water at 200 F; water temperature drop 20 F entering air at 60 F (29.92 in. Hg barometric pressure); and heater operating free of external resistance to air flow. Variations in entering water temperature, entering air temperature and water

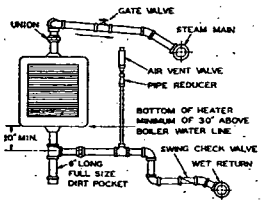

Fig. 14 .... Unit Heater Connection to Low-Pressure Steam Closed Gravity System

flow rate will affect capacity. This code prescribes a method of translating the heating capacity as obtained under test conditions to other conditions of air and water temperature.

Gas-Fired. Gas-fired unit heaters are rated in terms of both input and output in accordance with the approval requirements of the American Gas Association.

Oil-Fired. Ratings of oil-fired unit heaters are based on heat delivered at heater outlet in Btu per hour.

Electric. Electric unit heaters are rated on the energy input to the heating element, expressed in terms of kilowatts, or Btu per hour.

Effect of Resistance Upon Capacity. Unit heaters are customarily rated at free delivery type units. If outside air intakes, air filters, or ducts on the inlet or discharge are used, a reduction in air and heating capacity will result because of this added resistance to air flow, unless compensating changes are made in fan speed. This reduction in capacity will depend upon the characteristics of the heater, and on the type, design, and speed of the fans, so that no specific percentage reduction can be assigned for all heaters at a given added resistance. The heat output to be expected under other than free delivery conditions should be secured from the manufacturer.

Effect of Inlet Temperature. Changes in entering air temperature will influence the total heating capacity in most unit heaters and the final temperature in all units. Since many unit heaters are located some distance from the occupied zone, consideration should be given to the possible differences in temperature of the air actually entering the unit from that being maintained in the heated area. This is especially true with down-blow unit heaters. In general, the temperature gradient (temperature difference per foot of elevation) when using unit heaters, is less than when using gravity heating units.[5]

Higher velocity units and units with lower discharge air temperature, will maintain lower temperature gradients than units with higher discharge temperatures. Valve-controlled or bypass-controlled units employing continuous fan operation will maintain lower temperature gradients than will units employing intermittent fan operation. Directional

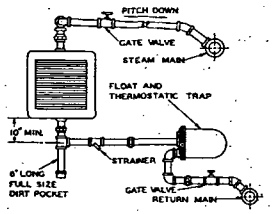

Fig. 15 .... Unit Heater Connection for Low-Pressure Steam Open Gravity or Vacuum Return System

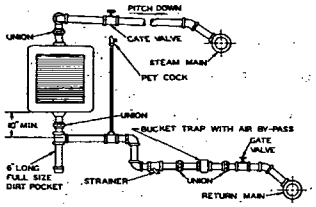

Fig. 16 .... Unit Heater Connection to High-Pressure Steam System

control of the discharged air from a unit heater can also be an important factor in effecting satisfactory distribution of heat and reducing floor-to-ceiling temperature gradients.

When some outdoor air is introduced, the temperature of the mixture of outdoor and recirculated air must be calculated and used as the entering air temperature at the heater. For recirculating heaters located *at the floor* or with *intakes at the floor*, the temperature of air entering the heater should be assumed to be the same as that to be maintained in the room itself.

Automatic Control of Unit Heaters

The controls for a steam or hot water unit heater can either provide (1) *on-off operation* of the unit fan or (2) *continuous fan operation* with modulation of the heat output.

For *on-off* operation a room thermostat is used to start and stop the fan motor. A limit thermostat, often strapped

to the supply or return pipe prevents fan operation in the event heat is not being supplied to the unit.

Continuous fan operation eliminates the intermittent blasts of hot air resulting from on-off operation, and the stratification of temperature from floor to ceiling which often occurs during the *off* periods. In this arrangement a proportional room thermostat controls a valve modulating the heat supply to the coil or a bypass around the heating element. A limit thermostat or auxiliary switch stops the fan when heat is no longer available.

Control of direct-fired and electric units is usually accomplished by intermittent operation of the heat source under

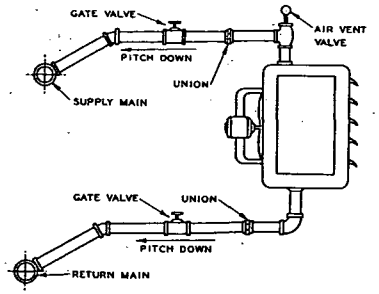

Fig. 17 .... Connection of Horizontal Unit Heater to Hot Water System

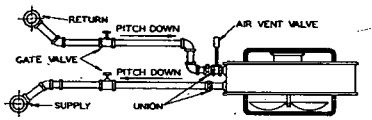

Fig. 18 .... Connection of Vertical Unit Heater to Hot Water System

control of the room thermostat, with a separate fan switch to run the fan when heat is being supplied. For a more general discussion of automatic control, refer to Chapter 43.

Unit heaters may be used in summer as a means of providing air motion. In such cases the source of heat is shut off and the thermostat is provided with a bypass switch that will permit fan operation independently of the controls.

Piping Connections For Unit Heaters

Piping connections for steam unit heaters are similar to those for other types of fan blast heaters. The piping of unit heaters must conform strictly to the system requirements while at the same time permitting the heaters to function as intended. The basic piping principles for steam systems are discussed in Chapter 26.

Rapid condensation of steam, especially during heating-up periods, is characteristic of steam unit heaters. The return piping must be planned to keep the heating coil free of condensate during periods of maximum heat output, and the steam piping must be ample to carry a full supply of steam to the unit to take the place of that condensed. Adequate sizes of piping are especially important where a unit heater fan is operated under on-off control because the condensate rate fluctuates rapidly.

Recommended piping connections for unit heaters[6] are shown in Figs. 14 to 18.

In steam systems the branch from the supply main to the heater should pitch toward the main, and be connected to its top to prevent condensation in the main from draining through the heater where it might reduce capacity and cause noise.

The return piping from steam unit heaters should provide a minimum drop of 10 in. below the heater so that the head of water required to overcome resistances of check valves, traps, and strainers will not cause condensate to remain in the heater.

Dirt pockets shown in Figs. 14 to 16 are essential, and strainers are recommended as an additional means of retaining dirt and scale which might affect operation of check valves and traps. Return piping between the heater and strainer should be of the same size as the heater outlet. Strainers should always be installed in the steam supply line if the heater is equipped with the steam-distributing type of coils or is valve-controlled.

An adequate air vent is required for low-pressure closed-gravity systems. The vertical pipe connection to the air vent should be at least ¾ in. IPS to permit separation of the water from the air passing to the vent.

In vacuum systems, if thermostatic instead of float-and-thermostatic traps are used, a cooling leg must be provided ahead of the trap.

In high-pressure systems it is customary to vent the air through a pet cock which is left slightly open at all times. Where possible it is advisable to install pressure reducing valves to permit operation of the heaters at low pressure. Traps used must be suitable for the operating pressure encountered.

In connecting piping to hot water unit heaters, the piping should be pitched to permit escape of air to the high point in the piping where it can be vented to the atmosphere. An air vent at the heater is used to facilitate air removal or to vent the top of the heater. Provision should be made for complete drainage of the system, including nipple and cap drains or drain cocks where units are located below mains.

Maintenance

Regular inspection based upon a schedule determined by the amount of dirt in the atmosphere will insure maximum economy in operation and maintenance of heating capacity.

Heating elements should be cleaned when necessary by brushing or blowing with high-pressure air, or by using a steam spray. Removal of the heating element and washing with a mild alkali solution, followed by thorough rinsing with water, may be necessary in certain installations.

Dirty fan blades may cause unbalance and vibration with consequent noise and damage to bearings. Hence, fan blades should be cleaned when necessary. Vibration or noise may also be caused by improper fan position or loose set screws.

There is considerable difference in the attention required by the various types of motors used with unit heaters. This is particularly true of lubrication, the instructions for which must be carefully followed for trouble-free operation. Excessive lubrication may cause lubricant to reach and damage the motor. An improper lubricant may cause failure of bearings. Instructions for care of the motor on any unit

heater should therefore be obtained from the manufacturer and should be kept at the unit.

Fan bearings and drives must be given the lubrication and other attention specified by the manufacturer. If the unit is direct-connected, the couplings should be inspected periodically for wear and alignment. V-belt drives should have all belts replaced with a matched set if one belt shows wear.

Periodical inspections of traps, check valves, and air valves, and the replacement of worn parts are important maintenance items. Strainers should be cleaned regularly.

When filters are incorporated in the unit, they must be cleaned or replaced when dirty.

For prevention of corrosion in unit heaters, see Chapter 55, Corrosion and Water Formed Deposits, Causes and Prevention, in this edition, and also Bulletin 12, *The Care and Maintenance of Steam and Hot Water Unit Heaters*, published by the Air Moving and Conditioning Association, Inc.

CHAPTER 16

UNITARY AIR-CONDITIONING EQUIPMENT

Definitions, Classification, and Components of Unit-type Equipment, Remote and Self-contained Units, Room Air Conditioners, Ratings of Unit Air Conditioners, Application of Unitary Equipment, Unit Air Coolers

THIS chapter presents the physical characteristics of air-conditioning and air-cooling units; a suggested procedure for selection of units; and some of the factors involved in the application of unitary equipment. In general, factory-produced unit equipment can be obtained to accomplish all of the functions possible from field assemblies, but the advantages of unit equipment are most apparent in small and moderate capacities. Above 12,000 cfm capacity, or approximately 40 tons of refrigeration capacity, handling and assembly costs generally favor the use of field-assembled units. Multiple application of unitary equipment is frequently justified for large gross tonnage installations where zoning or a minimum amount of ducts is desirable.

DEFINITIONS

The term *air-conditioning* unit has been loosely used as a name for all types of factory produced air-handling, cooling, or heating units. A joint committee[1, 2, 3] on Rating Refrigerating Equipment has defined the various types of unitary equipment as follows:

1. A *Cooling Unit* is a specific air-treating combination consisting of means for air circulation and cooling within prescribed temperature limits.[1]

2. An *Air-Conditioning Unit* is a specific air-treating combination consisting of means for ventilation, air circulation, air cleaning, and heat transfer, with control means for maintaining temperature and humidity within prescribed limits.[2]

3. A *Cooling Air-Conditioning Unit* is a specific air-treating combination consisting of means for ventilation, air circulation, air cleaning, and heat transfer, with control means for cooling and maintaining temperature and humidity within prescribed limits.[1]

4. A *Self-Contained Air-Conditioning or Cooling Unit* is one in which a condensing unit is combined in the same cabinet with the other functional elements. Self-contained air-conditioning units are classified[3] according to the method of rejecting condenser heat (water-cooled, air-cooled, and evaporatively cooled), method of introducing ventilation air (no ventilation, ventilation by drawing air from outdoors, ventilation by exhausting room air to the outdoors, or ventilation by a combination of the last two methods), and method of discharging air to the room (free delivery or pressure-type).

5. A *Free Delivery Type Unit* takes in air and discharges it directly to the space to be treated without external elements which impose air resistance.[1]

6. A *Pressure-Type Unit* is for use with one or more external elements which impose air resistance.[1]

7. A *Forced-Circulation Air Cooler* is a factory encased assembly of elements by which heat is transferred from air to refrigerants.[3]

CLASSIFICATION OF UNIT-TYPE EQUIPMENT

Field assembled apparatus as described in Chapter 19 can be designed in shape, size, and capacity for any application, with the refrigeration and heating system exactly balanced to a specific load condition.

To obtain the economies of factory production, component assemblies are available in the size ranges of greatest usage. In addition to assemblies of high-side equipment in condensing units, the fan-coil units are factory made in various types as indicated by the preceding definitions.

If the condensing unit and the cooling and heating coil surfaces are carefully selected, and if proper consideration is given to reduction of piping losses, the performance of the combined system will compare favorably with field assembled apparatus. *A system in which the air handling unit is separated from the condensing unit, is called a remote system.* The conditioning unit is designated as a remote unit. Capacities of remote units usually range from 2 to 100 tons.

The self-contained air-conditioning or cooling units are widely used in capacities through 15 tons, and are available in larger sizes. Each model is designed for a specific cooling capacity and range of air delivery. Experience has demonstrated that well designed and properly applied equipment of this type produces excellent results in commercial comfort installations. In most designs of the larger self-contained units, the equipment can be adjusted to approximate the load calculations through a selection of the air quantity. An increase of air quantity in this type of equipment increases the sensible heat proportion, and a decrease of air quantity tends to provide a lower leaving dew point and a high proportion of moisture removal. However, the usual field practice is to adjust the fan speed for quietness and air distribution rather than for ratio of latent to sensible loads as indicated by a load estimate.

To meet the requirements of individual comfort in small rooms and offices, self-contained units, called room coolers, find extensive and economical application. These units are usually restricted to summer and intermediate season operation, and range from ⅓ to 1½ tons of refrigeration capacity.

A special application of remote units is found in the unit air cooler which is used extensively in refrigeration work. Its primary function is to reduce temperatures in insulated and sealed storage spaces, and humidity control is a secondary consideration. Because of the small temperature differences between the coil and room temperatures, unit coolers handle three to five times as much air per ton as remote units used in air conditioning.

The attic fan or exhaust fan is sometimes referred to as a cooling unit, but since it contains no element of heat transfer, it is treated in Chapter 22, Fans.

COMPONENTS OF UNIT-TYPE EQUIPMENT

The unitary equipment is designed for the air-conditioning loads of most common occurrence. Highly special projects and projects of infrequent occurrence may require field-assembled equipment for best results. Field modifications

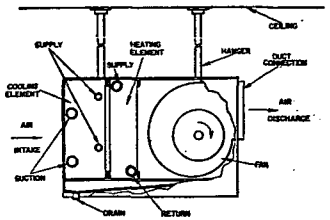

Fig. 1 . . . . Horizontal Remote Type Unit Air Conditioner

generally prove inadvisable except by the most experienced engineering personnel. The basic design considerations of unitary equipment are discussed in the following paragraphs.

Remote Units

Remote units can be obtained in two general classes, horizontal as shown in Fig. 1 and vertical as in Fig. 2. The construction of both is essentially the same, except for the drain pan and filter locations.

Casings. Casings are generally constructed of sheet metal with angle iron frames and with removable panels for access to coil connections, blower bearings, filters, and drain. Casings should be airtight. Panels should be tight-fitting with cam or similar fastenings for easy opening. Panel openings at coils for heavy units should be large enough to receive coils after the casing is suspended. Frames should be fitted with lugs strong enough to suspend horizontal units. Nonmetallic casings are of advantage in small remote units for reducing sound, particularly when propeller-type fans are used.

Insulation. Remote units are available with waterproof and verminproof, sound and heat barrier insulation on the inside of the casing. They are also available with flanges and flanged access doors to permit insulation after installation.

Drain Pans. Because of the corrosive effect of mild picric, carbonic, and sulfurous acids absorbed by condensate, drain pans are usually made of 14 gage or heavier metal. They should be hot dipped galvanized after fabrication, or otherwise treated to resist corrosion. Some manufacturers extend the drain pan under the entire unit, but in any case it should extend far enough to catch any condensate carried over from the coils. The drain connection should be readily accessible for cleaning and, in air-conditioning work, should be generously sized and trapped. Some municipal codes require a minimum size of 1¼ IPS.

Blowers. The usual practice among manufacturers is to use blowers having external resistance capacity in keeping with the size and type of application for which the unit is designed. *For example, the larger self-contained air conditioners* have blower and motor arrangements for delivering the design air quantities against the larger external static pressures that are encountered when applying these units for use with supply and return-air duct systems. In a well designed unit, the relation of the blower and the coil surface is arranged, through testing, to assure adequate uniformity of air distribution over the heat-transfer surface.

Some of the smaller suspended-type units, Fig. 3, use propeller fans with a trailing edge blade in order to obtain required pressure characteristics with quiet operation. Since most of the motors driving these fans are direct-connected and use brushes for starting, adequate access should be provided for maintenance and inspection.

Cooling Coils. The cooling and dehumidifying coils used in unit air conditioners are essentially the same as those used in central station units. A proper balance of coil capacity with the other components of the packaged air conditioner is an essential of good design and performance. Ample coil capacity is a requirement for good operation at light loads and low air quantities.

Where multiple circuits are used in the larger coils, equal distribution of the cooling medium to the various circuits is vital in order to develop full capacity of the coil. The cooling coils also perform the function of dehumidification. To prevent carryover of condensate, some coil designs require eliminator sections even at the normal face velocities of 400 to 600 fpm.

In addition to condensing the moisture out of the air, the design and arrangement of the cooling coil should provide for quick and effective draining of the condensate into the pan. Proper manufacturing practices to provide for uniform fin spacing and laboratory development to determine coil-surface arrangements are among the requirements for good drainage from the cooling and dehumidifying coils of self-contained air conditioners.

Heating Coils. Heating coils of unit air conditioners are usually conventional blast coils, and can be obtained with or without non-freeze steam distribution features. They usually match the cooling coils in face area, and are one or two rows deep depending on the heating requirements. Where coils are selected for hot water and have more than two rows of tubes, the air resistance and the space requirements of the cooling and heating coils should be carefully checked.

Humidification. Spray-type humidifiers are usually used in remote systems, but in some cases pan-type humidifiers or steam humidifiers are also used. Some condensation on the inside of the unit casing may occur with possible water damage if the unit is located in a cold space without adequate insulation. Spray-type humidifiers should be located so that no carryover of moisture occurs.

Filters. It is almost axiomatic that all units should have filters. Some small suspended units of 1 ton capacity or less, with low coil-face velocities and propeller fans, are equipped

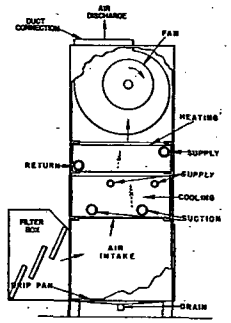

Fig. 2 . . . . Vertical Remote Type Unit Air Conditioner

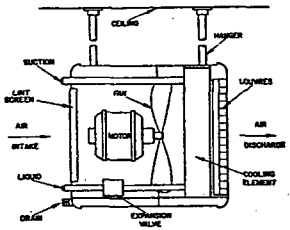

Fig. 3 . . . . Suspended Propeller Fan Type Unit Air Conditioner

only with lint screens or operate without filters, but in them the coils must be periodically cleaned and there is constant danger of clogging of the drain, with the possibility of water damage. Filters used are usually of the throw-away type, although cleanable filters are available for most of the larger units. Care should be taken to insure adequate filter surface, since the cross-sectional area of the unit is seldom adequate for filter area. V-shaped or staggered filter arrangements are quite commonly used to increase filter area.

Motors. In some units where the motor is mounted inside, adequate access for maintenance and clearance for tightening belts are imperative. When motors are mounted in this manner, the heat equivalent of the motor input must be added to the heat load to be absorbed by the system, and this requires a lower exit air temperature at the coils. Usually, however, the motor is located outside of the casing where it is readily accessible for service. In this case, only the brake horsepower required by the fan is transformed into heat to be included in the load calculations.

In either application, motors should be selected with adequate horsepower to handle the design volume of air against the resistance of the system when the coils are wet, and then checked against the possible horsepower requirements for the increased volume of air obtained when the coils are dry.

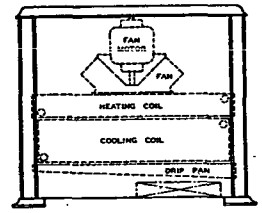

Fig. 5 . . . . Remote Floor Type Room Unit Air Conditioner

Other Types of Remote Units

Features of various other types of remote air conditioners are given in the following paragraphs.

Spray-Type Unit. Fig. 4 shows a spray-type unit used by designers who prefer air-washing and coil-wetting features. These units are equipped with a pump that sprays water or brine over the coils. Due to the direct mixing of the condensate and the spray, provision must be made for overflow in summer and replacement of water evaporated in winter.

Dehumidifying Units. In a further modification of spray-type units, absorbent brine solutions such as lithium chloride are used to remove moisture from the air. As explained in Chapter 42, the latent heat of the moisture removed is changed to sensible heat, so that coils must be used as after-coolers to obtain the right dry-bulb temperatures. Factory-produced units are also available for use with solid adsorbents such as silica gel.

Another recent development as a manufactured item is the small refrigeration-type dehumidifying unit for control of moisture in residential basements.

Remote Room Units. For individual rooms, with cooling load requirements of ½ to 1½ tons, remote units are available in attractive casings for installation within the room. A suspended type is shown in Fig. 3 and a floor type, such as is

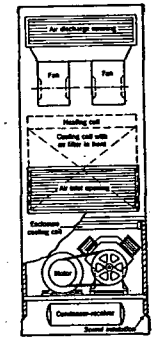

Fig. 6 . . . . Self-Contained Water-Cooled Air Conditioner

usually installed in place of an existing radiator, is shown in Fig. 5. Furnished with chilled water from a central plant, these units offer a satisfactory method of conditioning existing office, hotel, and apartment rooms. These units may be obtained with filters and outdoor air connections, but for most satisfactory applications are used as supplements to the central systems that supply properly conditioned and filtered air to the areas served.

Induction units, using primary conditioned air under pressure to induce local circulation, are described in Chapter 19.

SELF-CONTAINED UNITS

A typical large self-contained air-conditioning unit is shown in Fig. 6. It is essentially a remote vertical-type conditioner mounted on top of a sound-insulated enclosure containing the condensing unit. Air distribution is obtained by means of grilles mounted in the discharge plenum, when the unit is located in the conditioned area. Duct distribution of conditioned air can be obtained by removing the plenum, connecting directly to the blower discharge, and safing the top of the unit.

The heat generated by the compression of refrigerant gases and that given off by the electric motor are removed from the compressor compartment in four ways: (1) by the use of a water coil in the compressor compartment, (2) by utilizing the cold suction gases, (3) by drawing part of the return air through the compressor compartment; and (4) by circulating room air through the compressor compartment by means of a fan attached to the motor shaft.

Most self-contained conditioners are constructed with enough sound-isolation material for installation directly in the conditioned spaces of the higher-sound-level commercial-type of applications. Special sound treatment means are to be supplied as part of the installation when applying these conditioners to spaces having low sound-level requirements. Conditioners may be installed outside the conditioned area and the connecting supply and return-air ducts can be acoustically treated as required for the specific installation.

ROOM AIR CONDITIONERS

A room air conditioner is a factory-made encased assembly designed primarily as a unit for mounting in a window or through a wall, or as a console, for free delivery of conditioned air to an enclosure and without ducts for conditioned air supply or return. It includes a prime source of refrigeration and dehumidification and means for circulating and cleaning air, and may also include means for ventilating, heating, or performing other functions.[4] Most room air conditioners are used in residences and apartments, although many are installed in small commercial establishments. A number of multistory buildings have been completely conditioned with room units.

Although most room air conditioners are designed for conventional window mounting, many are made for mounting in casement windows, walls, or as console types in front of windows or walls. In such units, the arrangement of the basic components is often quite different from that employed in window units because emphasis may be placed on minimum depth or height rather than on width. Since great strides have been made in recent years in the reduction of overall unit dimensions, the current trend is toward units that can be mounted essentially flush with the inner wall face and protrude very little beyond the outer face. A recent innovation is the small, light-weight *portable* room air conditioner.

Most room air conditioners have air-cooled condensers although water-cooled versions have appeared from time to time. In air-cooled units, condensate disposal is typically provided by equipping the condenser fan with a slinger ring which picks up condensate and throws it on the condenser coil where it is evaporated into the condenser air stream and coincidentally provides some evaporative condensing effect.

Sizes

Room air conditioners are available in capacities ranging from about 3000 Btuh up to 18,000 Btuh or more. Sizes have been popularly designated in terms of the nominal horsepower of the compressor motor, although this is not necessarily an accurate indication of unit capacity. Units are available in sizes up to 2 hp, with the ¾ hp and, more recently, the 1 hp units being most popular.

The National Electric Code[5] limits the amperage rating of motor-operated equipment installed on multi-outlet branch circuits to 50 percent of the circuit rating, and on single-outlet branch circuits to 80 percent of the rating. For the typical 14-gage (15 ampere) house circuit, this effectively limits room air-conditioner amperage ratings for multi-outlet and single branch circuit installations to 7.5 and 12 amperes respectively. Many room air conditioners are designed for maximum performance within these amperage limits, regardless of nominal compressor horsepower.

Component Descriptions

Although many different types and variations of components have been used in room air conditioners, it is possible to give a fairly typical picture of current production. Hermetically-sealed refrigerant circuits are now universally employed, and the compressors are usually of the welded-shell reciprocating type operated by capacitor-start, capacitor-run, or permanent-split capacitor motors. Both evaporator and condenser coils are usually of aluminum plate fin and copper coil construction. Capillary tubes are normally employed as the expansion device, although valves are sometimes used for special purposes. Both centrifugal and axial-flow fans are used, sometimes one of each, with the latter equipped with a slinger ring for condensate disposal. One shaded-pole or permanent-split capacitor fan motor, mounted on the condenser side or in the partition, is frequently employed to operate both fans although in some designs two fan motors are used. A throw-away or cleanable type of filter is standard equipment. Grilles and an increasing number of other parts are being constructed of plastic. A slide-out chassis, containing the complete refrigerant and air circuits, is often used. Nonflammable and nontoxic refrigerants (ASA B9.1, Group I Classification[6]) are used exclusively.

Features

A thermostat and adjustable louvers for directing the conditioned air have become standard features on most units. A ventilation or outdoor-air damper is almost always included and sometimes an exhaust air damper. Two-speed fan motors are frequently used to give quieter operation during off-peak load conditions. Special filters and other air purification devices are featured on some models.

Some room air conditioners are designed as heat-pump units to provide heating during the intermediate seasons, or for year-round conditioning in some climates. Resistance heating has also been incorporated into some units for the same purpose.

Electrical Characteristics

Room air conditioners are normally designed to operate on single-phase, 60-cycle power at 115, 208, or 230 volts. Units for the export market are made for 50-cycle operation. Attachment plug requirements, which are related to the *National Electrical Code* ampere limitations, are specified by Underwriters' Laboratories, Inc.[7]

The rapid public acceptance of room air conditioners has presented special problems to the utility companies who must supply power to meet the electrical demands of these units during summer heat waves. As a result, recommended maximum starting currents and minimum power factors have been established for room air conditioners and are listed in *ARI Standard* 110-56.

Rating

Room air conditioners are tested for rating under the provisions of the *ASRE Standard* 16-56[8] at standard rating conditions of 80 F db and 67 F wb room air temperature and 95 F db and 75 F wb outdoor air temperature for air-cooled units. Rating requirements are specified in the *ARI Room Air-Conditioner Standard* 110-56. That organization is presently conducting a room air-conditioner rating compliance program.

Other Design Considerations

Air-flow rates vary considerably, with evaporator air quantities of 350–400 cfm per ton and condenser air quantities of 650–700 cfm per ton being approximately representative of current practices. Sensible heat factors usually average about 0.70, and performance factors (Btu per watt hour) about 6.5.

Room air conditioners should be designed to operate satisfactorily at the maximum conditions they might normally encounter. They should also be expected to perform without dripping or blowing of water from the unit. Standard test requirements for such considerations have been established by ARI in *ARI Standard* 110-56.

Safety requirements for room air conditioners are prescribed in the *American Standard Safety Code for Mechanical Refrigeration* B9.1 and the Underwriters' Laboratories *Standard for Room Air Conditioners*.

Selection

Many room air conditioners are sold over the counter without careful attention being given to matching the capacity of the unit with the requirements of the load. The ARI has available a fairly simple Cooling Load Estimate Form for Room Air Conditioners[9] which can be used to make a reasonably proper selection. Most manufacturers also have cooling load calculation forms available and many have even simpler quick-selection charts or devices.

Installation

An installation accessory package is usually furnished with most units. These are designed so that an installation can be completed in an hour or so by one or two men using a few common tools. Accessory packages and wall sleeves are sometimes available for casement windows and through-wall mountings.

The only connection that is necessary for air-cooled units is to insert an electrical plug into a convenience outlet of the proper rating.

Controls for Room Cooling Units

Control devices provided for self-contained cooling units generally will include all necessary means for automatic operation. Provision is also made for adding auxiliary external controls, when desired. Remote units are not generally equipped with controls. Control of remote units and the addition of auxiliary controls for self-contained units can be made by application of the control principles outlined in Chapter 19 Central Systems for Air Conditioning and Chapter 43 Automatic Control.

RATINGS OF UNIT AIR CONDITIONERS

Two standards have been used for rating and testing of unit air conditioners: (1) *Standard Method of Rating and Testing Air Conditioning Equipment*,[1] covering all types of air-conditioning units except the self-contained type and (2) *Standard Method of Rating and Testing Self-Contained Air Conditioning Units for Comfort Cooling*[2] covering the self-contained type. (*ASRE Standard Methods of Rating and Testing Air Conditioners, ASRE Standard* 16-56, covers rating and testing of all types which operate nonfrosting when cooling and dehumidifying at standard rating conditions.)

The standard rating of a self-contained unit, for the conditions specified in Table 1, includes all items which apply to the function of a unit such as: (1) name of unit, (2) functions which unit performs, (3) data on cooling, (4) data on heating, (5) data on air flow, and (6) data on humidification.

The standard rating conditions for unit air conditioners, other than the self-contained type, are identical with those in Table 1, except that entering wet-bulb temperature for cooling is expressed as 50 percent relative humidity (66.7 F wet-bulb) instead of 67 F wet-bulb temperature. In addition, the saturated suction refrigerant temperature for comfort cooling is specified at 40 F. This condition is omitted from Table 1 for self-contained units because it is not separately controllable in the testing of a unit that includes the evaporator and condensing unit.

APPLICATION OF UNITARY EQUIPMENT

One of the chief advantages resulting from use of factory produced units is the saving in installation and field assembly labor, a factor that should always be kept in mind when selecting a location for these units. Because of their compactness, the tendency exists to put them in closets, storage rooms, and other inaccessible places, where installation is so difficult that much of this cost advantage is lost.

Access panels are provided on units for the proper servicing and maintenance of the equipment. Adequate outside clearance at these panels is essential. Wherever there is danger of freezing of coils or clogging with dirt, sufficient clearance should be available for replacing them without removing parts of the building.

The outstanding source of difficulties in unitary systems is usually dirty filters. The characteristics of the light-weight fans used are such that air volume drops off rapidly with increase in static resistance. Since changing of filters is an unpleasant duty likely to be neglected unless it can be done easily, the operator should be at the same level as the filters, rather than under them, when they are being removed.

Variable-pitch motor pulleys are usually provided for adjustment of the air quantity. The fans and motors of most

Table 1.... Standard Rating Basis for Self-Contained Air-Conditioning Units

Functions	Types of Units	Rating Condition		
		Item	Description	Value
All	All	a	Barometric pressure	29.92 In. Hg
	Water-cooled, air-cooled, and evaporatively cooled condensers	b	Unit ambient and air entering room—air inlet	
			(1) Dry-bulb	80 F
			(2) Wet-bulb	67 F
		c	Ventilation air	See Note
Cooling	Water-cooled condensers	d	Water temperature entering unit	75 F
		e	Water temperature leaving unit	95 F
	Air-cooled and evaporatively cooled condensers	f	Air entering outdoor air inlet	
			(1) Dry-bulb	95 F
			(2) Wet-bulb	75 F
Heating	All types provided with heating function	g	Unit ambient and total air entering unit	70 F
		h	Heating medium, pressure or temperature	
			(1) Dry saturated steam	16.7 psia
			(2) Water in	180 F
			(3) Water out	160 F
Humidifying	All types provided with humidifying function	i	Unit ambient	70 F
		j	Total air entering unit	
			(1) Dry-bulb	70 F
			(2) Wet-bulb	53 F
Air circulation	All	k	Filters	New and clean

Note: Rating shall be based on both ventilation and recirculated room air entering at 80 F dry-bulb and 67 F wet-bulb temperature. (The *Note* as given in the code has been condensed in order to remove material not pertinent to this chapter.)

conditioners are selected for the usual range of external resistances commonly used with the specific size of conditioner. The larger conditioners are capable of serving larger areas and therefore require fan and motor capacity for the greater external duct resistances that may be imposed on such conditioners.

When locating unitary equipment, floor and beam loadings should be carefully checked. Suspended horizontal units can add 50 to 100 lb per square foot to the loading on the floor above. Should this floor be already heavily loaded, or be a roof structure designed for a 40 lb per square foot snow load, excess beam deflection may occur and cause cracking of plaster or concrete fireproofing. A small fire, normally of little consequence, may cause a rupture of a heavily loaded structure and permit the equipment to drop with extensive property damage. Self-contained units should be carefully installed since their weights run as high as 200 lb per square foot. When they are installed in street floor shops, the extra precaution of placing a column beneath them in the basement is an inexpensive method of reducing vibration, as well as providing insurance against overloaded floor beams.

The services required for operation of unitary equipment should conform to the many restrictive, but necessary, local municipal codes. Existing buildings seldom are wired adequately for the electrical load imposed by the starting of an air-conditioning compressor on any branch circuit. Even the smallest room cooler can draw enough current to reduce the voltage of a lighting circuit to the point where it is visibly apparent. This voltage drop may even affect the life of the unit due to the relatively slow starting. The cost of a separate electrical circuit of adequate capacity from the main panel is more than justified; it is a necessary expense in the majority of installations.

A water supply of adequate capacity and pressure is necessary to prevent overloading of electrical equipment by high head pressures. The average city water supply pressure is adequate for installations up to the third floor. Since most water-cooled units require about 20 psi pressure, including control valve losses, it is important that any units served by gravity from roof tanks be checked carefully if located less than 40 ft below the tank.

Drain connections from condensers should flow to an open and properly trapped sink as required by most city codes. This prevents back pressures on the city water system in the event of condenser failure. A check valve should also be installed in the water supply as a further precaution against contamination.

When installing small remote or self-contained units with outdoor air connections in buildings more than 6 stories high, the effect of wintertime stack action in elevator and stairwells requires special attention. This stack action is the cause of negative pressures on the lower floors, tending to draw cold air through the units, and positive pressures on the upper floors preventing adequate ventilation and disrupting air distribution. It can also cause annoying whistling at door openings and lead to serious complaints in hotels and offices. Wherever the removal of such units is impracticable, it is important that carefully fitted, felt-edged dampers be installed in the outdoor air intakes and that they have adequate locking devices.

One further consideration when installing self-contained units in conditioned areas is to ensure that space is adequate for any maintenance or repairs to be required in future years.

Sound Isolation

Both suspended and vertical floor-mounted units can transmit vibration through the supports. Wherever such transmission of sound might be objectionable, the supports should be isolated through rubber-in-shear or other sound deadeners. (For design of suitable sound deadeners see section Controlling Vibration from Machine Mountings in Chapter 25.)

UNIT AIR COOLERS

Unit air coolers are intended principally for product cooling, but are often used for cooling spaces to low temperatures. They differ from normal air-conditioning units only in features required to produce lower temperatures. In using such units, dry-bulb temperatures should be considered first, after which room moisture conditions and air distribution should

be considered, depending on the product being cooled or stored.

Products to be cooled or stored may be divided into four general classifications based on their sensitiveness to moisture loss.[3] Selection of the proper temperature differential between storage-room air temperature and evaporating refrigerant temperature will produce adequate moisture control for all practical purposes. The differentials required for gravity circulation and for forced air circulation are different, the latter requiring closer differentials. The four classes and differentials which have been successfully used are as follows:

Class 1. Products requiring high room-moisture content, which are highly susceptible to moisture loss and are being stored for extended periods, for example, eggs.

Gravity Circulation	18 F or less.
Forced Air Circulation	6 to 9 F.

Class 2. Products similar to Class 1 but which are being stored only for a limited time as in retail stores where the turn-over is usually 3 days or less, for example, cut meats.

Gravity Circulation	18 to 22 F.
Forced Air Circulation	9 to 12 F.

Class 3. Products requiring moderate room moisture content and which are moderately susceptible to moisture loss, for example, carcass meats and some fruits.

Gravity Circulation	21 to 27 F.
Forced Air Circulation	12 to 20 F.

Class 4. Products from which there is a very low moisture loss or none at all and where room moisture content is not important, for example: canned goods, furs, woolens, bottled goods, dried fruits, foods packaged in good moisture vapor barrier packages.

Gravity Circulation	25 F and up.
Forced Air Circulation	20 F and up.

When using Class 4 application, with finned evaporators and automatic defrosting at each cycle of the condensing unit, it is important to avoid using too wide differentials with very low refrigerant temperatures. In many applications, prime-surfaced evaporators prove unsuitable for this type of defrosting and will require some positive method of defrosting.

Unit coolers can perform satisfactorily in installations requiring accurate control of relative humidity, air motion, and dry-bulb temperature, and thereby prevent excessive weight loss, mold and slime growth, and moisture absorption by hygroscopic materials such as dried fruits.

Unit coolers, especially in the smaller sizes, are very similar in appearance to unit heaters. Copper, aluminum, or steel prime or finned-surface tubes are used. Propeller or centrifugal fans either blow or draw room air over the tubes. The fan and coil are generally enclosed in a casing provided with a drip pan. The motor horsepower requirements are a function of resistance due to coil construction and arrangement, and air volume required. Fin spacing is based principally on operating temperatures. For operation below 35 F, fin spacing is preferably not more than four to the inch. Above 35 F it may run as high as 8 fins per in., depending on room temperature and refrigerant temperature used. Both direct expansion refrigerants and brine are used successfully as cooling mediums.

Unit coolers may be arranged for either free or duct delivery. Face velocities vary, depending principally upon the intended application of the unit. In the larger sizes particularly, speed adjustment of the fan is generally provided to permit variation of the air delivery. While unit coolers are usually installed in the storage space, remote installation combined with appropriate ductwork may be required by space or other considerations. Units are available for floor, wall, or ceiling mounting, thus providing an upward, downward, or horizontal discharge. Power, refrigerant, and drip pan connections are required, plus additional connections for defrosting, if necessary.

For storage temperatures below 35 F, some positive means of defrosting is mandatory. At 35 F or higher storage temperatures, cycling of the condensing unit with low-pressure control at proper settings will provide automatic defrosting at each cycle. At above 35 F design refrigerant temperatures, frost and ice formation will not normally occur.

Various methods of defrosting are used. In one method, hot gas is supplied to the interior of the tubes uniformly throughout the coil. The entire refrigerant circuit is thus contacted to obtain complete defrosting of all frosted surfaces. Electric defrosting generally involves the incorporation of heating elements within the construction of the coil, or the use of strip heaters in a dampered closed-air circuit. Warm water may be sprayed over the coil surface for defrosting. With storage temperatures above 32 F, defrosting may be accomplished by shutting down the refrigeration system and circulating the room air over the coil. In every case, defrosting requires a cessation of refrigeration on the unit being defrosted. Where continuous operation of the system is desired, a brine spray over the coil may be used unless it might damage the product in storage, or cause too much corrosion of room fittings, ducts, etc.

Ratings

Since various means of expressing unit cooler capacity are utilized in the industry, different manufacturers suggest different methods of selection. The engineer should be aware of the conditions and factors which affect rating, selection, and performance of a cooler. These items are discussed in following paragraphs.

The refrigerating capacity of the unit may be either gross or net, the latter being less than the gross by an amount equal to the heat equivalent of the input to the unit cooler motor. In either case, the capacity should be given for a particular air volume. Air throw data are also valuable.

Dry or flooded rating conditions should be stated, as well as temperature level. The temperature level determines whether the coil surface is wetted or frosted, and it will also establish the refrigerant-side pressure drop for any given load applied to a specific unit cooler. The refrigerant-side pressure drop increases as the evaporating temperature decreases, and thus temperature level exercises a significant effect on the average coil-surface temperature and the consequent condensing-unit selection.

Coil capacity rating is usually expressed as total heat absorbed with no distinction between sensible and latent heat. The *rating* expresses the capacity in terms of Btu per (hour) (Fahrenheit degree temperature differential *between the refrigerant and the air*). The term *basic rating* may be used. This is the Btu per hour absorbed with one Fahrenheit degree differential between room air and evaporator refrigerant temperature. When the total load has been obtained from the load calculations, a temperature differential between the air and the refrigerant is selected. It is based on product classification previously discussed. The extent of dehumidification will be a function of this temperature differential. Moisture conditions in the storage space are dependent upon the correct selection of this temperature differential. It offers a quick and sufficiently accurate practical basis for coil selection.

Where close control of relative humidity is desired, heating coils or electric heaters for reheat may have to be added. The use of air-conditioning psychrometric techniques is only required for accurate humidity control.

Cooling equipment is usually rated on the basis of the overall room-to-refrigerant temperature differential instead of using the intermediate average coil-surface temperature. If the tentatively selected unit cooler does not possess the proper capacity, it may be possible to adjust the fan speed to a new air volume. At the new air volume and the new overall differential, the cooler may be able to deliver the necessary cooling capacity. If not, the procedure must be repeated with another size of unit cooler, the final selection being based on the proper balance between unit cooler and the condensing unit to maintain the Btu per hour heat removal and temperature difference at design room temperature.

Procedures for rating and testing room coolers are given in an ASRE Standard[8] which establishes four groups of conditions (numbered I to IV) under which units may be rated. Many manufacturers establish and publish their ratings in accordance with this standard in which forced circulation air coolers are classified according to air side surface conditions as (1) dry coil, (2) sprayed coil, and (3) spray (no coil); or according to type of air delivery to room as (1) free delivery fan, or (2) pressure fan. Natural convection air coolers are classified according to type as (1) external baffle, (2) built-in baffle, and (3) without baffle.

Arrangement and Operation

The refrigerant is usually supplied to the evaporator through a thermostatic expansion valve, thus obtaining dry expansion in the evaporator. In other designs, float-valve feeding is used as a means of metering the refrigerant into the evaporator. The refrigerant circuit in the coil may be of the continuous-flow type from inlet to outlet, or it may have means for internal recirculation of the refrigerant. The coils having the *dry-expansion* or *continuous flow from inlet-to-outlet* circuits may be of the upward feed or the downward feed arrangements. Upward flow is generally regarded as producing more refrigerant holding capacity and more effective use of the surface. However, with some refrigerants and in some systems, the downward-feed system has been found to produce better oil-return characteristics. Many direct-expansion installations use liquid-vapor heat exchangers to increase the coil utilization without undue risk of returning liquid refrigerant to the compressor.

Where two or more evaporator coils are to be attached to a single condensing unit, and different evaporator temperatures are desired, a back pressure valve may be installed to limit the minimum evaporating temperature of the warmer coils. This valve also finds application where fluctuation in the evaporator temperature prevents accurate control of air temperature and humidity.

Except in product precooling, the objective of air distribution is to absorb the heat load as it comes into the room while maintaining a desirable degree of ventilation-air movement through hygroscopic cargoes that are not encased by vapor-barriers. In cold storage practice, this generally requires the securing of as uniform an air distribution as possible to every part of the product zone, with employment of diffusion of air over the product and the prevention of direct blasts against the product. These requirements must be recognized when selecting the unit coolers and their outlets and when selecting the locations for the unit coolers. It is important to note that the quantity of air in motion in the refrigerated space is not only that passing through the coils. A quantity of air many times in excess of the air handled by the units is always set in motion by the induction effect of the moving cooled air. Therefore, in evaluating the velocity for any given area, the total air set in motion must be considered. It is a function of the type of outlet, the discharge air velocity, and the unit location relative to restrictive walls and product.

Unit location is also important from the standpoint of occupant comfort, low-velocity outlets being preferred for floor type units. High-velocity outlets are acceptable in fur storage vaults, ice cream hardening rooms, and other spaces where air motion is not an important factor.

In general, unit air coolers should not be suspended in front of door openings, or close to them where moist warm air will be drawn directly into the unit each time the door is opened, thereby causing excessive frosting and loss of capacity. Better performance will be obtained by placing the unit air cooler where the air will be discharged toward the door. If the shape of the space is such that this location would result in excessive air velocity over the product, then the location of the unit air cooler should be changed so that the air is discharged parallel to the wall in which the door is located.

Control of Unit Air Coolers

Although most unit air coolers can be adapted to any control cycle, continuous fan operation is recommended to avoid stratification and wide fluctuations in space temperature. Should the unit be completely self-contained, control of the direct-expansion refrigeration unit may be obtained from the temperature of the recirculated air and from suction pressure. In the case of multiple unit systems supplied with refrigerant or chilled water from a central source, a valve in the supply to each cooling coil may be controlled thermostatically from space temperature.

CHAPTER 17

ELECTRIC HEATING

Resistors, Heating Elements, Electric Heating Units, Electric Space Heating Applications, Types of Electric Heating Systems, Equipment and Installation Methods, Calculating Capacities, Induction and Dielectric Heating, Power Considerations

ELECTRICITY as a source of heat represents thermal energy in a refined form, easily applied to space heating, and readily distributed and controlled. For many applications, including use to supplement heating systems of other types, the compactness, simplicity, responsiveness, accuracy of control, safety, and cleanliness of electric heating may carry greater weight in choice of method than operating cost and initial investment. Electric heat often is more expensive on a direct-heat-equivalent basis than heat from conventional fuels. Economical service requires careful application in the design of system, adaptation of building structure, choice of control devices, and in method of operation by the user.

Using the power-to-heat conversion constant, 1 kilowatt equals 3,413 Btuh, resistance heating calculations are expressed directly in terms of kilowatt power requirements.

Definitions of *Resistor, Heating Element*, and other terms applying to resistance electric heating practices will be found in Chapter 1.

All equipment, materials, and construction used in electric heating systems should comply with the requirements of the *National Electrical Code*, with local codes, and be listed as approved by Underwriter's Laboratories Inc., or other recognized certifying agency.

ELECTRIC HEATING UNITS

An electric heating unit is a frame, casing, or other supporting means containing one or more heating elements, electric terminal connections or leads, and electrical wiring and insulation, all assembled into a unit. There are many varieties of housing, material, and arrangement of heating elements, operating temperatures, ratio of radiant to convective heat delivery, directional control for radiation, natural or forced convection, automatic or manual control, and electric load limiting features. Many specific types of units are discussed in the section Equipment and Installation Methods.

RESISTORS AND HEATING ELEMENTS

Electric resistors usually are composed of metal-alloy wire or ribbons, non-metallic carbon compounds in rod or other shapes, or printed circuits. Heating elements may have exposed resistor coils mounted on insulators, metallic resistors embedded within refractory insulation encased in a protective metal sheath, or a printed circuit encased in glass sheets. Fins or extended surfaces may be used to add heat-dissipating area. Elements are made in many forms. Strip elements are used for clamping to surfaces for heat transfer by conduction in some convection air heaters and some low temperature radiant heaters. Ring and plate elements are common in electric ranges and many small air heaters. Metal or oxide conductive films on glass and ceramics have been used usually in panel form. Tubular elements may be immersed in liquids, may be used bare, may be formed into coils, or may be cast into metal or plastic, and used in water heaters, ranges, and air heaters.

Cloth fabrics, incorporating flexible resistor wires, are employed for many low temperature purposes such as heating pads, sheets, blankets, aviators' clothing, and some radiant panel heating installations.

Special incandescent lamps with tungsten or carbon filaments and glass or quartz envelopes are designed to produce maximum energy in the infra-red portion of the spectrum and applied as radiant heaters.

ELECTRIC SPACE HEATING APPLICATIONS

Complete electric heating systems are now finding wide application not only in residences but also in many commercial and industrial establishments. Auxiliary electric space heating is often used for convenience, for instance: (*a*) for local use when the main heating system is shut down, (*b*) for local use where the main heating system is inadequate, (*c*) for temporary heating, (*d*) for special conditions involving separate or remote control, (*e*) for isolated locations, (*f*) for cases where minimum initial cost is the dominant factor. Portable units readily satisfy some of these requirements.

Compact electric heating units are sometimes installed in main supply or branch ducts of central-fan steam and water systems to provide the final temperatures and relative humidities required for comfort or process air conditioning. Electric heaters installed for use primarily in the heating cycle can also be utilized for reheat in the cooling cycle.

In control of systems, the flow of air over the electric heaters should be constant while the input to the heaters should be varied. This is necessary because of the basic difference between electric heating and other methods such as steam heating. Steam is approximately a constant temperature source of heat at any given pressure, and, consequently, a change in air flow over a steam coil does not greatly alter the coil surface temperature. Hence, the heat output of a steam coil varies in proportion to the air volume, but the surface temperature of the coil remains about the same. With electric heat the energy input and output are constant, and if the electrical energy input remains constant, the temperature of the heating elements will vary inversely with the air flow. Therefore, face and bypass dampers should not be used in electric heating, because the reduction in air flow and the corresponding rise in heater temperature would endanger the operating life of an electric heating element.

Automatic regulation of the electrical input is usually accomplished through a proportional-type step controller that energizes or de-energizes heaters in increments small enough to prevent excessive cycling. The electrical input per heater, or step, is normally determined by the permissible change in supply air temperature per step. High-limit thermostats are sometimes used to de-energize the heaters if the heater tem-

   2. Fuel-fired furnace converted to electricity
   3. Heat pump systems—See Chapter 39

peratures become excessive for any reason such as a reduction in air flow. Heaters must be de-energized on fan shutdown. (See Chapter 43 for general information on controls.)

TYPES OF ELECTRIC SPACE-HEATING SYSTEMS

The inherent adaptability of electric energy for transmission, conversion, and regulation, and the relatively high unit cost in terms of thermal equivalent, as compared with fuels traditionally used for space heating, necessitates and justifies greater attention to efficient utilization.

Types of electric heating equipment and complete heating systems in current use are listed in Table 1. The sequence shown is for convenient reference only, and does not indicate the relative extent of use, quality of performance, or installation cost and operating expense. Installations of all types listed are in successful operation, but performance and cost depend in large measure on proper application to the local conditions.

EQUIPMENT AND INSTALLATION METHODS

Convector with Metallic Resistors

Heating units for wall mounting, recessed or surface type, are made with resistors of incandescent bare wire or lower temperature bare wire or sheathed elements. An inner liner or reflector is usually placed between resistors and casing to provide a secondary air passage promoting circulation and minimizing rear casing temperature. Depending on details of unit construction, the convection heat delivery constitutes between 40 and 70 percent of total output, with the remainder dissipated into the room as radiant heat.

Ratings usually are from 1000 to 8000 watts (3400 to 27,300 Btu per hr) with some models down to 500 and up to 15,000 watts. Voltages are the standardized values of 120, 208, and 240. Similar models equipped with air circulation fans are available, giving convection heat delivery up to 90 percent. Other types, using similar components but without a fan, are arranged as *floor furnaces* to be installed between floor joists. A manual switch and thermostat integral with the unit are usually provided.

The location of electric convectors should be governed by the same principles that determine arrangement of steam or hot water convectors with respect to air movement.

Small portable units are available with ratings up to 1650 watts for operation at 120 volts. Higher wattage units are made for 208 or 240 volt application, and require suitable heavy duty receptacles.

Unit Ventilators

Unit ventilators with electric heating elements of the metal sheath type with extended surface are used to provide heating and ventilating of school classrooms. Overheat switches are usually provided for each element in the heating section to de-energize the elements in case of interrupted fan operation. Ratings are available up to 30 kw in the larger sizes of units. Auditorium unit ventilators of the same type are rated up to 300 kw. The total capacity of the unit ventilator is made up by numerous smaller heating elements so temperature control can be accomplished by energizing or de-energizing the elements one at a time. The application of unit ventilators is described in Chapter 15, Unit Ventilators and Unit Heaters.

Unit Heaters

Electric unit heaters include a suitable built-in fan which circulates room air over heating elements; they are employed for the same uses as other forms of unit heaters (steam, hot water, gas, oil), if conditions are favorable to electric heating. They are especially adaptable for supplemental heating, for small occupied rooms in otherwise unheated buildings and for unattended equipment enclosures in which temperature must be maintained above freezing. Location and arrangement of such unit heaters are discussed in Chapter 15.

Baseboard-Type Unit

Metal casing proportioned to resemble and replace conventional baseboard along walls contains one or more resistors placed horizontally. These should be rated from 80 to 250 watts (270 to 850 Btuh) per linear foot of baseboard unit. Resistors may be bare wire, sheathed element, cast grid, finned, or ceramic extended surface. The vertical dimension is usually 4 to 9 in. and projection from face of wall from 1½ to 3½ in. Location follows the same principles applying to hot water type baseboard installation described in Chapter 14. The maximum surface temperature of the housing should be limited to 190 F.

Baseboard-type units using glass panels 6 to 8 inches high and 30 to 42 inches long are available for operation at maximum surface temperature limited to 250 F.

Large high-wattage unit-type heaters are available for ceiling or high wall mounting. These are similar to steam and hot water unit heaters in appearance and function. Resistors may be placed in room air conditioners to permit operation as forced air heaters when desired.

Resistor Portable Heater with Focusing Reflector

An example of the focusing-reflector-type heater is the parabolic or circular bowl having, in its center, an incandescent wire coil resistor on a ceramic core, often screwed into a porcelain or other approved type receptacle. Usual ratings are 500 to 1650 watts for 120 volt use. Heat emitted is 75 to 85 percent radiant.

Sectional focusing-trough-type reflectors are made with low temperature resistors or with *quartz lamps* to be suspended from the ceiling or bracketed from the wall. Rated capacities are 200 to 1500 watts per linear foot of unit. Installations of this kind are usually to handle the perimeter heat loss. In a modified form, similar units are employed for infra-red heating and drying in industrial processes.

Steam Radiator with Immersion Element

Radiators equipped with an immersion element screwed into a bottom opening, are usually sealed after charging with water and antifreeze compound. A safety valve or thermal relief plug is provided to protect against excessive pressure and temperature in case heat dissipation is unduly curtailed by obstructions to air convection. The steam-and-water intermediate heat transfer does not affect overall thermal efficiency, but gives the unit operating characteristics adapted for certain applications. Units may be permanently connected by conduit, or used as portable heaters with cords.

Ceiling-Panel Installations with Conductive Rubber

Panels of laminated construction containing electrically conductive rubber, with rating of 22 watts (75 Btu) per sq ft, for 115 and 230 volt service, are built in standard sizes 3 x 4 ft, 4 x 4 ft, and 4 x 6 ft. They consist of a layer of special rubber about 1/64 in. thick sealed between layers of phenolic resin-impregnated electrical insulating paper. The assembly is covered on each side with a sheet of aluminum foil. Overall thickness is 1/16 in.; weight is 0.4 lb per sq ft. Metal strips embedded along edges of the rubber sheet serve as potential leads. Electric terminal blocks are provided on each panel and standard raceway moldings are furnished for wiring connections. An earlier type of construction using asbestos-board backing to form rigid panels ¼ in. thick has been discontinued.

Under normal operating conditions, the surface temperature of an automatically controlled ceiling panel is about 100 F. When panels are turned on in a cold room or with continuous operation, the maximum temperature reached is 120 F.

Since it is not permissible to cut heating panels, the entire pattern for ceiling must be planned in advance, with particular attention to coverage near exposed walls. Attachment to smooth surfaces may be made by a special adhesive applied on the ceiling along a 1½ in. fastening margin provided around the four sides of each panel. A highly sensitive room thermostat with narrow operating differential should be used in each room.

Ceiling-Panel Installations with Embedded Conductors

Resistors or cables for embedding in ceilings to form panel-heating installations are electrically insulated with coverings resistant to high temperature, water absorption, aging effects, and chemical action with plaster, cement, and soil. Cable units identified by a color code are furnished in nominal standard lengths from about 75 to about 1800 ft, and are rated from 200 to 5000 watts for standardized voltages of 120 or 240. The outside diameter of the cables is usually about 1/8 in. Non-heating leads 7 ft long are attached to each unit to connect at thermostat or connection box without running cable beyond the ceiling. The length of cable or leads must not be altered. The identification label showing rating may not be removed. Manufacturer's instructions should be followed regarding installation procedures.

The lath used is of non-metallic fire-resistant type. The cable is secured to the lath with staples spaced not over 16 in. apart. Each cable is tested after fastening on lath, and after first plaster coat has been applied, for continuity of circuit and for insulation resistance of at least 100,000 ohms measured to ground. The minimum spacing between cable passes is 1½ in. and is generally used near cold walls, with up to double that spacing near interior areas of the room. Non-heating leads outside the ceiling should be installed by approved wiring methods. Cables must be kept away from metallic materials and from areas of ceiling additionally heated by recessed or surface mounted lighting fixtures. All general power and light wires should be run above thermal insulation or at least 2 in. above the heated ceiling surface.

For plastered ceilings, non-insulating plaster is applied in two or three coats with the first coat troweled in the same direction in which the cable runs. Ceiling cables, properly engineered, installed, and operated will not cause ceiling cracks. While new plaster is drying out, the system should not be energized and the range and rate of temperature change should be kept low by other heat sources or by ventilation until plaster is thoroughly cured. The use of vermiculite or other insulating plaster is contrary to code provisions since it causes cables to overheat.

For laminated ceiling construction, cables are stapled to non-metallic lath as for plaster, and then a second layer of non-insulating ceiling board is applied with a layer at least 1/8 in. of plaster or similar compound to sandwich the cable firmly in place and improve heat transfer.

A highly sensitive room thermostat with narrow operating differential is recommended for each room. Chapter 30 includes data on panel heating with electric panels.

Electric Wall Panels

Cable embedded in walls similar to ceiling construction is occasionally found in Europe. Because of possibility of damage due to nails driven for hanging pictures or from building alteration, most codes prohibit such panels in the United States. Interference with radiation caused by furniture placement and interior decorations reduce the desirability of wall panels.

Radiant Convector Wall Panel

Glass electric heating units, sometimes designated as radiant panels, depend on the heating effect produced by passage of current through a thin coating of conductive material fused to one face of a panel of ¼-in. thick special glass. The conductive layer may be sprayed-on aluminum or *printed* metallic oxide patterned to form a grid several thousandths of an inch thick, or fused-on material to give a uniform coating less than 0.0001 in. thick over the entire active face of panel. Normal glass operating temperatures are 300 to 400 F, with maximum permissible temperature around 650 F.

Electric wiring connections are made by a variety of means

to the panel, with leads provided for easy field connection. The panel is supported on insulators within a metal frame, with a reflector behind the glass arranged to provide space for air circulation. Protective guards are usually provided to reduce hazards to a minimum.

Glass units are usually rated between 600 and 3000 watts, for standardized voltages of 120, 208, or 240 volts. Starting current for some types exceeds normalized current by 10 to 50 percent. However, there are types with substantially no current surge. Frame sizes vary from about 30 x 24 in. for 1000 watt size to 42 x 6 in. for baseboard models, and are arranged for recessed or for surface mounting. Thermostats integral with the unit are optional. Portable units with cord are available.

Radiant panels using tubular elements built or cast into extended aluminum panels have emissivity characteristics similar to glass panels.

Electric Floor Panels

Resistor cables of the same type used for ceilings are used for floor panel systems in concrete slabs. Precautions to be observed in construction of slabs for panel heating are covered in Chapter 12 and 30. Non-insulating cement finish 1⅝ in. thick is poured and troweled above cables fixed to a minimum 3 in. slab. In some areas, cables may be stapled to wood nailing strips fixed in the surface of the rough slab. When the slab is made of light-weight insulating concrete, cables may be stapled directly to the slab. Alternative special anchors are available to hold the cable at proper spacing during pouring, and are held by nails driven by hand or powder impact drivers. Otherwise, periodic temporary fastening with daubs of cement, plaster of Paris, strips of masking tape, or other nonconductive material must be used.

With monolithic finish, nailing strips are omitted and the cable is strung on frames with nail spacers; frames are removed when enough concrete has been poured to hold the cable in place. If desired, magnesite flooring, ceramic tile flooring, asphalt tile, or wall to wall carpeting may be used on the floor. Insulating-type concrete may be used below cable, but must not be used around or over cable.

Central Hot Water Systems

Heating systems of hot water type using radiators or convectors, discussed in Chapter 28, may be operated using an electric hot water boiler containing immersion elements (resistors). Resistors may be interlocked to prevent energizing when the circulating pump is not operating. The boiler water holding capacity should be sufficient to minimize cycling.

For off-peak operation where electric rate considerations justify, a water heating tank of large storage capacity may be employed. The system may be designed for a water temperature of 250 to 275 F at pressures up to 75 psig, with suitable piping systems for this pressure. An automatic valve may provide 140 to 160 F water at the pump by mixing hot water from the tank with cooler water from the return main. Another method employs the *flash* principle, withdrawing water at high storage temperature into a low-pressure separating chamber where steam is obtained as a result of the pressure reduction; however, power for pumping is substantially greater with this steam-accumulator method. Thermal insulation on boiler tank and piping must be adequate to minimize losses. High investment, space required for equipment, and loss of much of the convenience and economy of operation available with other forms of electric heat, tend to limit the application of this type of system.

Central Warm Air Systems

Systems employing resistors mounted in a frame or housing may be fitted into ducts with a fan forcing the air to the various spaces to be heated, or may replace the heat exchanger of fuel-fired furnaces to convert them to electrical operation. Much of the convenience and economy of operation available with electric heat is lost by such central system applications.

Heat Pump Systems

Heat pump systems are discussed in Chapter 39. Heat pump systems using air as a heat source lose capacity rapidly as the outdoor temperatures decrease, while water and earth heat source pumps sized for cooling also frequently reach the *balance point* at outdoor temperatures above outdoor design. Deficiency at temperatures below the *balance point* can be supplied by supplementary electric resistance elements. When these supplemental heaters are placed in individual spaces rather than centrally, the electrical demand is minimized, the individual spaces may be maintained at slightly different temperatures, and local reheat during the cooling cycle is readily available. An alternative provision for cold weather peaks is thermal storage in chemical salts and by other devices. Such processes are still in the development stage.

The installed cost of residential heat-pump systems is higher than that of resistance types. Resistance heating systems, except the minority using air circulation through ducts, do not lend themselves to consolidation with summer air conditioning. Use with an independent cooling installation may be preferable and attained with lower investment cost.

CALCULATING CAPACITIES

The procedure outlined in Chapter 12 for calculating the heating load may be used for electric systems. Load expressed in Btu per hour is converted to kilowatts by the divisor 3413 Btu per kilowatt. The National Electrical Manufacturers Association has published the *NEMA Manual for Electric House Heating* describing methods and giving heat loss factors for calculating load directly in kilowatts. All the energy applied to a resistor transforms itself into heat, unaffected by temperatures of the surrounding air and of surfaces receiving radiated heat. However, both electric power input and heat output are directly affected by voltage at the resistor terminals, being proportional to square of the voltage. Thus, a resistor rated 1000 watts at 240 volts, if used on a circuit at 220 volts, delivers 840 watts or 16 percent under the rated value, while at 208 volts the shortage is 25 percent.

The arbitrary addition of a percentage *safety margin* on the calculated heating load is not recommended. Such practice would increase the peak electric demand and often the cost of electric service.

The most economical electric heating systems from an operating standpoint are of decentralized type, with a thermostat provided on each unit or for each room. This permits each room to compensate for heat contributed by auxiliary sources such as sunshine, lighting, and appliances. This arrangement also gives a better diversity of the power demand due to non-coincidence of electric load from all units of an installation. Manual switches are often provided to permit cutting off heat or reducing temperature in rooms when not in use. When such operation is practiced, consideration should be given to provide adequate capacity for warm-up as compared to a system maintaining a constant temperature.

For sake of economy buildings intended to be heated electrically should be well constructed, have adequate thermal insulation and storm windows or double-glazed windows in more severe climates to minimize heat loss and weatherstripping to minimize infiltration. The relatively high electric cost for thermal energy, about $5.40 per million Btu at $0.018 per kwhr, for example, as compared with about $1.50 for oil at $0.16 per gal when utilized with 70 percent efficiency, gives economic justification for substantial expenditure to reduce heat consumption. The large majority of dwellings heated economically by electricity have heat factors (quotient of seasonal energy consumption in kilowatt hours, divided by degree days and by volume of gross heated space expressed in thousands of cubic feet) between 0.15 and 0.3. The features necessary to hold consumption within these limits result in construction that for 5000 degree-day climate with 0 F outdoor design temperature, gives a calculated heating load of 3400 to 5100 Btu per hr per 1000 cu ft gross volume. Heat factors up to 0.4 are not uncommon, but experience shows that such high heat requirement may result in excessive operating cost. General practice is to provide adequate thermal insulation with electric heating installations.

POWER CONSIDERATIONS

Rates for Electric Service

The cost of electricity varies due to several factors. The main elements are the annual charges, including taxes, on capital invested and those expenses necessary to keep the electric utility system at all times in a state of *readiness to serve* the load. The cost of generating the energy is secondary. Electricity is not stored, but must be produced instantaneously when and as required by the user. Consequently, the time of power use, both daily and seasonally, and relation between rate-of-use or demand and the energy consumed within a period (load factor) have large effects on costs and the rates charged. Special low rates sometimes are available during certain prescribed *off-peak* hours of use, when the system load is low.

Space heating is a load whose magnitude is determined basically by weather, and is affected to a much lesser extent by the electric customer's use of his premises. Most of the heating loads in a region occur simultaneously, thereby tending to create peaks for which the capacity of the electric system must be adequate. Accordingly, rates contain, in one way or another, charges both for demand and energy. Demand may be indicated directly by a demand meter or be derived from manufacturers' rating data shown on nameplates of the heating equipment. In block-type rates, where demand is not specifically mentioned, it is in part reflected by higher charges per kilowatt-hour in the earlier blocks.

Control of Electric Demand

To obtain electricity for space heating at minimum cost, it is necessary to keep the user's kilowatt demand as low as possible, by provisions in original design of the installation and by judicious methods of operation. Excess heating capacity should be avoided, but without jeopardizing satisfactory performance in cold weather. A variety of control methods can be applied to minimize both demand and consumption. Decentralized control with a thermostat in each room or on each heating unit, together with manual switch to cut off any unoccupied room, is one method. Sequence switching whereby electric service to individual rooms or circuits is shifted in rotation by an automatic timing device and sequence is modified by outdoor thermostat or by total electric load, is another.

Load-limiting controls of several types have come into use. These are generally arranged to measure the customer's total power demand, which for a residence may be grouped as lighting and miscellaneous appliances, refrigerator and water heater, cooking range, and the space heating system. When the demand exceeds a preset value, one or more heating circuits are cut off progressively in rooms least affected by the interruption. Experience shows that with electric floor or ceiling panel heating, temperature drop occurs slowly, at the rate of about 1 deg per hour for concrete slabs and 2 deg for plaster construction or rigid panels properly backed with thermal insulation. Moreover, electricity consumed by lighting, appliances, and cooking ranges is contributing some useful heat at such times.

Another form of limiting control for 120/240-volt 3-wire circuits provides complete or sequence transfer of space heating units from 240 volts to 120 volts, thereby reducing the electric input to one quarter whenever the total load of general-service component exceeds a preset limit. This method lends itself to use of an outdoor thermostat actuating a relay, whereby in mild weather the entire heating system operates at 120 volts and with lengthened cycles obtains more uniform room temperature. For reducing temperature at night, if desired, a clock-operated master thermostat can be provided to lower the heating-system voltage. On some electric utility systems, centralized control by means of a pilot-wire or carrier-current actuating a relay is applied to house-heating installations.

With any type of control, time-delay relays should be used in order that upon restoration after an emergency service interruption or whenever a master thermostat calls for heat, the individual circuit or units will come on non-simultaneously over a period of a few minutes. This is advisable especially for types of resistor units that have a power input, when cold, as much as 50 percent above the rated value at normal operating temperature.

Operating Costs

With increased numbers of electric heating installations, operating cost estimates and experience records are accumulating. Experience records are indicating that actual consumption may be less than conventional calculations and comparisons would indicate. This is particularly true with thoroughly insulated structures or for applications having short hours of maintained temperatures and long reduced temperature periods.

The *NEMA Manual for Electric House Heating* applies the following formula for estimating the cost of electric heating:

$$\text{Annual kilowatt-hour consumption} = \frac{HL \times DD \times C}{TD}$$

where

C = constant (see text below).
HL = heat loss of building, kilowatts.
DD = annual degree days for area.
TD = difference between indoor and outdoor design temperature, Fahrenheit.

The constant C depends on a number of variables such as weather conditions in the locality, orientation, design and construction of the building, living habits of the occupants,

Table 2 . . . . Relation of Resistor Voltage to Heat Delivery

Condition	Volts	Heat Delivered %
Electric system, nominal value	120/240	103.3
For design of equipment, at terminals	118/236	100
Range, as basis for design		
Minimum	110/220	86.8
Maximum	124/248	110.5
On secondary distribution system		
Favorable zone, as to voltage conditions		
Minimum	110/220	86.8
Maximum	125/250	112.0
Tolerable zone		
Minimum	107/214	82.2
Maximum	127/254	116.8
Emergency conditions	90/180	58.3

design of heating system, and internal sources of heat. Experience with many thousands of electric heating installations has shown that a conservative value for C is 18.5. Values of C as low as 12 have been reported on individual installations. It is recommended that a value of C of 18.5 be used unless local experience of a statistical nature has established a more reliable value for the particular area concerned in the estimate.

For block-type electric rates, multiplying the annual kilowatt-hour energy consumption by the cost per kilowatt-hour indicates the annual cost. For demand rates, the assistance of the local utility company should be secured to estimate demand and energy uses by the month on the particular rate involved. It may be pointed out that residences with thermostatic control *in each room* generally establish a maximum of 75 percent of the total calculated heat load as the highest demand requirement for heating.

Voltage Requirements

The preferred nominal system voltage at point of electric utilization by equipment, for single-phase 3-wire systems necessary with space heating, is 120/240 volts, as stipulated by standards of the electrical industry (*EEI Publication* R-6 and *NEMA Publication* No. 117 issued May 1949). For household heating appliances mentioned in the standards, such as air heaters, water heaters, and cooking ranges, the *equipment voltage rating for design* is specified as 118/236 volts, and the range of *voltages to be used as a basis of design* extends from 110/220 minimum to 124/248 maximum. However, natural variations exist from time to time in the conditions at different points in any secondary distribution system and will affect both voltage level and range of fluctuations. Under emergency conditions on electricity supply systems, voltages of the order of 90/180 may be encountered. Heat delivery by resistors with these voltage values, expressed in percent of rated delivery with the normal 118/236 volts (at terminals) is given in Table 2.

Voltages stipulated for secondary distribution systems are at point of service entrance to the building; the drop of voltage in the house supply wiring to terminals of the heating equipment may be 2 to 3 percent, thus reducing heat delivery by some 5 to 8 percentage points below the *favorable zone* and *tolerable zone* values included in the last column of Table 2. Accordingly, it is necessary the designers of electric heating installations obtain specific information from the local electric utility company on both existing and anticipated future conditions at the location, before specifying the capacity and voltage for equipment, wiring, and controls.

CHAPTER 18

WARM AIR HEATING SYSTEMS

Forced Warm Air Systems; Air Distribution; Supply Outlets and Return Grilles; Duct Construction; Simplified Methods of Design for Perimeter Systems of Loop, Radial, and Extended-Plenum Types; Return Duct System for Perimeter Installations; Inside Wall Delivery Systems; Design of Large Systems; Automatic Controls; Adjustment of System; Warm Air Ceiling Panel Systems; Summer Operation; Gravity Warm Air Systems

WARM air heating systems may be conveniently divided into two classifications depending upon the manner in which the motive power for circulating the warm air is supplied. In *gravity* systems, the motive head is due to the difference in weight between the heated air leaving the top of the furnace casing and the cooler return air entering the bottom of the casing. In a *forced* warm air heating system, all or part of the motive head is supplied by a fan. Although a great many gravity warm air heating systems are in use, only a limited number of new gravity installations are now being made. Emphasis will therefore be placed upon the design and installation of forced warm air heating systems.

FORCED WARM AIR SYSTEMS

In forced warm air heating systems, the air circulation is effected by motor-driven centrifugal fans, commonly referred to as blowers. The advantages of forced air systems are:

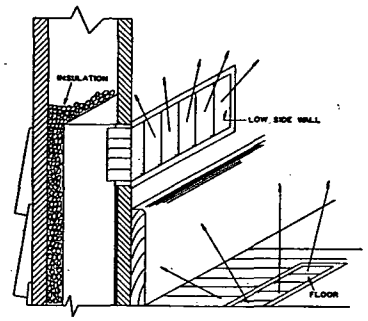
1. The furnace may be placed in any part of the structure.
2. Distribution ducts can be made small enough to be inconspicuous and out of the way, or be completely concealed from view where desired.
3. Circulation of air is positive, and in a properly designed system, can be controlled in such a way as to give a comfortably uniform temperature distribution.
4. Humidity control is readily attained.
5. The air may be cleaned by filters or other means.
6. If properly designed or suitably adapted, the same air distribution system can be used for summer cooling as for winter heating.
7. The use of the fan permits flexibility in the location of supply and return grilles as required to obtain proper distribution of air for comfort.
8. Ventilation air may be positively introduced and conditioned.

The construction features of forced warm air furnace units and the function and selection of the various parts of a system are discussed in Chapter 35 and other publications.[1]

AIR DISTRIBUTION

The conditions of comfort obtained in a room are influenced greatly by the type of supply outlet used, and the locations of the supply outlets and return grilles. In general it has been found that changes in the type, air velocity, and location of the supply outlet affect the room conditions much more than the changes in the location of the return grilles. Three methods of locating outlets and grilles are in common use. One method is to locate the supply register near the floor so that the warm air from the register *blankets* a cold wall, and mixes with the cold air descending from the exposed walls and glass. A second method is to locate the supply openings near the floor, or high in the side wall, on the inside wall, and the return openings near the greatest outside exposure. A third method is to locate all supply openings around the outside wall, near the source of the greatest heat loss, usually beneath the windows, and to use grilles designed to blanket the cold area. This causes mixing of the warm air delivered with the cool air from the heat loss area and the cold air from infiltration, thus effectively preventing drafts. It has been called *perimeter* heating.

In any case, the warm air registers should be so located and so designed that the air stream never discharges directly against people at rest. Tests[2] in Warm Air Research Residences No. 1 and No. 2 at the University of Illinois, have indicated that nearly continuous blower operation gave better results than intermittent operation. This type of operation is more commonly achieved by suitable adjustments of air quantity and fan switch settings than by continuous operation of the blower.[3]



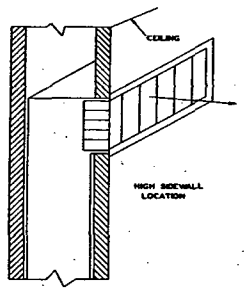
Supply Outlets and Return Grilles

The type of supply outlet that should be used depends upon the type of distribution system to which it is applied. With perimeter duct systems, the supply outlets are usually located in the floor, in the baseboard, or low in the side-wall and underneath a window. In order to be most effective, perimeter diffusers must deliver the air upward and in a fan-shaped pattern so as to blanket the window or cold wall with warm air, thus mixing with and tempering the cold air which usually descends along a cold surface. Furthermore, since delivery of the air outward into the room, rather than upward, is likely to impinge upon the occupants it should be avoided. With certain types of perimeter diffusers, the air velocity at the diffuser face is limited only by the pressure available at the diffuser and the noise characteristics of the outlet.

Tests with *inside wall* supply systems conducted in Warm Air Heating Research Residence No. 1 have indicated that comparable results are obtainable with either high side-wall or baseboard registers, if proper registers and air velocities are selected.

Baseboard registers should be of a deflecting-diffuser type that will direct the air downward toward the floor and diffuse it at the same time. For baseboard registers, air velocities over 500 fpm should be avoided as they may cause discomfort.

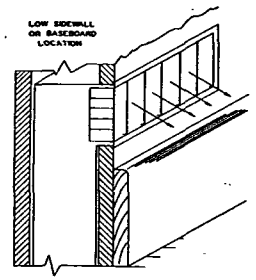
High side-wall registers should be of a type that will deliver the air horizontally or in a slightly downward direction, and should be so located as to avoid impingement of air on ceiling or wall. Directional flow diffusing type regis-



[a] *Registers set to direct air upward along the wall at as wide an angle as possible.*

Fig. 1.... Recommended Type of Floor or Low Side-wall Installation on Outside Wall[a]

ters should be used to insure best results. Register air velocities should be such that the air velocity will be about 50 fpm three-quarters of the distance from the register to the opposite wall.



Velocities through registers may be reduced by the use of registers larger than the connecting ducts. Diffusers should be used to spread the air uniformly over the register face. Basic rules for the location and selection of registers, together with explanations of factors affecting operation, are given in Section 6 of Manual 4, Sections 3 and 4 of Manual 10, or Section B of Manual 7, published by the National Warm Air Heating and Air Conditioning Association.[4, 5, 6]

Registers should be well proportioned and decorated to harmonize with the trim. Air supply registers should be

[a] *Horizontal vanes, in back or front, to give downward deflections not to exceed from 15 to 22 deg.*

Fig. 2.... Recommended Type of High Side-wall Installation on Warm Wall[a]

[a] *Vertical bars with adjustable deflection, or fixed vertical bars with deflections to right and left not exceeding about 22 deg. For low side-wall location, the deflection for horizontal, multiple vane registers should not exceed 22 deg. For baseboard locations, the deflection for horizontal, multiple vane registers should not exceed about 10 deg.*

Fig. 3.... Recommended Type of Baseboard and Low Side-wall Installation on Warm Wall[a]

equipped with dampers, and all registers should be sealed against leakage around edges. The register types shown in Figs. 1, 2, and 3 have been recommended as standard by the National Warm Air Heating and Air Conditioning Association.

Return-air grilles may be located in hallways, near entrance doors, under windows, in exposed corners, or inside walls, depending on location of supply outlets. Baseboard returns are preferable to floor grilles. It is usually considered desirable to have them located in or near outside walls when supply outlets are located on inside walls. With this type of system, it is desirable to locate return grilles in as many rooms as possible. When used in perimeter systems, the return grilles may be centrally located. In basementless struc-

Table 1.... Recommended Thickness for Duct Materials

Round Ducts Diameter, In.	*Minimum Thickness*		*Minimum Weight of Tin-Plate*
	Galv. Iron, U.S. Gage	*Aluminum B&S Gage*	
Less than 12	30	26	IC (107 lb)
12 or more	28	26	IX (135 lb)
Rectangular Ducts Width, In.	*Minimum Thickness*		*Minimum Weight of Tin-Plate*
	Galv. Iron, U.S. Gage	*Aluminum B&S Gage*	
Ducts Enclosed in Partitions			
14 or less	30	26	IC (107 lb)
Over 14	28	26	IX (135 lb)
Ducts Not Enclosed in Partitions			
Less than 14	28	26	—
14 or more	26	24	—

Note: The table above is in accordance with the requirements of the National Board of Fire Underwriters to provide adequate fire protection. Industry practice is to use heavier gage metals where maximum duct widths exceed 24 in.

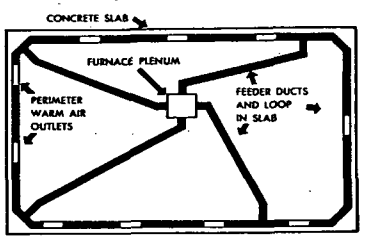


Fig. 4.... Perimeter-Loop System with Feeder and Loop Ducts in Concrete Slab

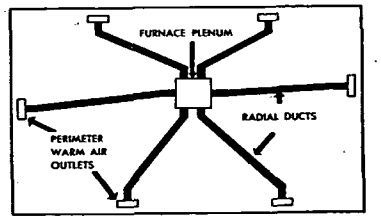

Fig. 6.... Perimeter-Radial System with Feeder Ducts in Concrete Slab or Crawl Space

tures, it is usually convenient to locate the return openings either high in the wall or in the ceiling. So far as the heating is concerned, however, this is merely a matter of convenience because low returns have been found to work equally well. It is usually not recommended in residential systems that any one return serve an area having a heat loss of more than 60,000 Btuh.

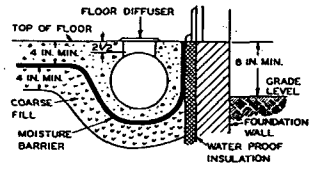
Dampers

Suitable dampers for air direction or volume control are essential to any duct system. Special care must be used in the design of any system, to minimize resistance. Sharp elbows, angles, and offsets should be avoided. Three types of dampers are commonly used. *Volume dampers* are used to completely cut off or reduce the flow through ducts. *Splitter dampers* are used where a branch is taken off a main trunk. *Squeeze dampers* are used for adjusting the volume of air flow and resistance through a given duct. A damper with positive locking device should be provided for each main or duct branch. Labels placed on ducts should indicate the room being served. Damper positions should be marked to indicate proper summer and winter settings, and to reveal tampering.

DUCT CONSTRUCTION

The ducts may be either round or rectangular in cross section. The centerline radii of elbows should preferably be not less than one and one-half times the pipe diameter for round pipes. The throat radius of a turn in a rectangular duct should be at least one-half the duct dimension in the plane of the turn. Warm air ducts passing through cold spaces or located in exposed walls, should have 1 to 2 in. of insulation.

Ductwork must be permanent, rigid, non-buckling, and non-rattling. Joints in ductwork should be airtight. Galvanized-iron or aluminum sheet are usually used in the construction of ducts, but other materials may be used under the proper circumstances. All return ductwork within six feet of the winter air conditioner shall be of noncombustible material.



Requirements of the National Board of Fire Underwriters state that heating supply ducts shall be constructed entirely of noncombustible material equivalent in structural strength and durability to the specifications in Table 1.

Supply ducts must be securely supported by metal hangers, straps, lugs, or brackets. No nails should be driven through duct walls and no unnecessary holes should be cut in them.

Supply air stacks should not be installed in outside walls unless it is impracticable to do otherwise. If it is necessary to do this, the stack must be effectively insulated against exposure. Failure to do this will materially reduce the heating or cooling capacity of the branch duct and will probably result in unsatisfactory comfort conditions in the room.

No supply air duct should come in contact with masonry walls. All supply ducts which pass through a masonry wall should be covered with at least ½ in. of insulation where they pass through the wall.

All supply ducts or outlets should be equipped with an adjustable, locking type damper for air volume control. The damper should be installed in the branch duct whenever it

The minimum thickness of concrete over the loop duct should be 2½ in. and continuous mesh reinforcing not less than 6 x 6–10 gage and 18 in. wide should be placed in the concrete and centered over the duct.

Fig. 5.... Cross-Section of Slab Construction Containing Perimeter Duct[a]

Table 2.... Diameter of Feeders in Perimeter-Loop System

Btuh per Feeder	*Length of Feeder in Feet*	
	0–15 Feet	*16–30 Feet*
	Inches	*Inches*

8,000 to 8,999	6	7
9,000 to 10,999	7	7
11,000 to 11,999	7	8
12,000 to 12,999	7	8
13,000 to 17,000	8	8

is accessible. Splitter dampers for volume control are not recommended.

Return systems having more than one return intake may be equipped with balancing dampers. This is particularly desirable with systems in which the supply outlets are located on the inside wall or in the ceiling of the conditioned rooms.

Special attention should be given to the problem of noise elimination. The metal duct connection to and from the furnace casing and fan housing should be broken by strips of fire resistant fabric. Motors and mountings must be carefully selected for quiet operation. Electrical conduit and water piping must not be fastened to, nor make contact with the fan housing. Installation of a fan directly under a return air grille is usually avoided.

SIMPLIFIED METHODS OF DESIGN

Simplified methods of design have been developed for several types of forced warm air heating systems. In general, the specific procedure chosen depends upon the type of system and the type of structure in which it is to be used. In most cases, more than one type of system may be used in a specific structure. It is therefore necessary to first choose the system desired and then determine the applicable design procedure.

Perimeter-Loop Systems in Concrete Slab Construction

The perimeter-loop system,[4] shown in Fig. 4, conveys the warm air through embedded ducts to perimeter diffusers. The air is delivered from the furnace to *feeder ducts* which extend radially to the *loop duct*. The air flows through the loop duct to the diffusers. The ducts serve the dual purpose of conveying the warm air and of warming the floor. Although the design of the concrete slab is not specifically the concern of the mechanical engineer, it is absolutely necessary that he understand the considerations involved lest improper construction be used with consequent adverse effect on the performance of the heating system. For information on slab construction, as well as duct placement, duct insulation, etc., see Manual 4 of the National Warm Air Heating and Air Conditioning Association.[4] A section of typically installed loop duct is shown in Fig. 5.

Simplified design procedures are contained in Manual 4. One of these procedures subject to the following limitations: total heat loss 100,000 Btuh, maximum perimeter 210 ft, and maximum length of uninsulated feeder duct 30 ft for area served by one furnace; is the following:

1. Calculate the heat loss for each room using the methods explained in Chapter 12. For subfloor and edge losses,[3] see Manual 3 of the National Warm Air Heating and Air Conditioning Association.
2. Determine the required furnace-bonnet capacity from the heat loss of the building.
3. Locate the diffusers on the plan. For best heating results, if a room has a heat loss of more than 8,000 Btuh or if it has two or more exposed walls, use two or more diffusers. Proportion the Btuh heat loss of each room among all diffusers in that room.
4. Locate the feeder ducts. First, divide the heat loss of the structure by 15,000 to determine the probable number of feeders. Second, locate the ducts so that they connect with the perimeter-loop at areas of greatest heat loss or in rooms where warm floors are particularly desirable. Third, locate the feeder ducts so that no more than 3 diffusers are in the section of loop duct between any two feeders. (The final number of feeder ducts may be larger than that originally estimated.)
5. Determine the size of feeder ducts using Table 2. Assume that the Btuh required by each diffuser will be supplied by the feeder nearest it. Determine the feeder duct diameter from its length and the total diffuser Btuh delivery carried by it.
6. Determine the total diffuser free area required in each room using Table 3. Measure the length of feeder duct under each room. Add to this *one-half* of the length of the loop duct, and determine the total diffuser free area required. Apportion this among all diffusers in the room.
7. The diameter of the loop duct should be uniform and equal to the diameter of the largest feeder duct.

Perimeter-Radial Systems in Concrete Slab Construction

The perimeter-radial system, Fig. 6, is similar to the perimeter-loop system in that the supply ducts are embedded in the concrete slab. The feeder ducts of the radial system extend directly from the subfloor plenum to the perimeter diffusers, and there is no loop duct around the perimeter of the floor. The feeders do provide floor-warming, but not to the same degree provided by the feeder and loop ducts of a perimeter-loop system. The same considerations of slab construction and edge insulation apply to both systems.

A simplified design procedure[4] using 6-in. diameter duct and subject to limitations of: 1,000 to 1,200 sq ft maximum area, not more than approximately 15 ft along perimeter between diffusers, and no radial duct substantially longer than 20 ft, is the following:

1. Calculate the heat loss of each room or area using the method explained in Chapter 12. For subfloor and edge losses, see[3] Manual 3 of the National Warm Air Heating and Air Conditioning Association.
2. Determine the required furnace-bonnet capacity from the heat loss of the building.
3. Locate the diffusers on the plan. Allow at least one diffuser for each exposed wall in each room or area of the building and preferably beneath window areas. For residential installations, limit each diffuser to a maximum of 7,000 Btuh. This is a preliminary estimate of the number of diffusers needed.
4. Measure the length and count the number of elbows in each feeder duct. Determine Btuh capacity of each feeder duct from Table 4. Use Table 4 (Section A) for side-wall and floor diffusers and Table 4 (Section B) for baseboard diffusers.
5. If the total Btuh capacity of all feeders to each room or area equals or exceeds the heat loss of that room or area, the number of feeders initially chosen is satisfactory. If the heat loss exceeds the Btuh capacity of the feeders, use and locate additional diffusers and feeder ducts.
6. The cfm values in Table 4 are used for designing the return-duct system.

Perimeter-Radial System in Crawl Space or Basement Construction

The perimeter concept of warm air heating has been applied to crawl-space and basement homes by locating the diffusers in the perimeter location and by warming the area underneath the floor of such structures. Although the construction of the crawl space and the foundation wall is the responsibility of the architect and the general contractor, it is important that the engineer check the construction to make certain that it will not adversely affect the performance of the heating system. Details on crawl-space construction are shown in Manual 4 of the National Warm Air Heating and Air Conditioning Association.[4] The crawl space or basement should be heated to provide warm floors.

A simplified design procedure[4] for an individual duct system is summarized as follows:

1. Calculate the heat loss of each room or area using the

The Equivalent Length Values used and included in calculating this table are: Diffuser and Boot = 40 ft; Plenum Take-off = 20 ft; Each Elbow = 14 ft. For each additional 14 ft equivalent length of boot and diffuser count one additional elbow.

All cfm values are based on standard air.

method explained in Chapter 12. Consider the basement or crawl space as a part of the structure and calculate its heat loss. Information in Manual 3' supplements that contained in Chapter 12, particularly with respect to crawl-space heat losses.

2. Determine the required furnace-bonnet capacity from the heat loss of the building.

3. Locate the diffusers on the plan. Allow at least one diffuser for each exposed wall in each room or area of building, and locate them preferably beneath window areas. For residential installations limit each diffuser to a maximum of 7,000 Btuh.

4. Determine the required Btuh delivery of each diffuser. Where more than one diffuser is used per room, proportion the heat loss equally among all diffusers.

5. Measure length and count number of elbows in each duct. From Table 5, determine the duct size (5 or 6-in. diameter)

The Equivalent Length Values used and included in calculating this table are: Diffuser and Boot = 100 ft; Plenum Take-off = 20 ft; Each Elbow = 14 ft. For each additional 14 ft equivalent length of boot and diffuser count one additional elbow.
All cfm values are based on standard air.

needed. Section A is for 5-in. duct, Section B is for 6-in. duct using side-wall or floor diffusers, and Section C is for 6-in. duct using baseboard diffusers.

Perimeter Extended-Plenum Systems in Crawl-Space or Basement Construction

The considerations involved in the design of extended-plenum systems are essentially the same as those of the individual pipe system. A simplified design procedure is summarized as follows:

1. Calculate the heat loss of each room or area using the method explained in Chapter 12. Consider the basement or crawl space as a part of the structure and calculate its heat loss. Information in Manual 3[3] supplements that contained in Chapter 12, particularly with respect to crawl-space heat losses.
2. Determine the required furnace-bonnet capacity from the heat loss of the building.
3. Locate the diffusers on the plan. Allow at least one diffuser for each exposed wall in each room or area of building, and preferably beneath window areas. For residential installations limit each diffuser to a maximum of 7,000 Btuh.
4. Determine the required Btuh delivery of each diffuser. Where more than one diffuser is used per room, proportion the heat loss equally among all diffusers.
5. Measure the length of each duct and count number of elbows from the extended plenum to the diffuser. Note whether top or side plenum take-offs are to be used. From Table 6, determine the duct size needed. (Note: Use that section of Table 6, Sections A to F, which applies *both* to the type of plenum take-off and diffuser to be used.)
6. The cfm values in Table 6 are used with Table 7 for sizing the extended-plenum system. No one extended plenum should exceed 35 ft in length.

Design of Return Duct System for Perimeter Installations

With perimeter systems designed in accordance with the foregoing simplified procedures, there is a circulating head of only 0.05 in. water available on the return side of the system. It is therefore necessary that the return ducts be adequately sized and be as short and straight as practicable. The return grilles may be centrally located, and the ducts may be located in the attic or other unheated spaces provided they are adequately insulated. Return air may be taken from basements and crawl spaces, but should not be taken from confined spaces in which the furnace is located.

The following simplified procedure[4] may be used:

1. Lay out the return-air duct system. Measure the length and count the number of 90 deg turns in each return duct.
2. Total the heat loss of the area served by each return duct.
3. Determine the required duct free area from the length of duct, the number of 90 deg turns, and the heat loss using Table 8. Also determine the free area of the return grille from Table 8.

Other Perimeter Systems

Each of the foregoing procedures can be used with approved furnaces that are capable of delivering their rated cfm air volume against a total pressure of 0.20 in. water external to the furnace. This available pressure is usually distributed on the basis of three-fourths (0.15 in. water) on the supply side and one-fourth (0.05 in. water) on the return side. Other systems, such as perimeter crawl-space plenum systems, may be designed by procedures outlined in Manual 4. In addition, procedures for designing 4-in. diameter duct systems are contained[5] in Manual 10 of the National Warm Air Heating and Air Conditioning Association.

Other systems of a proprietary nature but utilizing the perimeter concept of diffuser placement are in common use. These systems should be designed and installed in strict accordance with the manufacturer's recommendations. Such systems usually utilize smaller ducts (4 in. or less) and higher pressures (above 0.20 in. water). They also may require special streamlined, low resistance fittings and special diffusers. Some systems also employ higher bonnet temperatures. When either higher bonnet pressures or temperatures, or both, are to be used, care must be taken to ascertain that the furnace employed is capable of meeting the required conditions.

Tapered Extended-Plenum Starting Collar.

INSIDE WALL DELIVERY SYSTEMS

The concept of warm-air perimeter heating is relatively new. The older methods of introducing warm air into spaces use other outlet locations. One of the most common of these has been the use of register locations on a warm or inside

wall. For such systems, the combinations of parts selected as standard by the National Warm Air Heating and Air Conditioning Association are shown in Tables 9 and 10.

A simplified method for selecting the combinations of branches, boots, stacks, and registers, is given in Manual 7 of the National Warm Air Heating and Air Conditioning Association.* In this method, the sizes of the branch ducts are obtained from two tables giving their Btu capacities. The proper combination of parts for each branch can be determined if the following information is available.

1. Location of room, that is, whether on first or second story.
2. Actual horizontal length of duct from bonnet to boot, in feet.
3. Btu loss from room to be heated.

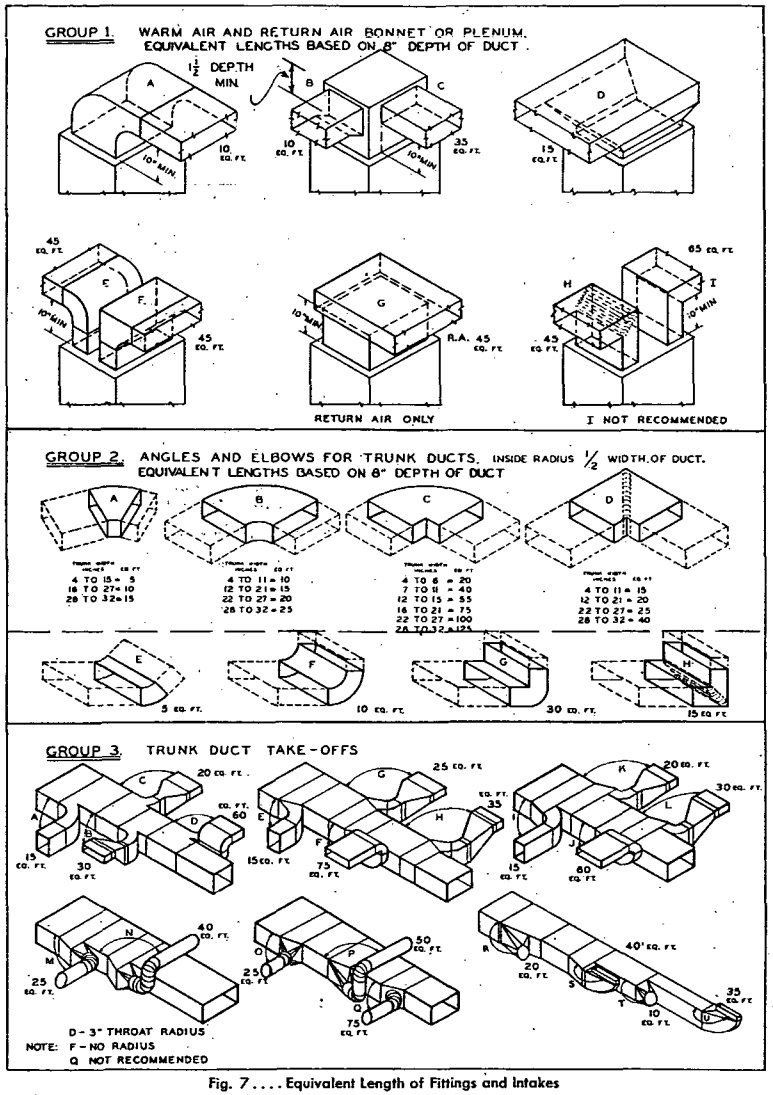
The Equivalent Length Values used and included in calculating this table are: Diffuser and Boot = 40 ft; Each Elbow = 14 ft; Top Take-off = 50 ft.
Tapered Extended-Plenum Starting Collar.

4. Equivalent lengths in feet of all fittings and of the register. Fig. 7 shows the values of equivalent lengths of fittings commonly used for domestic systems.

This simplified method is applicable to structures having heat losses not in excess of approximately 120,000 Btu per hour. The capacities shown in Tables 9 and 10 are based upon the most reliable data pertaining to friction losses and temperature drops in ducts. They are also based upon a 100 deg temperature rise of the air, and a static pressure available for overcoming friction losses in the external duct system alone of 0.20 in. of water. The use of this method requires that the fan in the fan-furnace assembly will be capable not only of overcoming the resistance of the external duct system alone, but also the resistances imposed by the blower inlet, the filter, and the furnace casing.

Tables 9 and 10 are applicable for the selection of both warm air and return air branches. A depth of 8 in. has been adopted as the standard for trunk ducts, and where a branch



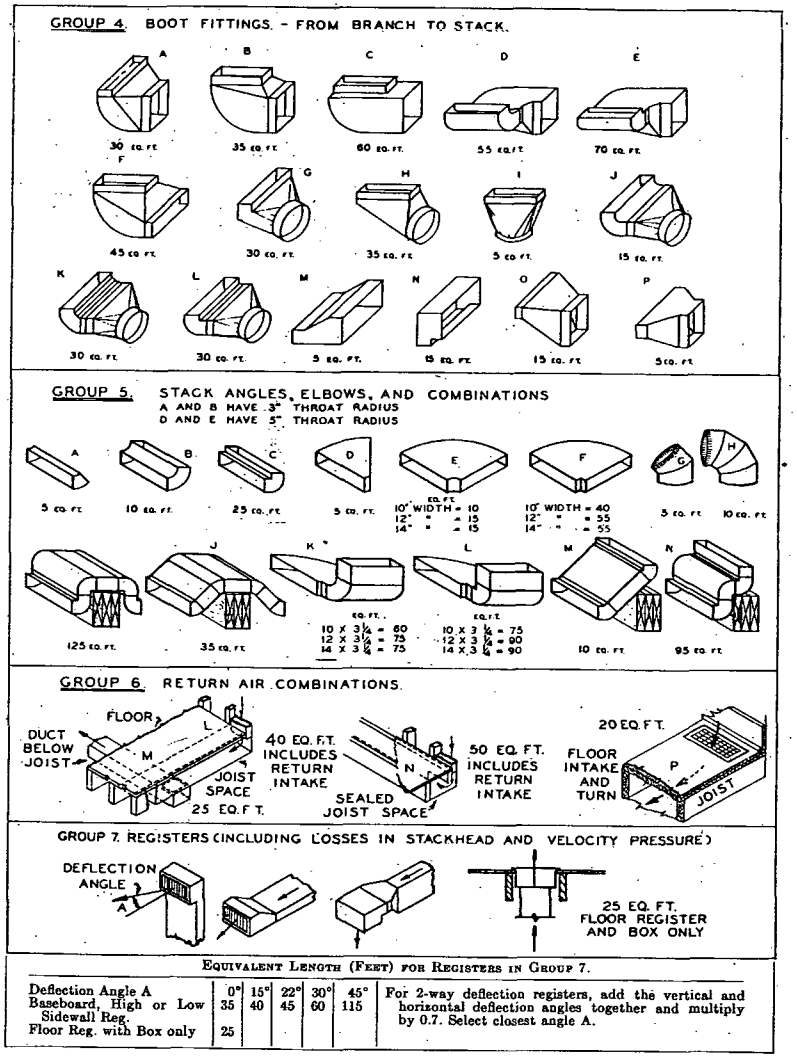


Fig. 7.... Equivalent Length of Fittings and Intakes

EQUIVALENT LENGTH (FEET) FOR REGISTERS IN GROUP 7.

Deflection Angle A	0°	15°	22°	30°	45°
Baseboard, High or Low Sidewall Reg.	35	40	45	60	115
Floor Reg. with Box only	25				

For 2-way deflection registers, add the vertical and horizontal deflection angles together and multiply by 0.7. Select closest angle A.

Fig. 7.... Equivalent Length of Fittings and Intakes (*Concluded*)

Table 7 .... Required Size of Extended-Plenum

Cfm Handled by Plenum	Plenum Dimensions Inches	Cfm Handled by Plenum	Plenum Dimensions Inches
Up to 300	8 x 8	701 to 800	20 x 8
301 to 400	10 x 8	801 to 900	22 x 8
401 to 500	12 x 8	901 to 1000	24 x 8
501 to 600	14 x 8	1001 to 1100	26 x 8
601 to 700	16 x 8	1101 to 1200	28 x 8

joins the trunk the required increase shown in the last line of Table 9 or Table 10 refers to an 8-in. trunk duct.

Where two branches form a trunk the longer branch is considered to be the trunk and its equivalent width (for 8-in. depth) is increased as required.

DESIGN PROCEDURE FOR LARGE SYSTEMS[a]

For buildings having a heat loss in excess of 120,000 Btu per hour, the design procedure given in Manual 9 of the National Warm Air Heating and Air Conditioning Association, may be used. Work sheets 9a, 9b, and 9c are available to simplify calculations.[a] The procedure consists of:

1. Calculation of design heat losses from individual spaces in the structure. The calculation of these losses is explained in Chapter 12.
2. Location of registers and return intakes on floor plan, showing types of registers, with distance from register to opposite wall and deflection of registers desired.
3. Laying out a proposed duct system for both warm air and return air sides of the system, and including details of types of fittings and the actual and equivalent lengths of each branch line from bonnet to register, without sizes. (See Fig. 7, Groups 1 through 6, for equivalent length of fittings.)
4. Determination of bonnet temperature.

If the rating sheet for a furnace-blower unit specifies a *fixed value of bonnet temperature*, find this temperature in the left-hand column of Table 11. If not specified, use the following procedure: Use Table 11 *for buildings* having a heat loss between 120,000 and 350,000 Btu per hr, or Table 12 for buildings having a heat loss greater than 350,000 Btu per hr. Select *shortest actual length*, including vertical risers and read downward in nearest column in Tables 11 or 12 until lower heavy diagonal line is reached, but do not cross line. Run horizontally to first column of table and note *bonnet temperature*. Also select *longest actual length* including vertical risers, and read downward in nearest column in Tables 11 or 12 until upper heavy diagonal line is just crossed. Run horizontally to left to obtain value for *bonnet temperature* in first column. Select as the design bonnet temperature any value between these two limits.

5. Determination of air volume to be delivered through each register and the respective register air temperatures.

Using Tables 11 or 12 and the design bonnet temperature selected, find the values of cfm per 1000 Btu for each duct length, and the corresponding register temperature.

6. Selection of register sizes and pressure losses to produce necessary throw, for the air volumes handled.

Use Tables 13 or 14 to obtain required free area and pressure loss of register. Tables 15 and 16 are used in sizing the duct system.

7. Design of duct system.
   - A. *Warm air branches.*
     - a. Use Table 16 to select maximum bonnet pressure *usually* required for the trunk carrying the maximum volume of air (cfm). If the maximum bonnet pressure is not high enough to accommodate the pressure loss through the registers, use a higher bonnet pressure. If the register pressure is critically large, it may be necessary to reduce it by either using two registers in place of one, or using smaller deflection angles.
     - b. Obtain actual duct loss by subtracting total register pressure loss, as determined from Tables 13 or 14, from maximum bonnet pressure.
     - c. Obtain the pressure drop in each duct per 100 ft by use of Table 15.
     - d. Determine duct size by means of air friction chart (such as Fig. 2, or Fig. 3, Chapter 21), volume (cfm), and pressure drop per 100 ft of duct.
   - B. *Return air branches.* (*Continued on p. 253.*)

Trunk Duct Increase, Inches			1	2	3	4	5	7	12

[a] Uninsulated ducts in heated spaces and insulated ducts in unheated spaces.

[b] Note: For return air a 14x2¾ in. stud space may be used instead of 10x3¼ in. stack. Where 12x3¼ in. or 14x3¼ in. stack is required, a 14x2¾ in. stud spaces may be used only when inside of stud space is smooth and without protruding plaster keys. The number of joist spaces for combination 47 is based on 2x8 in. joists. One space may be used with 2x10 in. joists.

The limiting factor for a duct combination is the stack capacity.

[a] Register temperature, Fahrenheit. (Use upper value in each group.)

[b] Register delivery volume in cubic feet per minute per 1000 Btu. (Use lower value in each group.)

[c] Register delivery volumes in column 1 are for zero length of duct.

B. *Return air branches.*
   a. Select a low value of actual duct loss obtained from step b under item A for the suction loss of return duct system.
   b. Proceed in sizing return air branches by the same method described for the warm air branches.

C. *Trunk ducts for warm air and return air sides of system.*
   a. Add air volumes of branches to be handled by each trunk duct.
   b. The friction loss per 100 ft of trunk duct is determined by taking the smaller of the two values for friction loss for the two ducts meeting at the junction.
   c. Determine trunk duct size by using an air friction chart, volume (cfm), and pressure drop per 100 ft of trunk duct.

8. Selection of Blower.
   A. Determine total cfm air delivery (the sum of all branch cfm values).
   B. Determine static pressure requirement.
      a. For furnace-blower combination units it is the sum of bonnet pressure and suction pressure.
      b. For blowers separately selected from the furnace it is the sum of bonnet pressure, suction pressure, filter loss, casing loss, losses through air washers, coils, and other devices.

9. Selection of Furnace.
   A. Determine register delivery (the sum of room Btu losses).
   B. Determine bonnet capacity.
      Bonnet capacity = (total cfm) × (temperature rise) × 1.089.
   C. Determine allowance for pick-up load. For buildings which are heated intermittently, such as churches and auditoriums, it is customary to add from 10 to 25 percent extra furnace capacity for warming of the structure.

AUTOMATIC CONTROLS

Air stratification, high bonnet temperatures, excessive flue gas temperatures, and heat overrun or lag in a properly designed system, can be largely eliminated through proper care in the planning and installation of the control system.[29] Best results are obtained when the fan is operated as continuously as possible, coupled with frequent, short cycles of burner operation. Controls usually employed are;

1. A *room thermostat* located in the occupied space at a point where there is good air circulation and where the temperature is representative of the area being controlled. It is the

Table 12.... Selection of Bonnet Temperature, Register Temperature and Register Delivery (CFM)[a,b]

(For Buildings Having a Heat Loss Greater than 350,000 BTU/Hr.)

Register Delivery Volume in CFM per 1000 BTU per Hr.

[c] Register delivery volumes in column 1 are for zero length of duct.

operating control which initiates the starting and stopping of the burner. It is frequently of the timed, two-position type. Refer to Chapter 43 for more information on types of room thermostats.

2. A *fan thermostat* located in the bonnet of the furnace to start the fan at a bonnet temperature beween 110 and 130 F and stop the fan at about 15 deg below the cut-in point. The lower settings are used for high side-wall register installations and the higher settings for baseboard register installations. For most satisfactory performance these settings should be as low as is feasible without resulting in drafts.

3. A *high limit control*, also in the bonnet of the furnace, to stop the burner independently of the room thermostat if the air temperature exceeds 175 F. The fan thermostat and high limit control are sometimes combined into a single unit.

4. A *humidistat* to regulate the moisture supplied to the rooms on systems which are equipped with humidifying means. This may be of the room type, usually located adjacent to the room thermostat, or it may be of the insertion type located in the main return air duct.

5. Primary and limit controls for the various types of gas burners, oil burners and coal burners (stokers) should be provided as required, and are discussed in Chapter 34.

ADJUSTMENT OF SYSTEM

More even room temperatures will result if the controls are adjusted to produce long period fan operation. This is accomplished in automatically-fired forced warm air heating systems when the control arrangement is of the type where the room thermostat controls the fire, and the blower control (fan switch) controls the blower operation. This procedure as outlined in detail in Manual 6 of the National Warm Air Heating and Air Conditioning Association, is as follows:[a]

1. Adjust the fuel input in proper relation to the heat loss of the structure.
2. Determine the temperature rise through the furnace.
3. Adjust the air volume to produce a temperature rise through the furnace of about 90 deg.
4. If adjustable, set the fan switch differential to a minimum of about 15 deg.
5. Adjust the fan switch cut-out point as low as practicable.
6. Balance the system by adjusting dampers to produce even temperature distribution between rooms.
7. Set the room thermostat at the desired room temperature.

Close control of room temperature is facilitated by the use of a room thermostat having a narrow operating differential. The heat anticipating thermostat is an example of such a device.

WARM AIR CEILING PANEL SYSTEMS

Warm air ceiling panel heating systems utilize a false ceiling suspended 3¼ in. from the ceiling joists which have previously been covered on the bottom with sheets of plaster-

[a] If register selected based on distance from register to opposite wall is unsatisfactory on account of size or pressure loss, it is permissible to shift one or more spaces left or right in the tables to obtain a more suitable register. If requirements fall in blank space, select two registers in place of one and divide CFM capacity between the two registers.

[b] Total pressure (static plus velocity) loss is based on FLAT FACE ADJUSTABLE BAR TYPE and does NOT include stackhead.

[c] Values on the right of line A and A′ should not be used in applications such as churches, auditoriums, and concert halls.

[d] Values on right of line B and B′ should not be used in applications such as residential work, motion picture theaters, court rooms, and schools.

[e] For floor and baseboard registers where a velocity of approximately 300 FPM is used, the free area = $\frac{\text{CFM} \times 144}{300}$ or approximately, $\frac{\text{CFM}}{2}$. Assume a pressure loss of 0.01.

Table 14 . . . Determination of Free Area and Total Pressure Loss of Register for No Deflection of Air[a, b, c, d, e]

board. Special hangers are used to suspend the false ceiling or heating panel from the joists. Steel supporting rods are installed through these hangers and metal lath is attached to the rods. The lath is then plastered to a thickness of ¾ in., making a completely sealed air space above the ceiling. Warm air is delivered to this sealed space through a standard warm air duct, installed in the usual manner. The air is then circulated over the entire ceiling being guided by sheet-metal baffles. After the air has passed over the ceiling, it is returned to the furnace through a return air duct for reheating. The system is closed, and no air is introduced into the heated space from the panel. (See also Chapter 30, Panel Heating.)

Because a warm air ceiling panel system involves a different type of ceiling construction, its installation is practically limited to new construction. Only automatically-fired and thermostatically-controlled furnace-blower units may be used with this system. The standard automatic heating controls consisting of a room thermostat, temperature limit control, blower control (fan switch), and primary control are all that are required. While warm air ceiling panel heating has particular advantages in one-story utility room houses, it can be just as effectively installed in one- and two-story houses with basements.

Complete design and installation procedure is given in Manual 7-A of the National Warm Air Heating and Air Conditioning Association.[11]

SUMMER OPERATION

During hot summer periods a slight cooling effect may sometimes be obtained by the circulation of basement air through the system. This beneficial effect is due to both the increased air movement in the occupied spaces and the small reduction in dry-bulb temperature brought about by passing warm air over the cooler basement walls and floor. In areas of high prevailing dew points, however, this practice may cause objectionable dampness to develop in the basement.

Complete summer air conditioning can be readily combined with forced warm air systems either by using factory-built units incorporating both refrigeration and heating equipment, or in *some cases* by adapting separate refrigeration equipment or well-water coils to *existing* warm air systems.

A more complete treatment of residential summer air conditioning is given in Chapter 46.

GRAVITY WARM AIR SYSTEMS

In *gravity* warm air heating systems the motive head producing flow depends upon the difference in weight between the heated air leaving the top of the furnace casing and the cooled air entering the bonnet of the casing. Hence, the motive head is very small and the system must allow free flow.

A gravity warm air furnace heating plant consists of a fuel-burning furnace or heater, enclosed in a casing of sheet metal, which is placed in the basement of the building. The heated air, taken from the bonnet on the top of the furnace casing, is distributed to the various rooms of the building through sheet-metal warm air pipes. The warm air pipes in the basement are known as leaders, and the vertical warm air pipes which are installed in the inside partitions of the building are called stacks. The heated air is discharged into the rooms through registers which are set in register boxes placed either in the floor or in the side wall, usually at or near the baseboard.

The air supply to the furnace is usually taken entirely from inside the building through one or more recirculating ducts, although in some cases an outside air supply duct is provided.

Gravity warm air heating systems may be designed[12] by following the procedures given in Manual 5 of the National Warm Air Heating and Air Conditioning Association. This publication also contains information terminology, outlet and return locations, and standard sizes of pipe and fittings. The data underlying this information and the design procedure are given in a circular[13] issued by the University of Illinois, and are based on research conducted there.

CHAPTER 19

CENTRAL SYSTEMS FOR AIR CONDITIONING

Features of Systems, Zoning, Humidity Control, Cooling Load, Heating Load, Air Quantity and Temperature Differential, Unitary-Central Systems, Low- and High-Pressure Induction Convectors, High-Velocity Systems, Fan and Coil Units, Evaporative Cooling, Precooling, Sensible Cooling with Unwetted Coils, Selection of System, Location of Apparatus

THE term, central, applied to an air conditioning system implies that the equipment such as fans, coils, filters and their encasement are designed for assembly in the field rather than in a factory as a unit. As a central system usually serves several different rooms, or spaces, individual controls are required for each room.

FEATURES OF CENTRAL SYSTEMS

One advantage of a central air-supply system is that one apparatus serving many rooms may involve a lower investment cost than that for a number of self-contained plants, each serving a single room. A central system may occupy basement or attic space that is relatively unimportant, whereas individual factory-assembled apparatus placed in each room may occupy otherwise valuable space. Another advantage of a central system is accessibility for servicing, since it is possible to provide doors in the encasement for cleaning and inspecting all of the component parts in a manner usually superior to that practicable with compact factory-assembled equipment. In addition service is concentrated in one or just a few places.

Central air-conditioning systems usually are connected by ducts with the various rooms served, and preferably have exhaust fans that may effect complete removal and disposal of any desired proportion of the air. The return-air fan may return air to the supply system for recirculation, as a measure of economy of fuel or refrigeration.

Central air-conditioning systems are served by heating and refrigerating equipment which may be located at some distance from the air-supply apparatus, and which may serve one or more central air-supply systems.

Fig. 1 is a sketch of a typical year-round central system. Outdoor air enters from an intake preferably on that side of the building least exposed to solar heat, and not close to the ground or to a sun-heated or dust-gathering roof. The outdoor-air damper is split into two sections, minimum outdoor-air and maximum outdoor-air, with the maximum outdoor-air damper interlocked with the return-air damper in such a manner that as the outdoor-air volume increases the return-air volume decreases. The return-air duct or connection could come from a return-air fan. All the air passes through filters which must have ample room on both sides of the filters for servicing. The filters may be of a mechanically-cleaned type, a replaceable-cell type, or may be electronic as described in Chapter 24.

The cleaned air passes to the equipment that changes its temperature and humidity. Except in very warm climates, heating or tempering coils are required to warm the entering outdoor air to a temperature above freezing, the heat being supplied by means of hot water or steam. Cooling coils provide the necessary sensible cooling and dehumidification. The coils may be chilled by direct expansion of an approved refrigerant within the tubes, or by a pump-circulated liquid such as water or brine. A water-tight drainage tank must be installed under the cooling coil and should extend for a distance toward the fan.

Reheater coils, utilizing steam or hot water, reheat the air in warm weather for control purposes or bring the air to its final temperature in cold weather. For humidification in dry weather, water sprays are used either separately as shown or combined with the cooling coils having the spray nozzles directed against the coil surfaces. The spray water may be circulated by a small pump from the water tank under the spray chamber.

The general requirements for the control of the various components of the central station apparatus are covered

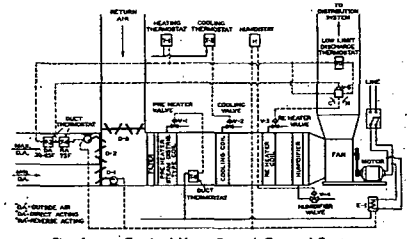

Fig. 1.... Typical Year-Round Central System

in Chapter 43. The functioning of a typical set of controls as illustrated in Fig. 1 is as follows:

Whenever the fan is started, solenoid air valve or relay E-1, actuated by the fan motor starter, opens minimum outdoor-air damper D-1, places humidistat H in service, and allows duct thermostats T-3 and T-4 to control the maximum outdoor-air damper D-2 and the return-air damper D-3.

When the fans stop, E-1 is de-energized to close the outdoor-air dampers and also to close humidifier valve V-4.

Thermostat T-1 positions steam valve V-3, on the reheater coil, to maintain a constant space temperature. As the space temperature rises, T-1 positions reheater valve V-3 to a closed or to a minimum open position, as determined by low limit discharge thermostat T-5. Duct thermostat T-6, in the preheater discharge, positions preheater coil valve V-1 to maintain a constant preheater discharge temperature.

On rising outdoor temperature, between 30 F and 65 F, duct thermostat T-3 located in the outdoor-air intake, moves maximum outdoor-air damper D-2 toward the open position

provided that T-1 is satisfied. At 65 F outdoor, D-2 will be fully open and return-air damper D-3 will be fully closed.

As the outdoor-air temperature rises above 65 F, duct thermostat T-3 positions V-5 in such a way as to bypass low limit thermostat T-5 so that reheater coil valve V-3 is operated directly from thermostat T-1. As the outdoor-air temperature rises from 65 F to 75 F, duct thermostat T-4 gradually closes maximum outdoor-air damper D-2 and opens return-air damper D-3.

Cooling thermostat T-2 positions cooling coil valve V-2 to admit more chilled water as the space temperature rises.

Humidistat H positions humidifier valve V-4 to maintain the desired humidity in the conditioned space.

ZONING AND ZONE CONTROL

It is apparent that while apparatus like that of Fig. 1 would be very desirable for any single room, since in that case the air could be delivered at optimum conditions, the cost of a complete individual system for each room and the space required for the equipment generally would be prohibitive. Economy is favored if the varying requirements of numerous rooms or zones can be simultaneously satisfied by air from a single central supply system.

Various methods are practicable for controlling the temperature, humidity and air movement in various rooms or zones. A measure of control is attainable merely by proportioning the flow of air to each room, though usually such control by throttling dampers is difficult to maintain and should be avoided when possible.

Another scheme is to install a properly proportioned coil in the branch air-supply duct serving each room or zone to warm the air to suit the occupants. For example, the air leaving the fan that serves several zones may be cooled, before entering the fan, to the condition favorable for one zone, and the air for each other zone may be reheated by the branch duct coil to the required temperature. It is also possible to circulate a heat absorbing medium in the branch duct coils to reduce the temperature of the air passing to rooms that would be overheated if they received air at the condition leaving the central air-supply system. When heat transfer devices are placed in branch ducts for improved temperature control, mechanically-circulated water gives excellent results as a heat carrier. The water usually is warmer than the air but it is possible to use water colder than the air.

It is practicable also to use single central air-conditioning equipment similar to that shown in Fig. 1, in conjunction with several fans, one for each room or zone. In such cases there may be a separate reheater on the suction side of each relatively small supply fan.

The designer must remember that the various supply fans will compete with each other for air, against the resistance interposed by the filters, coils, etc., that are used in common under such circumstances, and consequently, unless the fans are of backward-curved blade, non-overloading type, they may alternate in carrying more than their share of the air, and thereby cause the air distribution to be chaotic and unsatisfactory.

Another method of controlling temperature in various rooms served by a central air-supply system is shown in the sectional elevation, Fig. 2. The supply fan is placed immediately after the humidifier. When cooling the air in hot weather, the humidifier is not operated. The fan will deliver the air through the heating coil and through the cooling coil to the two air-pressure chambers *A* and *B* at the right of these coils. From these chambers many separate ducts, one of which is shown, each with a double-blade mixing damper, may convey the air to the various rooms. The mixing dampers, one of which is shown, are interlocked so that as the upper one closes, the lower one opens; selecting between them, air in the required quantity from either the warmer chamber *A* or the cooler one *B*. In cold weather no refrigerant is required in the cooling coil, and in hot weather no heating medium is circulated in the heating coil. With this scheme, the control of relative humidity in warm weather is not always sufficiently precise to meet requirements, since the untreated air delivered through the upper coil may be so high in relative humidity that it cannot compensate sufficiently for the nearly saturated air leaving the lower coil. A reheater could be placed if desired, at the right of the lower coil to bring the air in the lower chamber to the desired relative humidity. The simple arrangement of Fig. 2 is admirable in winter and, except where close control of relative humidity is important, may be acceptable in summer.

Another method of attaining temperature control in individual rooms with a year-round central air-supply system, is to install a booster fan between the main air-supply duct and the air-delivery opening to each zone or room, as shown in Fig. 3. Air can then be delivered from the central supply fan through the main duct at some desired condition, for instance, 60 F and 45 percent relative humidity. A double mixing damper near the intake opening of the booster fan, controlled by a thermostat in the room or zone that is served by the fan, is interlocked with an outlet exhaust damper in the spent-air opening, so that as more of the room air is recirculated, and as less new air from the main air-supply duct is delivered into the room, the spent-air outlet is throttled in proportion. In many large installations this principle is applied successfully for zoning different stories in multi-story office buildings, the main supply fan being on the roof, and each booster fan being used for supplying the rooms of one orientation of each story. In other cases the booster fans serve only single offices, and therefore are small enough to be concealed above ceilings alongside the main supply duct.

There may be installations in which the use of recirculated air for mixing with new refrigerated and nearly saturated air to control temperature and relative humidity is objectionable. In such cases the general recirculation arrangements of Fig. 1 may be omitted, and heat transfer coils located in the ducts may be used. In some cases where general recirculation is not acceptable, as for all the rooms in an entire building, use of the local circulation of Fig. 3 may solve the problem.

HUMIDITY CONTROL

In winter, room relative humidities in excess of 30 percent are seldom required in a system designed for comfort conditioning only, and a low saturating efficiency may be desirable, or even necessary, especially if the same volume of

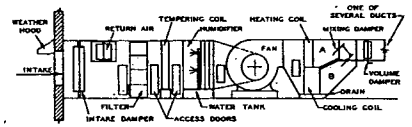

Fig. 2 . . . . Alternate Arrangement of Equipment for Controlling Air Conditions in Central-Air Supply System

air is handled as in summer. With a spray-type dehumidifier the main sprays may be shut off and only the eliminators need be flooded; which may give sufficient moisture. In other cases, such as those in which cooling coils are sprayed, the spray-water supply may be throttled. If the saturation efficiency of the sprays is too low, the spray water may be heated. The amount of heat put into the spray water by open or closed water heaters will be equal to that required to bring the dew-point temperature of the air entering the sprays up to that required before entering the preheater. It is possible, where clean steam is available, to introduce steam directly into the air stream to produce the desired dew-point temperature of supply air. However, the steam must be exceptionally clean, or objectionable odors will result.

It should be noted that the quantity of outdoor air to be introduced is affected by infiltration and leakage. Infiltration will reduce the quantity to be introduced by the system, while leakage may have to be offset by an increase in the quantity of outdoor air.

COOLING LOAD

The method of determining the cooling load for a conditioned space or spaces is outlined in Chapter 13. As pointed out therein, many of the items of heat gain are variable and do not reach their maximum values simultaneously. Proper consideration of these peaks and the avoidance of pyramiding these peaks in the cooling load calculations are stressed. Maximum solar heat gain on an east exposure is seldom coincident with the maximum outdoor wet-bulb temperature. A discussion of the factors affecting the actual instantaneous cooling load will be found in Chapter 13.

HEATING LOAD

Methods of calculating the heating load are shown in Chapter 12. Many of the factors outlined in Chapter 13, Cooling Load, such as zoning, non-simultaneous peaks, and diversity, apply in the reverse manner due to the heating requirements instead of the cooling requirements. However, these factors affect the heating load from the standpoint of control of inside conditions, overall performance, and economy of operation more than from a capacity of equipment standpoint. It is not only necessary to heat a building or space to its design conditions when there is but the merest fraction of normal occupancy, and when there are practically no lights, internal heat, or solar radiation, but it is also necessary to provide capacity to heat the building quickly when sudden cold follows relatively warm weather, as may

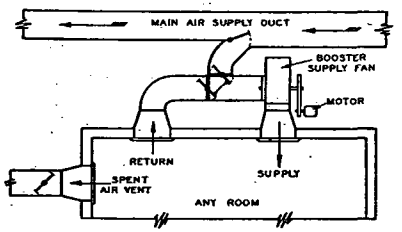

Fig. 3 . . . . Arrangement for Individual-Room Temperature Control with Central Air-Supply System

occur after a week-end or holiday shut-down. However, in normal operation during week-ends and holidays, buildings are usually kept at a holding temperature to prevent the freezing of services. In many cases, less fuel is required to operate the heating plant at a near-normal rate and maintain the building or space at a temperature of 50 to 65 F at such times, than to shut the system down and then bring the temperature back to normal through forced operation of the heat-generating equipment with a consequent loss in efficiency.

AIR QUANTITY AND TEMPERATURE DIFFERENTIAL

The difference between the room-air temperature and the supply-air temperature at the outlet to the room is known as the temperature differential. In the theoretical case of a dehumidifier having 100 percent saturating efficiency, and where this air is delivered directly to the room without temperature increases due to heat gain, then the temperature differential is the difference between room temperature and apparatus dew-point temperature. If duct heat gains are considered a part of the room load, this still holds true. The apparatus dew point, as outlined previously, is fixed by the latent and sensible loads of the space, but in many cases, it is desirable to deliver more air to the spaces than is indicated by the difference between the room temperature and the apparatus dew point.

It has been indicated that where a percentage of air is passed through the dehumidifier without being treated, the relationship is modified in direct proportion, and that if room air is passed through untreated, no effect on the heat balance results. Similarly, if room air is passed around the dehumidifier and mixed with the treated air, the heat balance is not adversely affected. Therefore, if the quantity of air passed through the dehumidifier is determined by the usual methods, room air can be passed around the dehumidifier and mixed with the dehumidified air, increasing the supply-air quantity and temperature and decreasing the temperature differential. Thus if the difference between the room temperature and the apparatus dew point indicates that 10,000 cfm at 30 deg below room temperature will be required to hold conditions, that quantity can be passed through the dehumidifier and cooled to 30 deg below the room temperature, then mixed with 10,000 cfm of room air, resulting in a supply-air quantity of 20,000 cfm and a temperature differential of 15 deg instead of 30 deg. Air-supply outlets and grilles having a high induction ratio are available, and through their induction effect cause a large amount of room air to be mixed with the supply air within a short distance of the grille. A proper selection of outlets may make it possible to introduce air at low temperatures and high velocities without causing objectionable drafts or cold spots, but care must be used to see that too little air motion is not a result. Small temperature differentials may be required for this reason. While the use of a large temperature differential results in a saving in initial cost of fans and ducts, and in the operating cost of fans, this differential should be carefully considered. If the sensible heat load of a space is subjected to substantial variations, small temperature differentials should be considered, since systems employing small temperature differentials require less precision in controls.

Reduction of air quantity by slowing down the fans for the winter season, and increasing the temperature differential, often is feasible. A saving in fan power can thus be effected, provided the air distribution remains adequate.

Extremes should be avoided in all cases. For summer air conditioning, low supply-air temperatures result in larger heat gains to the air passing through the ducts, as well as in poor control. Too high a supply-air temperature may result in excessive initial and operating costs. Suggested limits for the temperature differential are from 12 to 25 deg, the actual selection being based on the requirements of the particular case. For winter air conditioning, too high supply-air temperatures result in excessive heat losses from the ducts and stratification within the room unless thorough mixing is assured, while too low supply-air temperatures may cause drafts, high operating costs, etc. Suggested limits are from 15 to 35 deg. There can be no set rule, and each case should be judged according to its particular requirements of the installation.

Reference may be made to Chapter 20 for further discussion of the most satisfactory design difference between the entering air temperature and volume in relation to the desired room condition.

UNITARY-CENTRAL SYSTEMS

Many different types of central air-conditioning systems with room units of various designs have been developed for multi-room buildings, such as office buildings, hotels, and hospitals. The primary object in using these systems is to save space by reduction of duct sizes or by entirely eliminating ducts. In new buildings, small ducts may reduce the overall building height; in existing buildings, the use of small ducts is frequently imperative and may even play a decisive role in the acceptance of air conditioning for these buildings. Also, multi-room buildings frequently require a high degree of zoning or individual room control, which the systems must supply.

These buildings usually have a large perimeter relative to the floor area. Air-conditioning units are usually installed beneath the windows. Where the spaces to be conditioned extend a considerable distance from the outer wall into the interior of the building, as in some office buildings, a separate system or zone for the conditioning of the interior portions may be required. In these cases the interior system handles the relatively small and steady loads, due to such items as lights and people; while the exterior system must cope with the relatively large and variable loads imposed by sunshine and temperature difference through walls and glass. Descriptions of the four common unitary-central systems follow.

Induction Convectors—Low-Pressure Type

Induction convectors located in the room that is to be served, utilize a jet of primary conditioned air to mix with a stream of secondary room air as shown in Fig. 4. The mixture is discharged into the room through a grille at the top of the convector. Heating coils are located in the secondary-air stream. The output is controlled either by manually or automatically throttling the air jet. Heat may be supplied to the coil in summer as well as in winter. These induction convectors present several advantages. Since the secondary air stream is thoroughly mixed with the high-velocity low-temperature air stream before leaving the discharge outlet of the device, the resultant temperature of the mixture is satisfactory even though the primary air is introduced at a temperature too low for ordinary methods of distribution. One of these devices usually is provided under each window in place of the customary direct radiator, and combines the air-distribution system with the heating system. An air-conditioning system without induction convectors may require installation of direct radiation for maintenance of minimum temperatures during air-conditioning shut-down periods, but when induction convectors are used they may be selected with heating coils of sufficient capacity to maintain, by thermal circulation, a reasonable temperature when the primary-air supply system is shut off. The use of low-temperature, dehumidified air that has not been reheated or mixed with room air before delivery to the room, may permit a reduction in fan capacity and the use of smaller ducts. In some cases a bypass may be desirable in order to maintain the primary-air volume and to provide additional control. This system can provide a degree of zoning that is usually difficult with conventional design because the air delivered by each unit can be controlled individually. Selection of induction convectors should be made with due regard to noise level. The inductive capacity of the device increases with the jet velocity, but high jet velocities may result in objectionable noise.

The units are supplied with primary air from one or more central stations with the primary air providing all ventilation and handling the entire cooling load. The central apparatus is arranged in general conformity to Fig. 1 except that the central reheater is omitted since each unit has its own reheater. The controls are arranged to maintain a substantially-constant supply-air temperature equal to that required for maximum cooling. Final control is obtained by means of a room thermostat, or remote bulb thermostat in the unit having its measuring element in the recirculated-air stream. The controlling thermostat operates the coil supply valve and a damper operator on the primary-air damper in sequence. At maximum heating load the valve is wide open and the primary-air quantity is at a minimum. As the space temperature tends to rise, the valve is first gradually closed, then the primary-air quantity is gradually increased from minimum to maximum. Alternately the primary-air quantity can be kept constant while final control is achieved by the individual heating coils. If variable air quantities are to be handled by the primary-air fan, some form of fan-capacity control is necessary.

Induction Convectors—High-Pressure Type

Another type of induction convector, Fig. 5, employs nozzles that produce a high-velocity air jet without objectionable noise. The term, high pressure, is to some extent inaccurate, since the air pressure at the nozzles, while several times that used with a low-pressure induction convector, is still less than the total resistance pressure of a conventional central system. The high-velocity jet of primary air induces

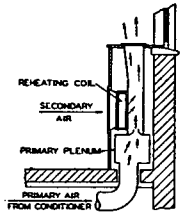

Fig. 4 .... Induction Unit (Low-Pressure Type)

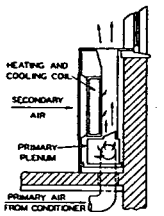

Fig. 5 .... Induction Unit (High-Pressure Type)

a flow of air from the room through coils located in the secondary-air stream and supplied with chilled water in summer and with hot water in winter. The chilled water removes a large portion of the sensible heat in summer and the hot water supplies the sensible heat loss in winter. The primary air is delivered at a sufficiently low dew point to compensate for the latent heat gain in summer. In winter the primary air is supplied at a sufficiently high dew point to take care of latent heat losses. Control of temperature is obtained by throttling the water quantity supplied to the secondary coil. The required flow of primary air is greatly reduced due to the fact that a portion of the sensible heat load is carried by the secondary air stream. Since the primary quantity is small, very high velocities can be maintained in the supply ducts without requiring fan power in excess of that for a conventional system. Therefore, the supply ducts or pipes can be very small and can be run in chases, or furred in at columns along with the water pipes. The primary air is treated in the usual manner to reach the required dew point and a surface or spray dehumidifier or a dehydrator may be used. The primary-air quantity is sufficient for ventilation purposes and frequently consists entirely of outdoor air.

Fig. 6 shows the general arrangement and control of the system. The operation of the controls is as follows:

The final temperatures in the spaces are controlled by individual valves, either automatic or manual, which throttle the flow of secondary water to the unit coils. Where automatic valves are used, the thermostats are of the heating-cooling type so that a rise in room temperature opens the valve when cold water is circulated and closes the valve when hot water is being supplied. Thermostat T1 controls the preheater steam valve V1 to maintain a temperature of about 45 F leaving the preheater. Thermostat T2 controls the maximum outdoor-air and return-air dampers so that the air entering the dehumidifier is maintained at 50 F whenever outdoor air conditions permit.

During the heating cycle, thermostat T3 and valve V2 are inoperative so that cool primary air is supplied to the units but at the same time thermostat T5 operates valve V4 so that the secondary water is heated. Thus the combination of cool primary air and hot secondary water can provide heating or cooling as required. The primary pump and water cooler are inoperative.

When the outdoor air is no longer suitable to provide sufficient cooling through the primary air system (typically about 50 F) the system is changed from heating to cooling operation. The primary pump is started and supplies chilled water to the dehumidifier. Thermostat T4 controls mixing valve V3 so as to maintain the secondary water at temperatures in the range of 50 to 55 F. At outdoor temperatures below 80 F thermostat T3 regulates reheater valve V2 so that warm primary air is supplied at the same time that cold

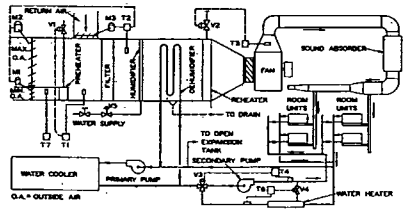

Fig. 6 .... Typical Induction Unit System

secondary water is fed to the units. The changeover from heating to cooling is usually manual and the exact time is not too important because both heating and cooling are available in either case. During the cooling cycle, thermostat T7 acting through thermostat T3 readjusts the primary-air temperature downward as the outdoor-air temperature increases from the changeover point to about 80 F so that above this temperature the primary air is at the apparatus dew point.

In some buildings the primary-air system and water circuits are zoned according to exposure, but because both heating and cooling are available at the units whenever either is needed, such zoning is not always used.

All-Air High-Velocity Systems

All-air high-velocity systems are air-conditioning systems in which the duct velocities and static pressures are such that special control and acoustic equipment is required for proper introduction of the conditioned air into the space to be served.

All-air high-velocity duct systems are of either single-duct or dual-duct types.

The *single-duct system* is usually zone controlled. The single supply temperature is established for each zone and therefore variations in individual rooms must be compensated by throttling the air supply volume. Throttling is limited to the lowest air quantity required for ventilation and for satisfactory air distribution which depends to a large degree on the performance of the type of air outlet used.

Dual-duct systems deliver the entire air supply to cold- and warm-air supply ducts, from which it is distributed into air-mixing valves or acoustic terminal devices. (A mixing valve is a mechanical device that serves to proportion air from a cold-air duct and a warm-air duct into a common outlet, or duct. An acoustic terminal device is an air distribution unit consisting of an air valve, acoustical attenuation chamber, and an air outlet.)

The proportion of cold air and warm air delivered to the air-mixing valves or acoustic terminal device is thermostatically controlled. This control, together with controls for maintaining fixed volumetric delivery, results in a constant volume of air supply at a temperature that satisfies the load.

Mixing valves may be used to deliver large quantities of mixed or blended air at high velocity to a single-duct system equipped with acoustic terminal devices supplying the needs of an entire zone or area. The air coming from the mixing valve may also be reduced in pressure (either in the mixing valve itself or by means of an additional valve or damper) so that it can be distributed by a conventional low-velocity duct system. In this case, noise attenuation is accomplished by a length of lined duct, or by a separate noise attenuator installed after the mixing valve.

For greater flexibility, acoustic terminal devices which usually are equipped with one air outlet only, may discharge into a low-velocity rigid or flexible duct equipped with several air outlets.

Refer to Chapter 21 on Air Duct Design for a discussion of the design of high-velocity ducting.

The general arrangement of a typical dual-duct system is shown in Fig. 7. In some arrangements, two supply-air fans are used with one fan supplying the cold-air duct and the other the hot-air duct. The warm-air fan handles only recirculated air so that operating economy is slightly improved.

The maximum outdoor-air damper and the preheater are controlled as in Fig. 1 so that when the temperature of the

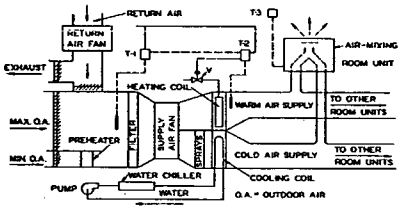

Fig. 7 .... Schematic Arrangement of Dual-Duct System

outdoor air is favorable it is used increasingly instead of return air.

The warm-air supply-duct temperature is controlled by a thermostat, T2, Fig. 7, in the air leaving the heating coil. Thermostat T2 is reset by thermostat T1 in accordance with variations in outdoor-air temperature. Whenever outdoor-air temperature is not low enough to accomplish the required cooling, the cold-air supply-duct temperature is regulated by the cooling coil. The final temperature in the conditioned areas is controlled by the individual air-mixing units.

Air-mixing room units under control of the room thermostat draw warm and cold air from the ducts in accordance with the room requirements, affording individual room control without zoning. Fig. 8 shows schematically one type of room unit designed for dual-duct systems. The warm and cold air pass through the three-way mixing damper which delivers air at the temperature required by the room. Some units are placed under windows, while others are mounted in the ceilings from which air may be delivered to the room through ceiling, wall, or window outlets. Some units are also provided with volume regulators to maintain a steady flow condition.

This system is best suited for multi-room or multi-zone installations, and may be of either high- or low-velocity and high- or low-pressure type with substantially the same control methods. It is often applied to high-velocity systems with long distribution mains, and consequently high-static fan pressures; although extremely high static pressures are seldom justified. With two supply mains, the system static pressures vary as a result of changing demands for heating or cooling. Thus volume regulation often becomes necessary. Extreme variations of flow to different rooms may be somewhat limited by static-pressure regulators and volume dampers at selected points along the mains. There are some installations where volume control at each room supply is desirable to maintain close control regardless of static-pressure changes in the ducts, and incidentally to facilitate balancing of the distribution system.

Air-capacity requirements are generally governed by summer cooling loads, and general practice is to supply the cold air to the cold-air duct at 25 to 30 deg below the established room temperature, this being satisfactory with suitably designed room outlets.

Fan and Coil Units

Another type of room convector used in connection with central cooling and heating plants is known as the *Fan and Coil* Unit (see Fig. 5, Chapter 16).

These units, like induction units, are located around the periphery of a building, usually under windows, and are equipped with fans and a water-type heating-cooling coil. They normally take air for ventilation directly from outdoors, and have a manual damper for adjusting the quantity of outdoor air within certain limits. Positive closing of this damper when the fan stops, can be obtained by adding a damper operator actuated by the fan-motor switch. Hot water supplied during the heating season frequently is varied in accordance with outdoor temperature. Cold water for use during the cooling season should be supplied at a fixed temperature low enough to provide the proper amount of dehumidification.

These units sometimes are used with a primary-air system that supplies the outdoor ventilation air and handles the latent load. In such cases the primary air unit is controlled as explained under the section Unitary-Central Systems, and may be of either the low- or high-pressure type.

The combined heating-cooling coil of each unit may be controlled by a valve in the water supply line to each unit, actuated by a thermostat in the room or recirculated air of the unit. The thermostat is of the heating-cooling type.

EVAPORATIVE COOLING

In climates where, on the hottest days, the outdoor wet-bulb depression is relatively great, it may be possible to replace mechanical refrigeration, or other cooling sources, and use the evaporative cooling effect. A well-designed air washer using recirculating sprays will reduce the entering dry-bulb temperature to within a degree or two of the entering wet-bulb condition. Thus, it may be possible that, with air entering at 100 F dry-bulb, 60 F wet-bulb, a leaving condition of 62 F dry-bulb, nearly saturated, can be obtained. Under some conditions of latent and sensible heat load, this evaporative cooling may be adequate.

At times when the outdoor wet-bulb temperature is not low enough to permit the use of straight evaporative cooling, it is still possible to use precooling convectors with refrigeration, well water, or a cooling tower, as the basic source of sensible heat removal to reduce the wet-bulb temperature of the air before it enters the spray chamber. Where internal heat loads are high, this scheme may be more economical than one using return air. Where the required supply-air dew point is too low to permit straight evaporative cooling, and where the sensible heat load is not too great, intentional partial saturation may be employed. In this case the low dew point of the outdoor air is utilized by permitting some of this air to pass through the humidifying sprays untreated, or to bypass the humidifier. All of these

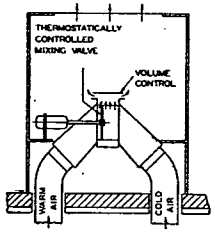

Fig. 8 .... Room Air-Mixing Unit for Dual-Duct System

remarks with regard to evaporative cooling are based on the assumption that all of the supply air will be taken from outdoors. Provision should be made in most cases for the return of some air from the conditioned spaces for control purposes, as well as for economy of fuel in winter.

PRECOOLING

Where sufficiently cold water from wells or streams is available, a saving in refrigeration may be obtained by the use, in location ahead of the dehumidifier, of precooling coils through which the cold water is circulated. The resultant cooling of the air decreases the load to be carried by the dehumidifier and refrigeration plant. In normal practice the water, after passing through the precooling coils, may be further utilized in the refrigeration plant condenser. The economic advantages of this scheme are apparent, and it is frequently used.

SENSIBLE COOLING WITH UNWETTED COILS

Under favorable atmospheric conditions where a large wet-bulb depression exists and the dew point of the outdoor air is sufficiently low at all times, acceptable cooling may be obtained by removing only the sensible heat from the outdoor air delivered to the rooms. Under this condition of a great wet-bulb depression, a temperature-reducing coil may be located in the air stream and supplied with water from a cooling tower. When humidity control is desired, sprays to saturate or partially saturate the air may be used downstream from the unwetted coil. Saturation or partial saturation after the coil will reduce further the dry-bulb temperature and the air quantity required. This system has very definite application in hot dry climates.

SELECTION OF TYPE OF SYSTEM

Low buildings with large floor areas may be divided into sections or zones with separate central air-supply systems to facilitate temperature control. In the case of large department stores it may be possible to provide a single conditioner, with a fan delivering the conditioned air to local mixing fans which supply the various departments or spaces. This application is limited by the practicability of running the large conditioned-air ducts to the various recirculating fans. Each vertical section of the building also may be supplied by a separate fan delivering conditioned air to local mixing fans. In many cases the most economical and satisfactory scheme may be to employ a hot water or steam reheater in each branch duct. Where vertical sectionalizing is not indicated, the building may be divided into horizontal groups, each handled by a central system and adequately zoned. In some large buildings, apparatus rooms for the systems may be located in the basement and attic and on intermediate floors.

In high buildings the necessity for horizontal sectionalizing may be suggested by the size of air-supply and return risers, and by the extent to which they encroach upon usable space. Each story should be cut off by doors from other stories, as otherwise the cool air tends to collect in the lower story and the warm air is forced to the upper story.

Balconies and large lobbies in theaters and similar high rooms frequently justify the use of separate zoning fans, to counteract the tendency of the heavier, cooler air to collect at the lower levels of these spaces.

Fans operate at full capacity continuously in many systems, and therefore should be selected for good efficiencies. In winter when higher temperature differentials are used, it is sometimes practicable to deliver smaller air quantities than when cooling.

In climates where winter temperatures fall below freezing, the tempering coils should be of the steam-distributing type; or if they are heated by a liquid, this liquid should contain some antifreezing substance such as ethylene glycol. If hot water is used in cold climates, the control of air temperature should be obtained by means of face and bypass dampers rather than by throttling the valves, to prevent damage due to freezing.

If zone reheaters placed in supply-duct branches are employed, they should be of such type as to be heated over the entire surface so that no temperature stratification can occur in the delivered air. Steam-distributing-tube coils or mechanically-circulated water coils are satisfactory in such cases, and throttling valves may be used.

Refrigeration equipment must be carefully selected to satisfy the particular requirements of each installation. For some small plants the evaporator may be placed in the air stream, when type of refrigerant and nature of occupancy permit. In many cases, chilled water coils are required by considerations of safety. Where low temperature and relative humidity are necessary, brine, often of calcium chloride, may be indicated.

Condensing requirements must have economic analysis. Wells, public water service, cooling towers, and evaporative condensers present possibilities for consideration. Condenser water may have a secondary use for roof sprays in hot weather, and is usually suitable for lawn sprinkling. Most health department rules in cities prohibit any connection from refrigerant condensers that might permit the water to be used for drinking or lavatory purposes.

Practically without exception, air cleaners should be provided for both outdoor and recirculated air.

Control of temperature and of relative humidity by automatic means is vital, if comfort and economical operation of air-conditioning equipment are to be attained.

The insulation of ductwork may be necessary to prevent condensation of moisture either inside or outside of ducts, housings, and fan encasements or to prevent a change of temperature in ducts passing through hot or cold spaces.

In general, the apparatus should be arranged to have a straight-line air flow. Each change in direction increases air resistance and, in addition, elbows and offsets may cause eddy currents resulting in stratification. The usual order of equipment location, beginning at the outdoor-air intake, is: weather hood or louvers, outdoor-air dampers, return-air connection, filters, tempering coils, cooling coils or sprays, bypass connection with or without preheaters, reheaters, fan and distributing ducts.

Screens at the intake prevent the entry of large foreign matter, birds, etc. A hood or louver at the outdoor-air intake prevents the entry of rain and snow. Since in most climates there are many days during which use of 100 percent outdoor air unheated or uncooled may be economical, the areas of all air-passing and treating apparatus should be large enough for such a volume, and the exhaust or spent-air equipment should be capable of discharging out of doors all of the air admitted.

The bypass connection normally connects the return-air duct system with the apparatus casing between the conditioner and the supply fan. Usually the bypass opening is sized to handle about 50 percent of the fan capacity where a variable bypass is used though extreme load variations

may require a larger size. It is at times good design to locate a reheating coil in the bypass connection to permit using some bypass air when heating is required. Since the relatively high resistance of the cooling coil or spray is to be balanced by the heating coil and bypass connection, enough heating surface can be provided to raise the temperature of the bypass air to the point where the mixture of bypassed air and conditioned air will have the required temperature. When a variable bypass is used, a damper working in opposition to the bypass damper should be placed across the face of the dehumidifier, for unless the resistances of the two are carefully balanced at all operating points, the proper mixtures of air will not be obtained. Outdoor air that has not been dehumidified should not be bypassed around a cooling coil or spray dehumidifier if accurate control of the delivered relative humidity is desired. Where the bypass is made a part of the dehumidifier or conditioner and is located on the top or side of it, the return-air connection should be arranged so that stratification of return air is insured, baffles being provided to accomplish this purpose if necessary. When return-air and bypass air connections are taken off a return-duct system, it may be necessary to install a back-draft damper between the return-air connection and the bypass connection. When the bypass damper is at maximum opening it may be much easier for outdoor air to pass through the return damper, into the return-duct connection and through the bypass, than for return air to pass through the bypass connection into the fan. Air tends to take the path of least resistance and, if the dehumidifier resistance is high, and if the return duct resistances are low, this situation is apt to occur. A recirculating air fan, instead of a back-draft damper, may be required for this case, if the failure of return air to reach the dehumidifier or conditioner is a serious matter under reduced load conditions.

LOCATION OF APPARATUS

In general, the outdoor-air intake, preheaters, and return-air connections precede the conditioner, while the bypass, reheaters, and fan follow it. In the case of a blow-through system, where the fan is located ahead of the conditioner, the leakage of air at the conditioner is outward, instead of inward, and may be accompanied by water leakage.

The location of the complete apparatus assembly, including the dehumidifier, will be dependent on the type of building, spaces available, structural characteristics, etc. The type of conditioner used may limit the location under certain conditions. Where cooling coils employing chilled water or brine as the cooling agent are used, there are few limitations with regard to location other than those of pumping power, working pressures, piping costs, etc. Where spray dehumidifiers are used, very definite limitations present themselves, and these may require certain extraneous equipment to make the system workable. If several spray-type dehumidifiers are located on different levels, thus involving different water pressures, a surge or storage tank, to which the return water from each dehumidifier can be taken, is required. Should the water level in the pan of the dehumidifiers be low in relation to that of the surge tank, return-water pumps will be required, and these pumps will have to be operated until the water supply lines are drained in order to prevent flooding of the lower dehumidifiers. Where spray dehumidifiers are on the same level, equalizing lines between the pans may be required if a storage tank is not provided. It is exceedingly important that watertight drained floors be provided under all overhead cooling systems, since water condensed out of the air generally will be present and may damage the interior finish of the rooms below the apparatus.

All of the various pieces of equipment from the outdoor-air intake through the fan usually are connected together by sheet-metal casings. Frequently, the building structure or specially constructed walls or partitions may be used to form a portion of the casing. In any case the casing or connection must be sufficiently sturdy for the required duty. Sheet-metal work must be well braced not only to prevent vibration under pulsations in air flow, but also to withstand the abuse of normal usage. Casings should be braced wherever access doors are installed, and all large panels should be adequately reinforced by structural steel.

Accessibility for Service

Each apparatus layout should be made with accessibility in mind. Where cooling convectors are used, space for removing and repairing or replacing them should be provided. Adequate space should be provided for the servicing and replacement of eliminators. Filters must be so located that the proper cleaning, replacement, or routine servicing can be accomplished without difficulty. Free access to the bearings of all moving machinery is a necessity. Provision should be made for the replacement of any parts that are subject to wear, deterioration, or damage, such as filters, fanwheels, motors, pump impellers, or heat transfer surface.

CHAPTER 20

AIR DISTRIBUTION

Definitions, Standards for Satisfactory Conditions, Principles of Air Distribution Ventilating Jets in Air Distribution, Outlet Performance, Outlet Types, Outlet Location and Selection, Directional and Volume Control, Return and Exhaust Intakes, Specific Applications.

CORRECT air distribution is essential in warm air heating, ventilating, and air-conditioning systems. Even though a system delivers the required quantity of conditioned air to a room, unsatisfactory conditions result if the air is poorly distributed.

This chapter deals with room air distribution only; the transmission of air through ducts is treated in Chapter 21, Air Duct Design. The objectives of this chapter are to:

1. Present the principles of room air distribution with a discussion of ventilating jets in air distribution.
2. Present general information on practical air distribution problems involving outlet performance, outlet types, location, selection, and outlet control.
3. Illustrate the use of the basic concepts and of the practical experience gained in air distribution in making specific applications.

Further pertinent information on air distribution will be found in Chapter 6, Physiological Principles; Chapter 12, Heating Load; Chapter 13, Cooling Load; Chapter 15, Unit Ventilators and Unit Heaters; Chapter 16, Unitary Air Conditioning Equipment; Chapter 18, Warm Air Heating Systems; Chapter 19, Central Systems for Air Conditioning; Chapter 25, Sound Control; Chapter 44, Instruments and Measurements; Chapter 48, Transportation Air Conditioning.

DEFINITIONS

The following definitions referring to air distribution equipment have gained general acceptance.

1. *Supply Opening or Outlet:* Any opening through which air is delivered into a space which is being heated, cooled, humidified, dehumidified, or ventilated.
2. *Exhaust Opening or Return:* Any opening through which air is removed from a space which is being heated, cooled, humidified, dehumidified, or ventilated.
3. *Outdoor Air Opening:* Any opening used as an entry for air from outdoors.
4. *Damper:* A device used to vary the volume of air passing through a confined cross-section by varying the cross-sectional area.
5. *Grille:* A covering for any opening and through which air passes.
6. *Register:* A grille equipped with a damper or control valve.
7. *Free Area:* The total minimum area of the openings in the air outlet or inlet through which air can pass.
8. *Core Area:* The total plane area of that portion of a grille, included within lines tangent to the outer edges of the outer openings through which air can pass.
9. *Free Area Ratio:* The ratio of the free area to the core area.
10. *Coefficient of Discharge:* Ratio of area at vena contracta to area of opening.
11. *Aspect Ratio:* The ratio of length to width of an opening or core of a grille.
12. *Vane Ratio:* The ratio of depth of vane to minimum width between two adjacent vanes.
13. *Plaque:* A ceiling outlet in which the supply air impinges against a plate or series of parallel plates, and is deflected horizontally in all directions.
14. *Diffuser:* An outlet discharging supply air in various directions and planes.
15. *Primary Air:* The air delivered to the outlet by the supply duct.
16. *Induction:* The induction of room air drawn into an outlet by the primary air stream (commonly called *aspiration*).
17. *Entrainment:* The entrainment of room air by the air stream discharged from the outlet (commonly called *secondary air motion*).
18. *Total Air:* The mixture of discharged air and entrained air.
19. *Entrainment Ratio:* The total air divided by the discharged air.
20. *Throw (Blow):* The horizontal or vertical axial distance an air stream travels on leaving the outlet (grille) before the maximum velocity is reduced to 50 fpm.
21. *Drop:* The vertical distance, the lower edge of a horizontally projected air stream drops between the outlet and the end of its throw.
22. *Rise:* The converse of drop.
23. *Envelope:* The outer boundary of an air stream moving at a perceptible velocity.
24. *Spread:* The divergence of the air stream in a horizontal or vertical plane after it leaves the outlet.
25. *Diffusion:* Distribution of air within a space by an outlet discharging supply air in various directions and planes.
26. *Radius of Diffusion:* The horizontal distance from the diffuser outlet to the perimeter of the space, within which air motion in the occupied zone is reduced to 50 fpm maximum.
27. *Outlet Velocity:* The average velocity of air emerging from the outlet, measured in the plane of the opening.
28. *Terminal Velocity:* The average air stream velocity at the end of the throw.
29. *Temperature Differential:* Temperature difference between primary and room air.
30. *Temperature Variation:* Temperature difference between points of the same space.

STANDARDS FOR SATISFACTORY CONDITIONS

The object of air distribution in warm air heating, ventilating, and air-conditioning systems is to create in the occupied zone of the conditioned room (floor to 6 ft above floor level) the proper combination of temperature, humidity, and air motion. To obtain comfort conditions within this zone, standard limits have been established as acceptable *effective temperatures*. This term comprises air temperature, motion, humidity, and their physiological effect on the surface of the human body. Any variation from accepted standards of one of these elements may result in discomfort to the occupants. The same effect may be caused by lack of uniformity of conditions within the space or by excessive fluctuation of conditions in the same part of the space. Such discomfort may

arise due to excessive room air temperature variations (horizontally, vertically, or both), excessive air motion (draft), failure to deliver or distribute the air according to the load requirements at the different locations, or too rapid fluctuation of room temperature or air motion (gusts).

With reference to permissible room air motion it is not possible to establish a specific standard covering the entire complex problem of air distribution. Velocities less than 15 fpm generally cause a feeling of air stagnation, whereas velocities higher than 65 fpm may result in a sensation of draft. Air velocities of 25 to 35 fpm in the occupied zone are most satisfactory, but air motion of 20 to 50 fpm will usually be acceptable, with the lower values used in cooling applications, and the higher values in heating applications. The permissible air motion depends to some degree on the geographic location of the air-conditioning installation. In addition the noise level created by the introduction of supply air should be kept within acceptable limits, and streaking or smudging of walls or ceilings should be prevented.

Reference should be made to Chapter 6, Physiological Principles, for information on effective temperature and comfort lines, and to Chapter 25, Sound Control, for acceptable room noise levels and noise generated by air outlets. Material in Chapter 51, Control of the Industrial Environment, and Chapter 50, Process and Product Air Conditioning, deals with the health, safety, and efficiency of workers, and with temperature and humidity requirements for products and manufacturing processes, respectively.

PRINCIPLES OF AIR DISTRIBUTION

Conditioned air is supplied to air outlets at temperatures and velocities which differ greatly from those in the occupied zone of the room. Proper air distribution, therefore, calls for (1) entrainment of room air by the primary air stream outside of the zone of occupancy in order that air motion and temperature differences will be reduced to acceptable limits before the air enters the occupied zone, and (2) counteraction of the natural convection and radiation effects within the room.

The complexity of practical room air distribution problems is due to innumerable variations in building construction, system design, and operating requirements, and makes the exploration of the basic character of air distribution imperative. The theory of room air distribution is not complete but a considerable fund of knowledge supported by experimental guidance is available for the solution of many air distribution problems. In particular, research at the ASHAE Research Laboratory and at Case Institute of Technology have advanced considerably the fundamental knowledge on ventilating jets in air distribution. Also, a comprehensive survey of the literature relevant to air distribution problems was made at the ASHAE Research Laboratory and is an indispensable and timesaving tool for every researcher in air distribution. (Refer to Bibliography: ASHAE Research Laboratory.)

The cooperative research program in air distribution at Case Institute of Technology was started in 1937. The early research dealt with methods of measurements and the available instruments; next the basic flow patterns of free round and rectangular jets in an open space were studied. A third phase was concerned with diffusion rates and characteristics of free jets from the more complex types of outlets, such as grilles with guide vanes, narrow slots, perforated panels, plaques, and round ceiling diffusers. The latest phase has dealt with air movement produced by non-isothermal jets, especially in confined spaces, and has included experimental work in cold-wall rooms during heating and warm-wall rooms during cooling. (Refer to Bibliography: Cooperative Research at Case Institute of Technology.)

VENTILATING JETS IN AIR DISTRIBUTION

A surprising similarity between the shape of jets exists at a short distance from the outlet face, whether the outlet is round, rectangular, grille-like, or a perforated panel. The jet discharged from a round opening forms an expanding cone, whereas jets from rectangular outlets rapidly pass from rectangular to elliptical cross-sectional shape at a short distance from the outlet face, and then to circular shape, at a rate depending primarily on the aspect ratio. Even in the case of wide-angle grilles and angular outlets, the similarities are such as to permit the same analysis of performance.

For many conditions of jet discharge, therefore, it is possible to analyze jet performance, and to determine (1) the angle of divergence of the jet boundary, (2) the velocity patterns along the jet axis, (3) the velocity profile at any cross-section in the zone of maximum engineering importance, and (4) the entrainment ratios in the same zone.[1]

In using the data presented in this section, however, the following must be kept in mind:

1. The method of finding jet velocities is based upon several approximations and, therefore, the two recommended equations must be used with caution for extreme axial and radial distances.
2. The characteristics of the low-velocity regions of ventilating jets are not yet well understood. Neither for axial nor radial jets are the effects at various Reynolds number fully known.
3. The quantitative treatment of the forces that govern room air distribution problems has been limited, and non-isothermal conditions involving buoyant forces have not yet been fully explored.

For equations describing the performance of non-isothermal jets resulting from the air distribution research at Case Institute of Technology see References 2 and 3. (Refer also to Bibliography: ASHAE Cooperative Research at Kansas State College.)

4. Most investigations have been concerned with *free* jets, whereas air streams in practical room air distribution are not free streams but are influenced by walls, ceilings, floors, and obstructions. (Refer to sections on Effect of Walls and Ceilings and Room Air Motion.)

Angle of Divergence

The angle of divergence is very definite close to the outlet face, but the boundary contours are somewhat billowy and are easily affected by external influences. Here, as in air distribution generally, room air movement is replete with local eddies, vortices, and surges, which are manifestations of unbalance in the forces acting within the air stream. These internal forces govern the air motion, yet they are extremely delicate.[4]

Measured angles of divergence (spread) for discharge into large open spaces have usually ranged from 20 to 24 deg with an average of 22 deg. Coalescing jets for closely spaced multiple outlets expand at somewhat smaller angles, averaging 18 deg, and jets discharging into relatively small spaces show even smaller angles of expansion.[5] Tests indicate that in cases where the outlet area itself is small compared to the dimensions of the space normal to the jet, the jet may be considered free as long as

$$X \leq 1.5\sqrt{A_R}$$

where

X = distance from face of outlet, feet.
A_R = cross-sectional area of the confined space, square feet.

Four Zones in Jet Expansion

In analyzing the performance of jets, four major zones can be distinguished. They may be roughly defined in terms of the maximum or centerline velocity existing at the cross-section being considered:

Zone 1: A short zone, extending about 4 diameters or widths from the outlet face (or vena contracta for orifice discharge), in which the maximum velocity of the air stream remains practically unchanged.

Zone 2: A transition zone, extending to about 8 diameters for round outlets, or for rectangular outlets of small aspect ratio, over most of which maximum velocities vary inversely as the square root of the distance from the outlet. For rectangular outlets of large aspect ratio, this zone is elongated and extends from about 4 widths to a distance approximately equal to the width multiplied by four times the aspect ratio.

Zone 3: A long zone, of major engineering importance, in which the maximum velocity varies inversely as the distance from the outlet. This zone is often called the zone of fully *established turbulent flow* and may be 25 to 100 diameters long (or equivalent diameters of equal areas), depending on the shape and area of the outlet, the initial velocity, and the dimensions of the space into which the outlet discharges.

Zone 4: A terminal zone in which, in the case of confined spaces, the maximum velocity decreases at an increasing rate, or, in the case of large spaces free from wall effects, the maximum velocity decreases rapidly in a few diameters to the velocity range below 50 fpm which is usually regarded as *still air*.

Centerline Velocity in Zone 3

Research has shown that maximum or centerline velocities in Zone 3 of straight flow isothermal jets can be determined with good engineering accuracy from

$$\frac{V_x}{V_o} = \frac{KD_o}{X} = \frac{K'\sqrt{A_o}}{X} \qquad (1)$$

$$V_x = \frac{K'V_o\sqrt{A_o}}{X} = \frac{K'Q}{X\sqrt{A_o}} \qquad (2)$$

$$= \frac{K'Q}{X\sqrt{A_c \times C_d \times R_{fo}}} \qquad (2a)$$

Table 1. . . . Recommended Values of the Centerline Velocity Constant K or K'
(See Equation 1)

Type of Outlet	K		K'	
	V_o = 500 to 1000	V_o = 2000 to 10,000	V_o = 500 to 1000	V_o = 2000 to 10,000
Free Openings				
Round or Square	5.0	6.2	5.7	7.0
Rectangular, large aspect ratio (<40)	4.3	5.3	4.9	6.0
Annular slots axial or radial[a]	—	—	3.9	4.8
Grilles and Grids				
Free area 40% or more	4.1	5.0	4.7	5.7
Perforated Panels				
Free area 3 to 5%	2.7	3.3	3.0	3.7
Free area 10 to 20%	3.5	4.3	4.0	4.9

[a] For radial slots use X/H instead of $X/(A)^{1/2}$. H is the height or width of the slot.

Note: K and K' are indexes of loss in axial kinetic energy. Interpolate as required. Departures from maximum value indicate losses in first and second zones when compared with the jet from a rounded-entrance, circular nozzle.

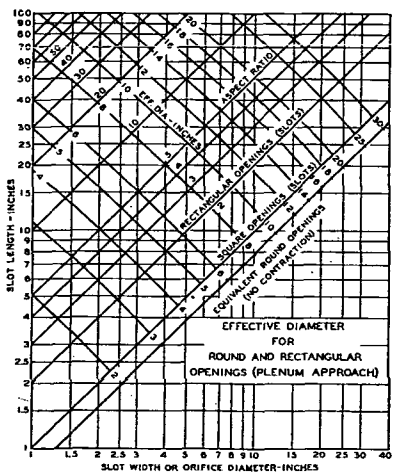

Fig. 1. . . . Effective Diameters for Round and Rectangular Openings (Plenum Approach)

where

V_x = centerline velocity, feet per minute.
$V_o = \frac{V_c}{C_d \times R_{fo}}$ = average initial velocity at discharge from open-end duct or across contracted stream at vena contracta of orifice or multiple-opening outlet, feet per minute.
V_c = nominal velocity of discharge based on the core area, feet per minute.
C_d = coefficient of discharge (usually between 0.65 and 0.90).
R_{fo} = ratio of free area to gross (core) area.
X = distance from face of outlet, feet.
K and K' = porportionality constants, with $K' = 1.13\ K$.
D_o = effective or equivalent diameter of stream at discharge from open-end duct or at a contracted section, feet.
$A_o = A_c \times C_d \times R_{fo}$ = effective area of stream at discharge from an open-end duct or at a contracted section, square feet.
A_c = measured gross (core) area of outlet, square feet.
Q = discharge from outlet, cubic feet per minute.

Equation 1 is nondimensional and requires only that consistent units be used, as in the above nomenclature. Values of K and K' are listed in Table 1.[1, 6]

Low velocity test results, in the range $V_x < 150$ fpm, indicate that the normal values of K and K' should be reduced about 20 percent for $V_x = 50$ fpm, as used in later Equation 4b for throw. Fig. 1 gives the effective diameter D_o in inches for single openings and includes the coefficient of discharge.[7] Similar values for grilles are available in the literature or can

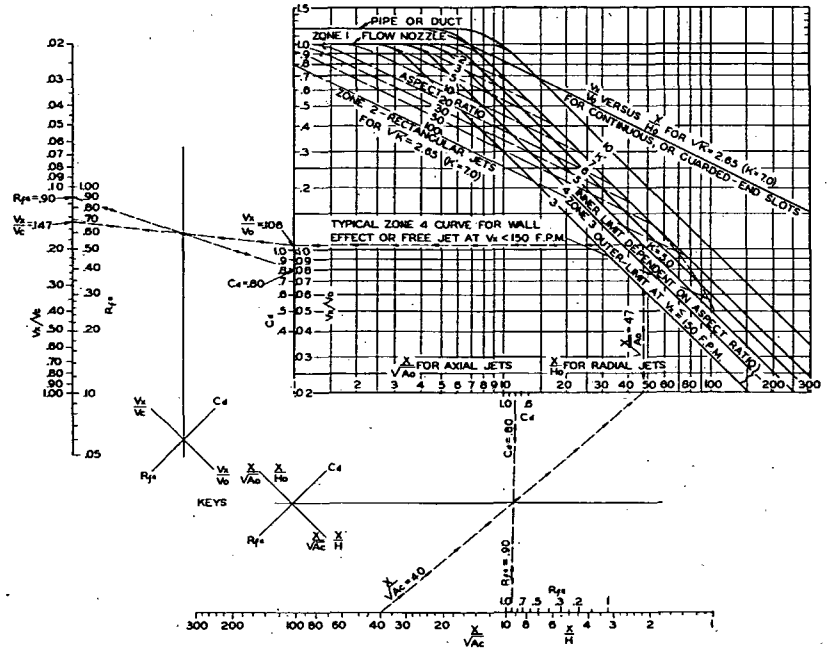

Fig. 2. . . . Chart for Determining Centerline Velocities of Axial and Radial Jets

be experimentally determined. Values of C_d and R_{fe} are required for determining V_0, D_0, and A_0 for orifice-type and multiple-opening outlets, and should, therefore, be included in catalog data of these outlets.

In the case of multiple-opening outlets and annular-ring outlets, the streams coalesce into a solid jet before actual jet expansion takes place. This coalescence affects the experimentally determined proportionality constants K or K' and accounts for some of the divergence in reported values for similar outlets.

Centerline Velocities in Zones 1 and 2

Experimental evidence indicates that in Zone 2

$$\frac{V_x}{V_0} = \sqrt{\frac{K'H_0}{X}} \qquad (3)$$

where

H_0 = width of jet at outlet or at vena contracta.

Approximately the same values of K' apply as for Zone 3 expansion from axial outlets.

In Zone 1, the ratio V_x/V_0 is constant and equal to the ratio of the center velocity of the jet at start of expansion to the average velocity, ranging from approximately 1.0 for rounded-entrance nozzles to about 1.2 for straight pipe discharge, but with much higher values for diverging-discharge outlets.

Determining Centerline Velocities

To permit correlation of data from all four zones, centerline velocity ratios are plotted against distance from outlet in Fig. 2 in accordance with the basic relation of Equation 2, and a nomogram for calculating the parameters

$$\frac{X}{A_0} \quad \text{and} \quad \frac{V_x}{V_c} \quad \text{from} \quad \frac{X}{\sqrt{A_c}} \quad \text{and} \quad \frac{V_x}{V_0}$$

through R_{fe} and C_d is given in the same illustration.

The variation of the centerline velocity ratio with distance from outlet, or more properly, from start of jet expansion, is also shown on Fig. 2 for Zones 1 and 2. V_x/V_0 is plotted against X/H_0 and, for a range of aspect ratios, against $X/\sqrt{A}$ for the single value of $K' = 7.0$. Values of V_x/V_0 for other values of K' may be obtained by direct proportioning of $\sqrt{K'}$ to $\sqrt{7.0}$.

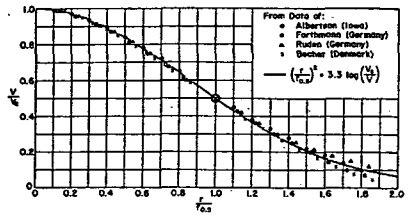

Fig. 3. . . . Cross-Sectional Velocity Profiles for Straightflow Turbulent Jets

The following *Example 1* which is solved on Fig. 2 will illustrate the use of the chart.

Example 1: A grille has a core area 12 in. x 18.75 in., $R_{fe} = 0.90$, $C_d = 0.80$, and $K' = 5.0$. Find V_x (velocity through core area) when V_x is 50 fpm for throw of 50 feet ($X = 50$).

Solution:

$$A_c = \frac{12 \times 18.75}{144} = 1.56 \text{ sq ft}$$

$$\frac{X}{\sqrt{A_c}} = \frac{50}{1.25} = 40$$

$$A_0 = 1.56 \times 0.80 \times 0.90 = 1.123$$

$$\frac{X}{\sqrt{A_0}} = \frac{50}{1.06} = 47.2$$

$$\frac{V_x}{V_0} = \frac{K'\sqrt{A_0}}{X} = \frac{5\sqrt{1.123}}{50} = 0.106$$

$$\frac{V_x}{V_c} = \frac{V_x}{V_0(C_d R_{fe})} = \frac{0.106}{0.80 \times 0.90} = 0.147$$

For $V_x = 50$,

$$V_c = \frac{50}{0.147} = 340 \text{ fpm.}$$

The quantity of air discharged is then,

$$Q = V_c A_c = 340 \times 1.56 = 530 \text{ cfm.}$$

Throw

Equation 2a can be used to determine the *throw* X of an outlet, if the discharge volume and the center velocity are known.

$$X = \frac{K'}{V_x} \cdot \frac{Q}{\sqrt{A_c \times C_d \times R_{fe}}} \qquad (4)$$

or, if

$$Z = \sqrt{C_d \times R_{fe}}$$

$$X = \frac{K'}{V_x} \cdot \frac{Q}{Z\sqrt{A_c}} \qquad (4a)$$

The maximum throw L is usually defined as the distance from the outlet face where the centerline velocity is 50 fpm. Therefore, for $V_x = 50$ fpm,

$$L = X = \frac{K'}{50} \cdot \frac{Q}{Z\sqrt{A_c}} \qquad (4b)$$

Velocity Profiles of Jets

In Zone 3 of both axial and radial jets, the velocity distribution may be expressed by a single curve (Fig. 3) in terms of dimensionless coordinates, and this same curve can be used as a good approximation for adjacent portions of Zones 2 and 4. Experiments have shown that temperature and density differences have but a small effect on cross-sectional velocity profiles.

Velocity distribution in Zone 3 can be expressed by the Gauss error-function or probability curve which is approximated by a simple equation using common logarithms

$$\left(\frac{r}{r_{0.5}}\right)^2 = 3.3 \log \frac{V_x}{V} \qquad (5)$$

where

r = the radial distance of the point under consideration from the centerline of the jet.

$r_{0.5}$ = the radial distance in the same cross-sectional plane from the axis to the point where the velocity is half the centerline velocity. ($V = 0.5\ V_x$.)

V_x = the centerline velocity in the same cross-sectional plane, feet per minute.

V = the actual velocity at the point being considered, feet per minute.

Experiments show that the conical angle for $0.5\ V_x$ and $r_{0.5}$ is approximately one-half of the total angle of divergence of a jet. The velocity profile curve for one-half of a straight-flow turbulent jet (the other half being a symmetrical duplicate) is shown in Fig. 3. For multiple-opening outlets, such as grilles, or perforated panels, the velocity profiles are similar, but the angles of divergence are smaller.

Radial Jets

In the radial jet the cross-sectional area at any distance from the outlet varies as the square of this distance, the same as for an axial jet. Experiments have shown that the centerline velocity gradients and the cross-sectional velocity profiles are similar to those of Zone 3 of axial jets and that the angles of divergence are about the same. In using Fig. 2, X/H should be used as abscissa instead of $X/\sqrt{A}$.

Jets from ceiling plaques have the same form as one-half of a free radial jet. The jet is wider and longer than a free jet, with the maximum velocity close to the wall. This is demonstrated in Fig. 4 which also indicates that under the conditions shown the width of the slot between ceiling and plaque has

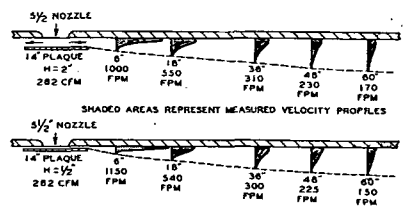

Fig. 4. . . . Air Jets from a 14-in. Ceiling Plaque for Two Slot Widths with Same Rate of Flow

little effect on the jet pattern or velocities at some distance from the plaque.[1]

For a basic equation for radial flow outlets resulting from the air distribution research at Case Institute of Technology see Jet Velocities from Radial Flow Outlets, by Alfred Koestel (ASHAE TRANSACTIONS, Vol. 63, 1957, p. 505).

Discharge from a Long Slot

When a long slot receives its air supply from one end only, the important design factor is the ratio of the area of the slot to the area of the supply duct, and both the air stream profiles and the duct pressure requirements are determined by this ratio.[8] Fig. 5 shows the changing profile as the slot area is increased for a rounded entrance slot (C_d = 0.93) with constant duct cross-section.

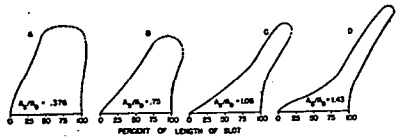

Fig. 5.... Shape of Air-Stream Envelopes as Slot Area is Increased

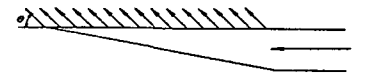

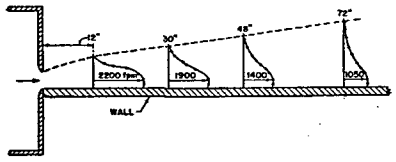

Fig. 6.... Uniform Air Flow from a Slot Supplied by a Tapered Duct

(V_o = 2260, A = 0.10, C_d = 0.78)

Fig. 7.... Jet Velocity Patterns for a Square Outlet Discharging along Wall or Ceiling

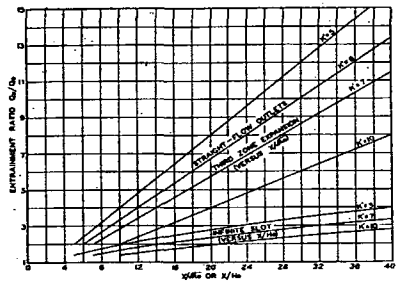

Fig. 8.... Entrainment Ratios for Straight-Flow Outlets

The air discharge from a slot in a tapered duct will be uniform (Fig. 6) for a relationship between discharge angle and slot-duct dimensions[8]

$$\cot \theta = \frac{A_s C_d}{A_d} \tag{6}$$

where

θ = discharge angle, degrees.
A_s = slot area, square feet.
A_d = duct cross-sectional area at upstream end, square feet.
C_d = coefficient of discharge.

Perforated Panels

When air is discharged from perforated panels of relatively large sizes the constant velocity core formed by the coalescence of the individual jets extends a considerable distance from the panel face. In this Zone 1 region the proportionality constants K and K' do not apply. Therefore, the proportionality constants given in Table 1 should be used only when the ratio (Distance from panel/$\sqrt{\text{Panel area}}$) is larger than 5. When the ratio is less than 5, the equation

$$V_x = V_o \cdot 1.2\sqrt{C_d \times R_f} \tag{7}$$

should be used for estimating centerline velocities.[12]

Effect of Walls and Ceilings

Jets discharging parallel to a wall with one edge of the outlet coinciding with the wall, take the form of one-half of an axial jet discharging from an outlet twice as large, similar to radial jets from ceiling plaques. Entrainment takes place practically only along the surface of a half cone and the maximum velocity remains close to the wall.[1] (See Fig. 7.) Values of K and K' are approximately those for a free jet multiplied by $\sqrt{2}$, that is to say, the normal maximum of 7.0 for K' for free jets becomes 9.9 for a similar jet adjacent to, and discharged parallel to, a wall, and in Fig. 2, $\frac{X}{\sqrt{2A_o}}$ should be used in place of $\frac{X}{\sqrt{A_o}}$

When a jet is discharged parallel to, but at some distance from a wall, its expansion in the direction of the wall is reduced and entrained air must be obtained by recirculation from the jet itself instead of from ambient air.[8, 11] The jet expands normally to within a short distance from the wall, which nearer to the outlet only affects velocity distribution in the outer shell of the jet, but further on also affects centerline velocities. This happens at some distance from a plane where the jet outline becomes parallel to the wall, and where the jet enters its fourth or terminal zone. Few engineering data are available on this important phase of jet expansion.[8]

Effect of Resistance on Return Path of Jet Air

Laboratory experiments on jets usually involve recirculated air with negligible resistance to flow on the return path of the jet air. Experience and experiments in tunnels of small cross-sectional area in mines, where considerable resistance is offered to the return flow of jet air to outlets, show that the expansion of the jet terminates abruptly at a distance that is independent of velocity of discharge and but slightly affected by size of outlet. Such distances are determined primarily by size and

length of return path. In a long 5 ft x 6 ft tunnel, a jet may not travel more than 25 ft whereas in a relatively short opening, 25 by 60 ft, it may travel more than 250 ft. Few engineering data are available on this phase of jet expansion but it can be of great practical importance.[8]

Entrainment Ratios

Equations for the entrainment of circular jets and of jets from long slots have been mathematically derived.[12] They are:

For third zone expansion of circular jets,

$$\frac{Q_x}{Q_o} = \frac{2}{K'} \cdot \frac{X}{\sqrt{A_o}} \tag{8}$$

For a long slot

$$\frac{Q_x}{Q_o} = \sqrt{\frac{2}{K'}} \cdot \sqrt{\frac{X}{H_o}} \tag{8a}$$

where

Q_x = total volume flow rate at distance X from face of outlet, cubic feet per minute.
Q_o = discharge from outlet, cubic feet per minute.
X = distance from face of outlet, feet.
K' = proportionality constant.
A_o = effective area of stream at discharge from an open-end duct or at a contracted section, square feet.
H_o = width of slot, feet.

Equations 8 and 8a have been used in plotting Fig. 8 for entrainment ratios.

OUTLET PERFORMANCE

The air distribution research sponsored by the AMERICAN SOCIETY OF HEATING AND AIR-CONDITIONING ENGINEERS has proved that the phenomena of room distribution are amenable to scientific research and rational interpretation, and has now reached a stage where a definite technique of experimentation in combination with semi-empirical theories can be of great help in the design of air outlets.

Practical room air distribution, however, is still predominantly an art, where decisions depend on isolated tests and judgments must be based on the accumulated experience of the behavior of outlets in the laboratory and in the field. Manufacturers' literature is available to provide data for the performance and application of various outlets. In designing a satisfactory air distribution system, the engineer must make use of this material, and weigh the different factors of the outlet performance which place considerable limitations on his proceedings. A short discussion follows regarding some of these factors which are: (1) jet pattern, (2) capacity, (3) temperature differential, (4) room air motion, (5) permissible noise level, and (6) smudging.

Jet Pattern

Refer to section Ventilating Jets in Air Distribution for a general discussion of the jet pattern. In selecting the *throw* and *drop* of outlets the following considerations are important: (1) throw, (2) effect of vanes, (3) effect of type of outlet, and (4) drop.

1. *Throw.* The throw of a wall outlet must be sufficient to produce satisfactory conditions over the area to be conditioned. Underblowing may cause heated air to rise too rapidly above the occupied zone and thus create excessive vertical temperature variation (stratification); in cooling operation it may cause cold air to drop into the occupied zone before supply and room air are mixed sufficiently, and thereby create a condition of acute discomfort (draft). On the other hand, overblowing will result in objectionable downdrafts from any surface the primary air stream may strike.

On the average, it is considered most practicable to select a throw which is three-fourths of the distance toward an exposed wall or window, as shown in diagram A of Fig. 9. However, structural characteristics, mounting height of outlet, temperature differential, and resultant drop or rise, or location of greatest heating or cooling loads strongly affect the selection of the optimum throw. In spaces with beamed ceilings, the outlets should be located below the bottom of the lowest beam level, and preferably low enough so that an upward or arched blow may be employed. The blow should be arched sufficiently to miss the beams and, at the same time, in such a manner as to prevent the primary or induced air stream from striking furniture and obstacles, and producing objectionable drafts.

2. *Effect of Vanes.* Vanes affect grille performance if their *depth corresponds at least to the distance between the vanes.* If the *vane ratio* is less than unity, effective control of the air stream discharged from the grille by means of the vanes is impossible. If it is higher than two, further improvement is slight.

A grille discharging air uniformly forward (vertical vanes in straight position), will have a *spread* of 14 to 24 degrees, depending on type of outlet, duct approach, and discharge velocity. Turning of the vanes will influence the direction and the throw of the discharged air stream.

A grille with *diverging vanes* (vertical vanes with uniformly increasing angular deflection to a maximum at each end of 45 deg) will have a spread of approximately 60 deg and the throw will be reduced considerably. With increasing divergence the quantity of air handled by the grille for a given duct *static pressure will decrease.*

A grille with *converging vanes* (vertical vanes with uniformly decreasing angular deflection) will have a slightly higher throw than a grille with straight vanes, but the spread will be the same for both settings. The air stream will converge slightly for a short distance in front of the outlet, and then spread somewhat more than the air discharged from a grille with straight vanes.

In addition to vertical vanes which normally spread the air horizontally, horizontal vanes may be used to spread the air vertically. However, spreading the air vertically entails the risk of hitting beams or other obstructions, or of blowing primary air at excessive velocities into the occupied zone.

3. *Effect of Type of Outlet.* Ceiling diffusers distribute the air with a horizontal spread of 360 deg and also have a downward air motion. Therefore, both throw (radius of diffusion) and mounting height are important and interdependent factors. Due to the 360 deg spread, the rate of induction is higher and the throw shorter than that for a wall grille handling the same air quantity at the same outlet velocity. Therefore, ceiling diffusers will frequently permit the use of higher air velocities than wall outlets, and consequently may be sized smaller to handle the same air volumes. If ceiling outlets are installed flush with the ceiling, impingement of the air stream along the ceiling surface restricts induction of secondary air, and the throw is increased approximately 40 percent above that of an unrestricted air stream. (Refer to Radial Jets and Effect of Walls and Ceilings in section Ventilating Jets in Air Distribution.)

Slotted outlets, due to their high aspect ratio, have higher induction than comparable round or square vaned outlets of

equal area handling the same air quantity, and their throw is shorter. (Refer to Discharge From a Long Slot in section Ventilating Jets in Air Distribution.)

The perforated panel is an excellent device for producing a large diameter stream with a uniform velocity across its entire area. Although this type of outlet can handle the greatest amount of air in proportion to room size, jet velocities must be kept low. (Refer to Perforated Panels in section Ventilating Jets in Air Distribution.)

For all types of ceiling outlets the following considerations should be noted: (1) if the temperature of the supply air is below that of the room, it should be thoroughly mixed with the room air before it enters the occupied zone; (2) air slightly above room temperature will usually be properly distributed by outlets selected for cooling; and (3) if the temperature of the supply air is substantially higher than that of the room, it should be projected downward in a broad diverging pattern to avoid stratification and to obtain proper mixing and controlled air flow.

4. *Drop.* The air discharged from a wall outlet should not reach the occupied zone until the velocity has fallen to about 50 fpm. Therefore, the outlets should be located high enough

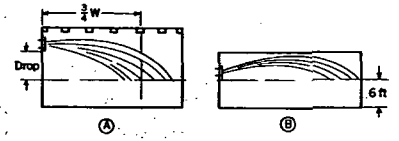

Fig. 9. . . . Throw of Wall Outlets

for the air stream at the termination of the throw to be not less than 5 or 6 ft above the floor level, or in other words, the drop should not be more than the difference between mounting height and zone of occupancy (see Diagram A of Fig. 9). As illustrated in Diagram B of Fig. 9 the maximum permissible throw for a given ceiling height may be obtained by locating the outlet low on the wall, arching the blow, and sweeping the air across the flat area. The air, as it traverses, will adhere to the ceiling. The objection to this method is the possible streaking of the ceiling with dirt.

Capacity

The quantity of air to be handled is determined by the heating, cooling, or ventilating requirements as given in Chapters 11 Infiltration and Ventilation, 12 Heating Load, and 13 Cooling Load. Manufacturers' rating sheets are usually consulted for selection of the proper number, size, and type of outlets for a given air quantity. The basis of rating should be carefully noted to make certain that resulting velocities are suitable for the application.

Temperature Differential

The temperature difference between supply and room air is highly important, because temperature control in the conditioned room is strongly affected by this difference. The greater the temperature differential, the greater the change in room temperature for a given change in the heating or cooling load. The use of outlets which cause a large amount of room air to be mixed with the supply air, permits the use of greater temperature differentials. (Refer to section Air Quantity and Temperature Differential, Chapter 19, Central Systems for Air Conditioning.)

Room Air Motion

To achieve a constant air motion in the occupied zone without exceeding acceptable velocity limits is one of the most important problems in air distribution. Some of the factors which may cause air motion to exceed these limits are: excessive air discharge velocities; high air volume per cubic foot of space (often referred to as number of air changes per hour); premature drop of cold air into the occupied zone; overblow causing spilling of high velocity air into the occupied zone; heating in severe climates by means of downward projection of hot air. These factors will not affect equally the various designs and types of air outlets, and their effect will also depend on the temperature differential, the mounting height of the outlet, and other circumstances. For instance, certain outlets will handle safely more air per cubic foot of space at higher discharge velocities than others, and downward projection of air may sometimes even be necessary if the supply air temperature is substantially higher than the room temperature. (Refer to section on Throw.)

Sometimes excessive air motion may be encountered in correctly designed air distribution systems due to drafts occurring, if stairways or exit doors are left open, or if windows are opened when design of system requires that they be closed. Discomfort is frequently attributed to drafts when it is actually due to too low room temperature. This may occur during the heating as well as the cooling season. Systems designed for heating and ventilation only may easily cause complaints of drafts when cooling is added.

The following papers give useful information with regard to room air motion: Room Air Distribution Research for Year 'Round Air Conditioning, Part I—Supply Outlets at One High Sidewall Location, by S. F. Gilman, H. E. Straub, A. E. Hershey, and R. B. Engdahl (ASHVE TRANSACTIONS, Vol. 59, 1953, p. 151); Room Air Distribution Research For Year 'Round Air Conditioning, Part II—Supply Outlets at Three Floor Locations, by H. E. Straub and S. F. Gilman (ASHVE TRANSACTIONS, Vol. 60, 1954, p. 249); Performance and Evaluation of Room Air Distribution Systems, by Alfred Koestel and G. L. Tuve (ASHAE TRANSACTIONS, Vol. 61, 1955, p. 533); Air Velocities in Two Parallel Ventilating Jets, by Alfred Koestel and J. B. Austin, Jr. (ASHAE TRANSACTIONS, Vol. 62, 1956, p. 425).

Permissible Noise Level

The increase of the noise level caused by an outlet is primarily a function of its discharge velocity and its size. The maximum acceptable noise level in a space may dictate completely the selection of the permissible outlet velocity. In addition, however, noise may be caused by excessive restriction of the free outlet area due to outlet design, by unnecessary turbulence due to one-sided air flow through the outlet, or by impingement of high velocity air on sharp edges.

The origin of excessive noise may be spotted by removing the outlet without stopping the air supply. If noise is still evident, other elements of the air-conditioning system or entirely different sources are at fault. High-pitched, rushing noise indicates that the duct system or excessive velocities in the duct are the cause, low-pitched rumbling noise points to the mechanical equipment of the air-conditioning plant.

When very high duct velocities are used, sound-absorbing lining or special acoustical filters (sound traps) must be

provided. High-pressure or high-velocity outlets for multi-room and other buildings are equipped with a special pressure reduction and sound attenuation box. (Refer to section Types of Air Outlets.)

For a general discussion of permissible room noise levels and air supply outlet noises, refer to Chapter 25, Sound Control.

Smudging

All air outlets have their particular *smudging* problems which have been studied by various investigators but cannot yet be considered solved. Smudging is due to dirt in the room air and in the air discharged by the outlets. Although the primary air may be carefully filtered, small particles of dirt and dust will not be captured by mechanical filters, and may finally be deposited on the walls or ceiling. With ceiling outlets, dirt streaking may be minimized by carefully controlling the discharge of the outlets, or by the use of special deflecting plates or anti-smudge rings. With wall outlets, dirt streaking may be minimized by preventing direct impingement of the air on any ceiling or room surface. Floor outlets may be objectionable as dirt collectors.

TYPES OF AIR OUTLETS

Air supply outlets for commercial, industrial, and residential applications are either side-wall- or ceiling-type outlets. In homes, baseboard and floor type outlets are also used. (Refer to Chapter 18, Warm Air Heating Systems.) As a great variety of outlets of various design are available in these four types, the final selection of a supply air outlet depends to a large degree upon the specific problems of the air distribution system to be used.

In addition to the comments which follow on use and application of outlets, reference should also be made to sections Outlet Location and Selection and Specific Applications.

Wall Outlets

Side wall outlets in general use are (1) perforated grilles, (2) fixed and adjustable bar and vane grilles, (3) registers, (4) wall diffusers, (5) slotted wall outlets, and (6) high-pressure or high-velocity wall outlets.

1. *Perforated Grilles.* These grilles have a small vane ratio and are not adjustable. They are useful primarily where directional air flow is unnecessary, and for applications where the grille size can be increased in order to provide the required free area.

2. *Fixed and Adjustable Bar and Vane Grilles.* Grilles with fixed bars or vanes are used for wall, floor, or baseboard applications when the performance is not critical or can be adequately predicted. Adjustable grilles are equipped with either vertical or horizontal adjustable bars or vanes or both, and are used where proper control of air motion is essential. Vanes should be designed for quiet operation.

3. *Registers.* Grilles equipped with dampers or adjustable valves for controlling volume distribution of the supply air are called registers.

4. *Wall Diffusers.* These outlets incorporate design features originally developed for ceiling outlets, and therefore make use of semi-conical or semi-pyramidal guide vanes instead of the straight vanes of the conventional side-wall outlet. In warm air perimeter systems they are used to blanket the outside wall with the warm supply air.

5. *Slotted Outlets.* These outlets are available in a great variety of designs, consisting either of elongated outlets with perforations, or flat outlets with a number of long narrow slots or a single narrow slot, or straight long outlets with one long slot or diffusing vanes. Due to their high aspect ratio, slotted outlets have higher entrainment than comparable round or square vaned outlets of equal area and consequently, the throw is reduced. (Refer to Discharge from a Long Slot in section Ventilating Jets in Air Distribution.)

Slotted outlets are particularly useful in connection with the linear design motif in architecture, for applications where it is desired to merge air outlets unobtrusively with the room decoration. They may be used for either ceiling or wall air distribution, including the so-called under-the-window application. In all applications, capacity limitations, proper duct approaches, and correct balancing of slotted outlets must be carefully considered, as correction after installation is difficult.

6. *High-Pressure or High-Velocity Outlets. Ejector nozzles* operate at high static pressure and convert this pressure into velocity pressure with resulting high induction of room air. They are mainly used for industrial process installations, particularly drying. Another type of ejector nozzle is sometimes referred to as a *louver nozzle* and has a 45 to 90 deg elbow, which can be rotated similarly to a universal joint about an axis perpendicular to the surface to which it is fastened. These outlets give a considerable degree of adjustability and are, therefore, useful for spotcooling in confined spaces.

High-pressure or high-velocity air-conditioning systems installed in multi-room and other buildings, use very high velocity and pressure so that the size of the ducts can be reduced. This in turn requires the use of *high-pressure or high-velocity air outlets* which reduce the velocity and pressure and attenuate the sound to predetermined values at the point where the air is discharged. It is also possible, of course, to use high velocity only in part of the system, for example in the main trunk ducts, and conventional velocities in the branch ducts. Special high-pressure control units are then installed at the end of the main duct, and the air is discharged through conventional air outlets in the various spaces of the building.

Various high-pressure or high-velocity outlets of different design, but usually consisting of a pressure reduction and sound attenuation box and a grille or diffuser, have been developed for high-velocity systems and are described in the literature of the manufacturers. These outlets may be used in the ceiling or in the wall of the air-conditioned space, including under-the-window installation, or in the ceilings of corridors. Refer to Unitary-Central Systems for multi-room buildings in Chapter 19, Central Systems for Air Conditioning, and to Design of High-Velocity Ducts in Chapter 21, Air Duct Design.

Ceiling Outlets

Ceiling outlets in general use are (1) ceiling plaques, (2) ceiling diffusers, (3) high-pressure or high-velocity ceiling outlets, and (4) perforated ceilings and panels.

1. *Ceiling Plaques.* Plaques are of simple design. The air from the supply opening impinges on a plate and is discharged horizontally. Plaques are inexpensive, but as the air is not always uniformly discharged in all directions, proper control is difficult.

2. *Ceiling Diffusers.* Ceiling diffusers are round, square, rectangular, or slotted outlets of various designs installed on, or parallel to, the ceiling. Performance of the different designs varies according to the principle employed. Some

have no internal induction, but hasten external induction by supplying air in multiple layers. Others have internal induction and distribute air over an entire hemisphere. The induction effect is greatest in the direction of the axis of the outlet, and least in the plane perpendicular to the axis and located at the ceiling level. Thus the induction is greatest in the vertical direction where the least throw can be tolerated, and least in the horizontal plane at the ceiling where the greatest throw is desired. (Refer to section *Slotted Outlets* under Wall Outlets.)

3. *High-pressure or High-velocity Outlets.* Refer to text in section Wall Outlets.

4. *Perforated Ceilings and Perforated Panels.* These devices discharge air through perforations in the ceiling or part of the ceiling, and share with slotted outlets the advantage of unobtrusive appearance. In addition, sound-absorbing materials may be used for the panels, or the panels may provide a luminous ceiling.

Outlet air velocities may be kept low by using large outlet areas, particularly in spaces with high room loads, high ventilating requirements, or low ceilings. Some perforated panels have a control plate frame which is inserted in the conventional ceiling duct. Supply air enters the plenum above the distribution plates through an adjustable air valve which can be set for varying air quantities and velocities. (Refer to Perforated Panels in section Ventilating Jets in Air Distribution.)

OUTLET LOCATION AND SELECTION

The design of the air-conditioning plant for a building depends on the use to which the building is put, on its size, and its construction type. The design of the air transmission and air distribution system is influenced by the same factors. Therefore, these factors must be considered in designing the air transmission system, and in selecting the type and location of the supply outlets. The location and selection of the supply outlets is further influenced by the interior design of the building, local sources of heat gain or loss, and outlet performance and design.

Use, Size, Construction of Building

The use, size, and construction of a building are three factors which may influence or even govern the selection of a particular type of air distribution system, as is shown by the development of special high-pressure or high-velocity transmission and distribution systems for multi-room and other buildings. Generally, the physical details of the individual rooms of a building, such as height and shape, and the location of beams and other obstructions, influence the possible location of the supply ducts which in turn influences the outlet locations. The location of the supply ducts—above the ceiling or within the walls, in a furred space above corridors, or in the conditioned room itself—has an important bearing, therefore, upon the design of the air distribution system. A particular method of air distribution may be highly desirable but it may be impossible to use it, due to the location of beams and masonry walls.

Refer to later section Specific Applications for a discussion of air distribution methods in various buildings.

Heat Gain or Loss

Local sources of heat gain or loss promote convection currents or cause stratification, and may, therefore, determine both the type and location of the supply outlets.

Generally, the outlets should be located to neutralize any undesirable convection currents set up by a concentrated heating load. If a concentrated source of heat is located at the occupancy level of the room, the heating effect may be counteracted by blowing the supply air toward the heat source, or by locating an exhaust or return grille adjacent to the heat source. The second method is more economical, as heat will be withdrawn at its source rather than be dissipated into the conditioned space. Where lighting loads are heavy and ceilings relatively high (five watts per sq ft and above 15 ft), the outlets should be located below the lighting load, and the stratified warm air removed by an exhaust or return fan. An exhaust fan is recommended if the wet-bulb temperature of the air is above that of the outdoors, a return fan, if it is below this temperature. Either method reduces the requirements for supply air. If the lights are exposed, less saving can be realized than if they are enclosed, as a considerable portion of the energy is radiant.

An important function of any supply outlet during *winter heating* is to maintain the temperature difference between the floor and ceiling at the lowest possible value. Since the air within a room is never so perfectly mixed that all of it is at exactly the same temperature, a certain amount of stratification is inevitable. Unless the supply outlets are properly selected and located, the temperature difference will be large enough to result in discomfort to the occupants.

The proper selection and location of outlets is particularly difficult for rooms with large windows and exposed wall areas. Heat is lost primarily through these areas, and room air in contact with these surfaces is chilled and flows downward, causing drafts near the exposed surfaces and floor.

This condition can best be prevented by locating the air outlets under the windows, by discharging warm air across the exposed surfaces, or by providing supplementary radiation under the windows, in addition to the wall or ceiling air distribution outlets. This solution must be used for comfort installations in northern latitudes (outdoor temperatures below 40 F), when the building walls are uninsulated or single-glass windows are used.

In buildings located in regions where winter heating is a minor problem, high induction by ceiling or wall outlets may be employed to mix properly the entire room air with the supply air and to prevent downdrafts along the exposed surfaces. In northern latitudes, this solution can only be used if the buildings have double-glass windows and insulated walls, as otherwise the induction effort required for neutralization of the downdrafts is so great that the air motion in the room exceeds comfort limits. Where comfort conditions are not critical as in factories for heavy maunfacturing, warehouses, etc., satisfactory results with high induction outlets can be obtained even in cold climates. For uninsulated walls and glass areas in these buildings some supplementary heating is often valuable. Wall diffusers, direct radiation, or warm panels will satisfy these requirements for supplementary heating.

The location of exhaust or recirculating air openings at the base of large areas of glass is sometimes effective in reducing downdrafts into the occupied space.

Great care should be exercised in the use of supply-exhaust air outlets for heating in northern latitudes when considerable exposed wall and window surfaces are involved. In such cases additional radiation is usually required. When the system is used for ventilating only during the heating season, direct radiation should be regulated to provide heat until room and outside temperature are balanced. To avoid

stratification, it is advisable to operate the fan continuously and to limit the temperature differential by supplying air at a high rate of change per hour.

Outlet Performance and Design

Outlets should perform efficiently and conform to the esthetic appearance of the room. The physical appearance of air outlets has been highly influenced by modern interior design, and to meet the demands of architects and engineers. Outlets to be installed flush with the ceiling and outlets with built-in lighting as well as square and linear-type outlets have been developed in the past years. Linear-type outlets and perforated ceilings or panels have the advantage of unobtrusive appearance.

Procedure for Outlet Location and Selection

In determining outlet location and selecting the type of outlets, it is customary to proceed as follows:

1. Study the plan of the building and note the amount of air to be supplied to each room. (For computation of the *required air quantity* for heating and cooling refer to the formulas given in Chapters 12, Heating Load, and 13, Cooling Load. The amount of outdoor air introduced into the room must be checked against the ventilation requirements of state or local codes.)

2. Select number of outlets for each room, considering air quantity required and distance available for throw or as radius of diffusion. The same factors, as well as distance from floor level available as mounting height, structural characteristics of the space, and consideration of appearance, will determine the type of outlet used.

3. Arrange location of outlets in the room. Generally, the outlets must be evenly spaced to distribute the air uniformly throughout the room. More air, however, must be supplied and directed towards areas with exceptional heat gain or loss. An important point to consider is the combination of proper outlet location and efficient duct design (see Chapter 21). Consult manufacturers' tables for recommended location and spacing of outlets.

Refer to Chapter 19 for a discussion of zone control.

4. Select size of outlets according to air quantities handled, permissible throat or discharge velocities, or effective throw, taking into consideration other factors, such as permissible noise level, etc. In order to determine whether the selection made will satisfy the requirements of the job, the type, size, and location of the outlet must be checked against manufacturers' ratings. The most important questions to be considered are:

   a. Will drafts be created because of divergence between rated throw (radius of diffusion) and distance between outlet and nearest obstacle (wall, beam, column, etc.) in the air stream.
   b. Will drafts be created because of excessive cooling temperature differential or too low mounting height of the outlet?
   c. Will drafts created because of too low velocity energy of the air stream cause excessive downward air flow in cooling installations?
   d. Will the air pass through the outlet at too high a velocity and thereby cause an excessive increase in noise level?

Balancing the System

In designing a system, the engineer aims to size ducts and outlets in such a manner that the supply of air is properly distributed. He may, however, feel it necessary to oversize certain trunks, branches, or outlets to allow flexibility or to permit future redistribution, so that the system as designed may not be self-balancing. Even if ducts are designed for self-balancing and outlets are properly selected, all air systems must be balanced, that is, the amount of air through supply ducts, supply outlets, outdoor air intakes, exhausts, return outlets, and ducts must be properly adjusted so that the air quantities correspond closely with the design quantities. Balancing, therefore, is part of the field test procedure to which each air-conditioning system should be subjected in order to determine whether the capacity and performance of the equipment correspond with the design.

For balancing, air systems may be equipped with dampers in supply, return, and outdoor air ducts, splitter dampers, or dampers in outlets. In selecting the desired type of damper or balancing method, the following points should be kept in mind:

1. Unfavorable effect on air stream and noise level should be avoided. This will often rule out blank-offs or dampers in outlets, unless such dampers are of special design.

2. It should be possible to alter outlet volume without altering the direction of discharged air, and to measure the amount of air handled without difficulty. Blanking off part of the area of supply outlets makes this difficult.

Generally speaking, it is most satisfactory to install dampers at some distance back of outlets so as to avoid disturbing the air flow. Dampers in both supply and return ducts form the most flexible means of controlling supply of air to the room and static pressure within the room. (Refer to following section Directional and Volume Control for discussion of various air distribution control devices.)

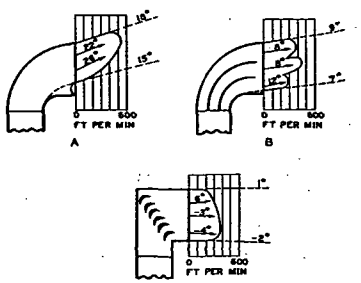
Instruments for balancing include instruments for measuring air quantities, static pressure, temperature and humidity. Commonly used instruments are the rotating vane anemometer, deflecting vane anemometer, thermal anemometer, smoke gun, clamp type ammeter-voltmeter, sling psychrometer and thermometers. Pressure, humidity and temperature recorders are sometimes useful. The Pitot tube and a manometer may be used on higher velocities, but only with the technique prescribed for its use by the manufacturer for the tube used. (See Air Flow Measurement in Chapter 44.)

The following balancing procedure is recommended for air systems:

1. Open all duct and outlet dampers.
2. Measure fan capacity. This can most often be done with a rotating vane anemometer inside the fan inlet plenum. For exhaust fans the discharge outlet will often serve.
3. Measure fan motor input.
4. Determine approximate flow at each outlet.
5. Adjust outlets or branches so that outlet deviation (from design quantity) is approximately the same (percentagewise) as fan capacity deviation (from total design quantity).
6. Recheck fan capacity.
7. Adjust fan speed or main trunk damper to make fan capacity equal to design. (The fan laws apply when changing speeds; quantity varies directly with speed,—power input as the cube of speed.) Use power input readings to check possibility of overloading the motor.

The procedure outlined may be shortened depending on the type of installation. For instance, where many outlets serve one room, exact balancing of each outlet may not be required, so long as drafts, noise and temperature differences are checked. Experience and judgment are valuable in determining how carefully or thoroughly a system must be tested and adjusted.

DIRECTIONAL AND VOLUME CONTROL



Duct Approaches to Outlets

The importance of the manner in which the air stream is introduced into the outlet cannot be overestimated. To obtain correct air distribution, the velocity of the air stream must be as uniform as possible over the entire connection to

the duct, and perpendicular to the outlet face. No air outlet can compensate for improper duct approach.

A wall grille installed at the end of a horizontal duct and a ceiling outlet at the end of a vertical duct receive the air perpendicularly and at (for practical purposes) uniform velocity over the entire duct cross-section, provided the system is carefully designed. However, very few outlets are installed in this manner. Most side wall outlets are installed either at the end of vertical ducts or in the side of horizontal ducts, and most ceiling outlets are attached either directly to the bottom of horizontal ducts or to special vertical take-off ducts which connect the outlet with the horizontal duct. In all these cases, special devices for directing and equalizing the air flow are necessary to obtain proper direction and distribution of the air.

The influence of the duct approach on outlet performance has been investigated for vertical stack heads with plain

Stack 14 in. x 6 in. Outlets 14 in. x 9 in. Stack Velocity 500 fpm
A. Rounded Throat and Rounded Back
B. Rounded Throat and Back and 2 Splitters.
C. Square Throat and Back and 6 Guide Vanes.

Fig. 10. . . . Outlet Velocity and Air Direction Diagrams for Stack Heads with Expanding Outlets

openings[13] or equipped with grilles[14] and for side outlets on horizontal ducts.[14] In the tests conducted with the stack heads it was found that it is necessary to provide splitters or guide vanes in the elbows at the top of the vertical stacks regardless of the shape of the elbows, whether of rounded, square or expanding types. Cushion chambers at the top of the stack heads have no beneficial effect. Fig. 10 shows the direction of flow, distribution and velocity (measured 12 in. from opening) of the air for various types of stack heads tested, expanding from a 14 x 6 in. stack to a 14 x 9 in. opening, without grille. The air velocity for each was 500 fpm in the stack below the elbow, but the direction of flow and the distribution pattern are generally indicative of performance obtainable with nonexpanding elbows of similar shapes for a range of velocities 200 to 1400 fpm.

In tests conducted with 3 x 10 in., 4 x 9 in., and 6 x 6 in. side outlets in a 6 x 20 in. horizontal duct at duct velocities of 200 to 1400 fpm (in the 6 x 20 in. section) it was found that multiple curved deflectors produced the best flow characteristics. Vertical guide strips in the outlet were not so effective as curved deflectors. A single scoop type deflector at the outlet did not improve the flow pattern obtained from a plain outlet, and was therefore not found to be desirable.

Directional Control

Many devices for directing and equalizing air flow in side wall and ceiling outlets are now commercially available, and should be used whenever necessary. They are indispensable for all side outlets in horizontal ducts and for most ceiling outlets.

Ceiling outlets are usually installed below horizontal supply ducts so that the supply air has to make a 90-deg turn before entering the outlet itself. The shorter the connection between bottom of duct and outlet, the greater is the need for directive devices to obtain uniformity of flow. Generally speaking, conditions and remedy in such cases strongly resemble those for side outlets in horizontal air ducts. Ceiling ducts often have a rectangular cross-section, while the connections to the ceiling outlets are circular. It will then be quite difficult to install turning vanes successfully, particularly if the ducts are shallow and the connection areas are comparatively large. This will be the case when more than one outlet is installed on one duct run, and restrictions of duct areas must be avoided. In such cases good results have been obtained by using a series of vertical guide strips, installed at right angles to the direction of air approach in the outlet connection where it leaves the horizontal air duct.

Volume Control

Various methods are used to regulate volume of supply and return (exhaust) air. Some of these accomplish only minor changes in volume; most of them, however, permit a range of adjustment from maximum air supply to complete shut-off.

When selecting type and location of such dampers, the following points must be considered, especially when the volume control feature is to be located near the air outlet itself: (1) deflection of air stream by the damper; (2) need and feasibility of directional control; (3) increase of noise level due to irregular and localized high air velocities caused by damper operation.

The following types of volume control are most frequently encountered:

1. *Slide Damper.* A single plate which can be pushed across the duct. Since its operation changes the free area of air passage in a one-sided manner, it should not be located near any air outlet, and its use is practicable only where no intermediate setting between full open and closed is required.

2. *Hit-and-Miss Damper.* Two slotted plates or discs, closely adjacent; by moving one of the two plates the respective slots may be opened or closed. This type of volume control may be installed close to an air outlet and it is easy to operate, but its main disadvantage is that even in the open position the air passage area is blocked by at least 50 percent. This requires oversizing of the air outlet in order to avoid excessive increase of noise level.

3. *Splitter Damper.* A single blade sheet metal plate hinged at one edge, usually located at the branch connection of a duct or outlet. It is easy to operate, but often causes irregular air flow in the duct. When used in connection with, and near an outlet, additional directional control is required.

4. *Butterfly Damper.* A single blade sheet metal plate hinged in the middle, usually located in a straight duct run.

Table 2. . . . Recommended Return Intake Face Velocities

Intake Location	Velocity Over Gross Area Fpm
Above occupied zone	800 up
Within occupied zone, not near seats	600–800
Within occupied zone, near seats	400–600
Door or wall louvers	200–300
Undercutting of doors (through undercut area)	200–300

It is easier to handle than a splitter damper, since only half the motion is necessary to change its setting. However, if located too close to an air outlet, it is objectionable because its operation frequently results in a condition whereby two high velocity jets are created along the sides of the duct, or the air spills immediately downward into the occupied zone.

5. *Louver Dampers.* Numerous designs have been developed incorporating a series of splitter or butterfly dampers across the duct or air outlet. Their main advantage consists in retaining greater uniformity of air flow, and in requiring less depth for installation. Some designs provide for louver blades moving in opposite directions, and while decreasing free air passage area, retain a constant air flow direction along the axis of the duct air outlet connection.

RETURN AND EXHAUST INTAKES

The *selection of return and exhaust intakes* depends on: (1) velocity in occupied zone near intake; (2) permissible pressure drop through intake; and (3) noise.

1. *Velocity.* The control of the room air motion for the maintenance of comfort conditions depends on the proper selection of the *supply* outlets. The effect of air flow through return intakes upon air movement in the room is slight. Air handled by the intake approaches the opening from all directions and its velocity decreases rapidly as the distance from the opening increases. Therefore, drafty conditions will rarely be encountered near return intakes. Recommended return intake face velocities are given in Table 2.

2. *Permissible Pressure Drop.* The permissible pressure drop will depend on the choice of the designer. Table 3 gives pressure drop through plain lattice intakes as a function of free area and face velocity.

Proper pressure drop allowance should be made for control or directive devices.

3. *Noise.* The problem of *noise* generated by return intakes is the same as that for supply outlets. In computing resultant room noise levels from the operation of an air-conditioning system, the return intake must be included as a part of the total grille area. The major difference between the supply outlets and return intakes is the frequent installation of the latter at ear level. When so located, it is recommended that the return intake velocity be not in excess of 75 percent of the maximum permissible outlet velocity.

The *location of return and exhaust intakes* does not critically affect air motion, unless room air velocities in the occupied zone near the intake exceed comfort limits. The locations of return or exhaust intakes are, however, important for obtaining the desired room temperature equalization.

Ceiling locations for exhaust outlets are recommended for

Table 3. . . . Approximate Pressure Drops for Lattice Return Intakes
Inches Water Gage—Standard Air

Percent Free Area	Face Velocity, Fpm						
	400	500	600	700	800	900	1000

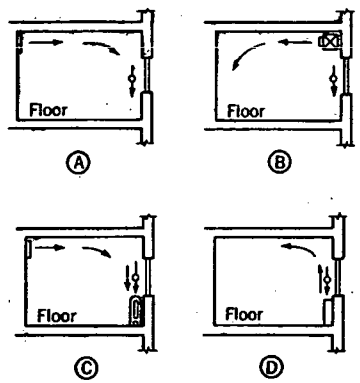
bars, kitchens, lavatories, dining rooms, club rooms, etc. where warm air will rise to the ceiling level. In heating installations, location of the return grilles in the ceiling or high on the wall is not recommended, as it may result in stratification of the conditioned air, and—depending on the relative location of supply and return outlets—in short-circuiting. (Refer to previous section Outlet Location and Selection.)

Some ceiling outlets combine the supply and return openings in a single unit. This method is used for heating as well as for cooling applications. However, the application for heating is more critical and requires consideration of ceiling height, amount of outside wall area, and number of air changes required. In some cases, stratification of warm air may cause short-circuiting. (Refer to previous section Outlet Location and Selection.)

Floor locations of returns are used in heating installations for ceiling or side-wall supply. When located so that air is drawn across exposed walls, the performance of the system may be somewhat improved. In general, floor locations tend *to collect dirt and refuse.*

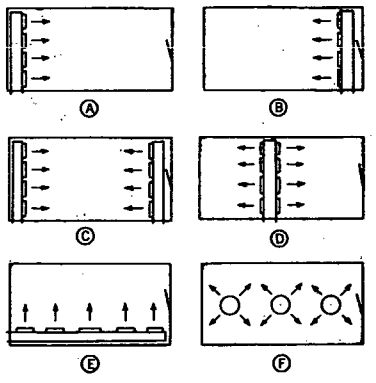


Wall and door locations of exhaust outlets depending on their elevation, have the characteristics of either floor or ceiling returns. In large buildings with many small rooms, the return air may be brought through door grilles or door undercuts into the corridors, and then to a common return or exhaust. The pressure drop through door returns should not be excessive; otherwise the air distribution to the room may be seriously unbalanced with the opening or closing of the doors. Outward leakage through doors or windows cannot be counted upon for dependable results.

SPECIFIC APPLICATIONS

For *theaters and auditoriums* the air distribution methods used are the downward distribution system with ceiling diffusers, and the horizontal distribution system with ejector nozzles or wall diffusers. Fig. 11 shows both methods. Ceiling distribution is accomplished by ceiling outlets under main ceiling and balcony. It is indicated when main ceiling or

Fig. 11. . . . Air Distribution Methods for Theaters, Churches, and Auditoriums



A. Satisfactory for cooling. Unsatisfactory for heating in severe climates where the outside temperature is consistently below 40 F, and single glass and uninsulated walls are prevalent.

B. Performance approximately that of A when small diffusers are used in bottom of the duct.

C. Satisfactory for cooling. Satisfactory for heating if direct radiation is properly controlled.

D. Satisfactory for both cooling and heating. The air should be discharged slightly away from the wall and for low velocities, should be fanned out parallel to the wall.

Fig. 12.... Distribution Methods for Small Rooms

A. *Rear Wall.* High outlet velocity, satisfactory if properly designed; possibility of excessive air motion and drafts if used for wrong application.

B. *Front Wall.* High outlet velocity, results same as A.

C. *Front and Rear Walls.* Moderate room air motion, outlet blows should not impinge giving rise to downdrafts in center.

D. *Center.* Moderate air motion, no impingement of air streams. Good results.

E. *One Side.* Moderate room air motion; should blow toward exposed wall. Good results.

F. *Ceiling.* Low room air motion. Good results. Outlets should be selected of sufficient size to allow for blocking when not located in perfect squares.

Fig. 13.... Small Store Cooling Distribution

balcony is cut up by architectural treatment or beams. The only critical points are under the balcony, and (occasionally) above the very rear of the balcony, where ceiling heights are low and where direct impingement of air is sometimes a hazard.

Wall or ejector distribution is particularly applicable for relatively long and narrow theaters. It is essential with this type of distribution that there be no interference with the movement of air throughout its entire path from the high velocity nozzles to the front of the theater. The ceiling should be smooth, without projecting beams or obstructing ornamentation. For large theaters, relatively high velocities can be used. These will work satisfactorily if adjustable outlets are used to avoid areas of local turbulence.

In small or medium size theaters, it is sometimes practicable to use side-wall or front-wall distribution. For the satisfactory operation of such a system during the winter heating period, the returns should preferably be located at the floor level and near the front of the theater to prevent cold spots resulting from exposed wall convection or infiltration from exits.

For *multi-room buildings* diagrams shown in Fig. 12 illustrate distribution methods for small rooms with exposed wall, such as offices, hotel (guest) rooms, hospital (patients) rooms, apartments, etc.

For *a small store* the cooling performance of various distribution methods is illustrated in Fig. 13.

CHAPTER 21

AIR DUCT DESIGN

Pressure Changes, Friction Losses, Circular Equivalents of Rectangular Ducts, Dynamic Losses, Pressure Losses in Elbows, Pressure Losses in Divided-Flow Fittings, Losses Due to Area Changes, Duct Design Methods and Examples, High-Velocity Duct Design, Duct Construction Details, Heat Losses from Ducts

IN THE design of air duct systems, the objective is to provide a system that, within prescribed limits of noise and space available for ducts, efficiently transmits the required flow rate of air (cfm) to each space while maintaining a proper balance between investment and operating cost. When the heating, cooling, or ventilation load is established, the total flow rate of air required can be determined by methods shown in Chapters 12 and 13. The problem is then to distribute the supply air properly among the spaces.

PRESSURE CHANGES

Ductwork imposes resistance to air flow which must be overcome by the expenditure of mechanical energy; this energy is ordinarily supplied by a fan. The portion of the airflow rate from the fan that is transmitted to a particular space is governed by the law that the loss in total pressure from the fan outlet must be the same along each air path. This also holds for the return-air system except that the loss in total pressure refers to the fan inlet. In air-conditioning and ventilating work the pressure differences are ordinarily so small that the equations for incompressible flow can be applied. Additional simplicity is obtained by considering the air to be at the standard density of 0.075 lb per cu ft.

At any cross-section in a duct the total pressure H is the sum of the static pressure P and the velocity pressure H_v. Thus,

$$H = P + H_v \tag{1}$$

Pressures are considered in units of inches of water. The velocity pressure is then given by

$$H_v = \left(\frac{V}{4005}\right)^2 \tag{2}$$

where V is defined by the equation

$$V = Q/A \tag{3}$$

where:

V = mean velocity of flow, feet per minute.
Q = air-flow rate, cubic feet per minute.
A = cross-sectional area of duct, square feet.

The total pressure H is a measure of the total mechanical energy at a cross-section. In any duct system, the total pressure always decreases in the direction of the air flow. Static and velocity pressure are mutually convertible and either can increase or decrease in the direction of flow.

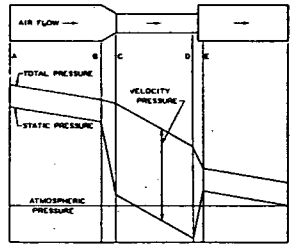
Typical pressure changes in a duct system are illustrated in Fig. 1. Between Sections A and B, the static and total pressures decrease uniformly because of friction between air molecules along the sides of the duct. Pressure losses in straight pipes are termed *friction losses* and are characterized by dependence upon Reynolds number. (See Chapter 4.)

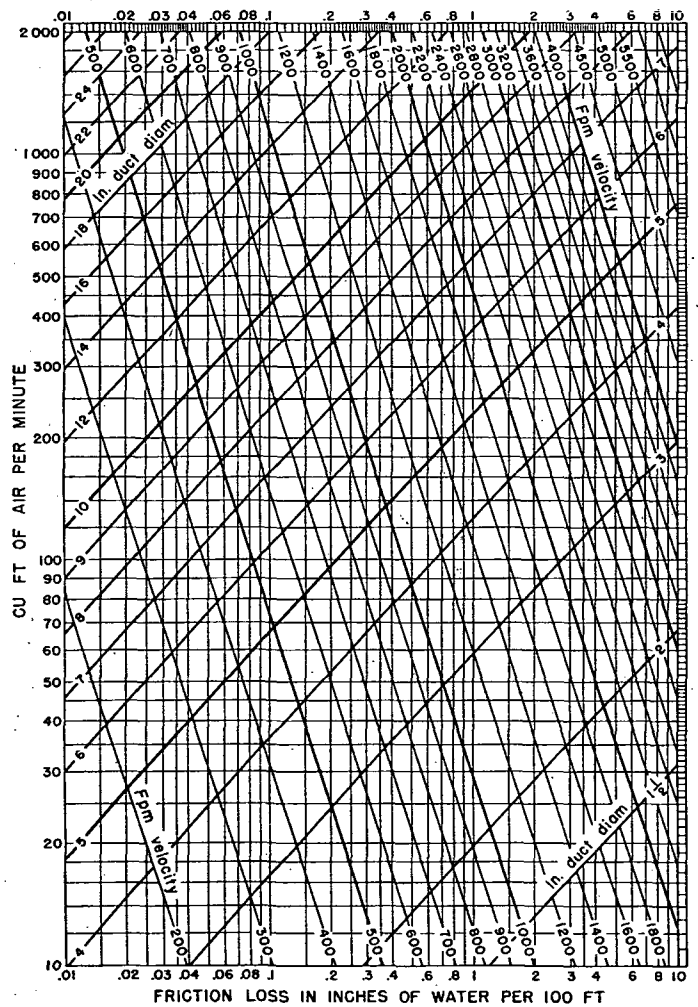
Section BC is a converging section. The duct area is reduced, and consequently the flow is accelerated. This is a stable and efficient process and the loss in total pressure is seen to be small. The marked decrease in static pressure is caused by conversion of static to velocity pressure in accordance with Equation 2.

Section CD presents the friction loss in the section of smaller duct. Since friction losses increase with nearly the square of the velocity, the pressure line falls much more rapidly than in Section AB.

An abrupt expansion occurs at DE. The duct area is abruptly increased and the flow decelerated. The process is an inefficient one and the loss in total pressure is therefore large. The velocity pressure is decreased at E in accordance with Equations 2 and 3, and the static pressure rises. This and the pressure loss at BC are termed *dynamic losses*, and are characterized by being essentially independent of Reynolds number. Dynamic losses occur because of changes in the direction or velocity of the air, and hence occur at duct transitions, bends (elbows), and obstructions such as dampers. As will be shown later, dynamic losses can be specified in terms of a constant times the velocity pressure at a cross-section under consideration.

Beginning at Section E the velocity pressure is constant, and the static and total pressures again decrease uniformly due to wall friction. The static pressure at F is zero, as referred to the atmosphere. The total pressure is the velocity pressure and is a measure of the kinetic energy of the stream as it discharges from the duct.





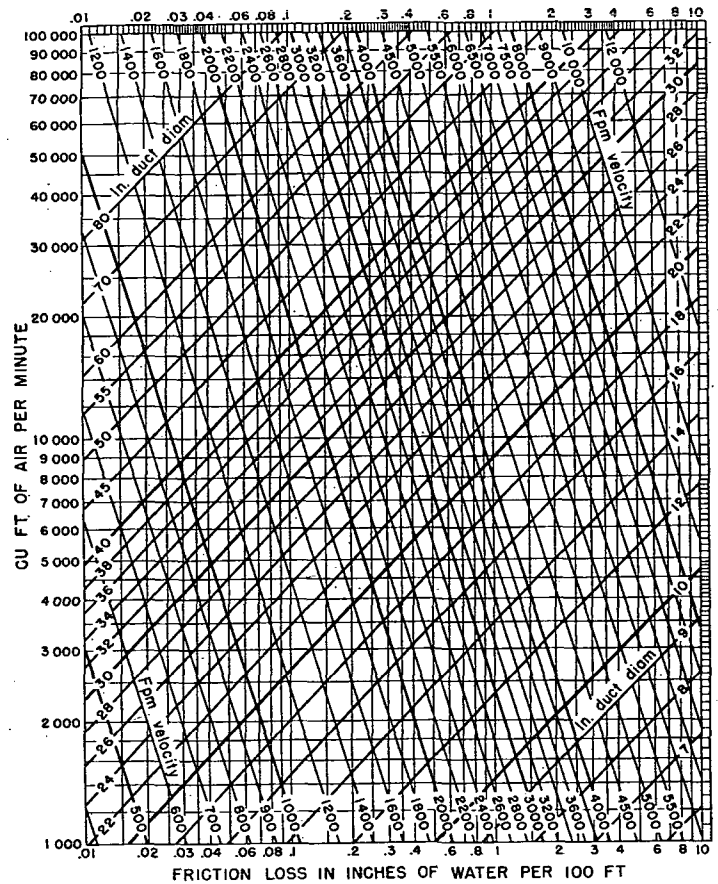


Fig. 1 . . . . Pressure Changes During Flow in Ducts

(Based on Standard Air of 0.075 lb per cu ft density flowing through average, clean, round, galvanized metal ducts having approximately 40 joints per 100 ft.) Caution: Do not extrapolate below chart.

Fig. 2 .... Friction of Air in Straight Ducts for Volumes of 10 to 2000 Cfm

(Based on Standard Air of 0.075 lb per cu ft density flowing through average, clean, round, galvanized metal ducts having approximately 40 joints per 100 ft.)

Fig. 3 .... Friction of Air in Straight Ducts for Volumes of 1000 to 100,000 Cfm

The distinction between *static* and *total pressure* is important, because the former is conventionally used as the *basis for system design*, but the latter determines the actual mechanical energy that must be supplied to the system. Note in Fig. 1 that the static pressure decreases and then increases in the direction of flow. Moreover, it even becomes negative (below atmospheric). Therefore, in dealing with static pressures, distinction must always be made between static pressure *loss* (Section *AB*) and static pressure *change* as a result of conversion of velocity pressure (Section *BC*).

FRICTION LOSSES

Pressure drop in a *straight* duct is caused by surface friction, and this friction loss is most readily calculated by means of the Air Friction Charts, Figs. 2 and 3, covering volume ranges of 10 to 2000 cfm, and 1000 to 100,000 cfm,

respectively. These charts were developed by the ASHAE Research Laboratory.[3]

The charts, Figs. 2 and 3, were constructed from the basic flow equation for the pressure loss in circular ducts (see Chapter 4):

$$H_f = f\left(\frac{l}{D}\right)H_v \qquad (4)$$

where

H_f = head loss due to friction, inches of water.
f = a nondimensional friction coefficient, which for air-conditioning work depends upon Reynolds number and the relative roughness of the conduit. Approximate values of f were taken from the work of Moody[2] where $\epsilon = 0.0005$ ft. (See Chapter 4, Fig. 4, Relation Between Friction Factor and Reynolds number.) It is numerically equal to the reciprocal of the number of duct diameters required to cause a pressure loss equivalent to one velocity pressure.
l = length of conduit, feet.
D = inside diameter of conduit, feet.
H_v = velocity pressure of mean velocity, inches of water.

The air friction chart is based on standard air with a density of 0.075 lb per cu ft, flowing through average, clean, round, galvanized metal ducts having approximately 40 joints per 100 ft. Fig. 2 should not be used to obtain values below the charts by extrapolation, because critical flow would occur in this region and values so obtained would be unreliable.

Variations in air temperature of the order of ±20 deg from 70 F affect duct friction very little. Figs. 2 and 3 can therefore be used for all air systems with temperatures from 50 F to 90 F.[1] For systems carrying air at much higher temperatures, however, the values found in the charts must be corrected.[3] To determine the friction loss in such systems, the *actual* flow rate or velocity existing at the nonstandard conditions must be used.

Changes in humidity, or the usual changes in barometric pressure or in the pressures required to circulate the air through the systems, have little influence on duct friction and can be disregarded in calculating friction losses in ordinary air-flow systems.[1] For unusual conditions, the friction values obtained from Figs. 2 and 3 must be corrected.[3]

For ordinary applications, an excellent approximation for nonstandard temperatures is

$$h_s = Kh_a \qquad (5)$$

where

h_s = friction loss under actual operating conditions, inches of water.
h_a = friction loss obtained from Figs. 2 and 3 using the actual flow rate or velocity existing under the nonstandard conditions, inches of water.
K = friction loss correction factor, obtained from Fig. 4, dimensionless.

For ducts of other than standard sheet-metal construction, correction factors may be obtained from Figs. 5 and 6. The correction factors shown in Fig. 5 were computed for the value of ϵ, the roughness in feet, shown in Table 1.[3] Most ductwork today is fabricated from galvanized-iron or aluminum sheet metal, or flexible tubing. Fig. 6 presents in graphical form the recommended correction factors for aluminum

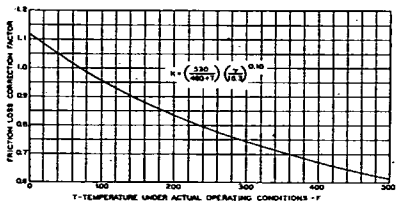

Fig. 4 .... Correction Factors for Density and Viscosity

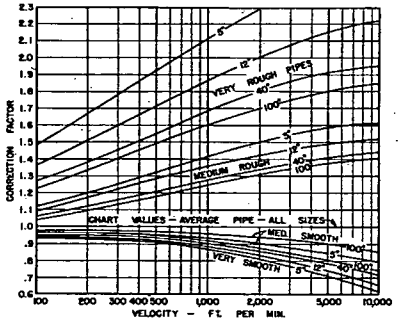

ductwork.[4] The correct friction loss for ducts of other than standard sheet-metal construction may be determined by multiplying the losses obtained from Figs. 2 and 3 by the factors found in Figs. 5 and 6.

Accurate experimental data on the absolute roughness for flexible tubing are not yet available. There is also little information on the friction loss in ducts lined with acoustical material. Until definite information is available, it is recommended that the correction factor for very rough pipes be used for uncovered soft material, and the factor for medium roughness be used for material behind perforated metal.

Example 1 illustrates the use of Fig. 3 to determine friction loss in a galvanized sheet-metal duct. *Examples 2, 3,* and *4* illustrate the use of Figs. 4, 5, and 6 in applying correction factors for ducts of other than sheet-metal construction and for air at high temperature.

Example 1: Determine the friction loss when circulating 10,000 cfm of air at standard density through 75 ft of 24-in. diameter galvanized duct.

Solution: Find 10,000 cfm on the left scale of Fig. 3 and move horisontally right to the diagonal line marked 24 in. The other intersecting diagonal shows that the velocity in the pipe is 3200 fpm. Directly below the intersection it is found that the friction per 100 ft is 0.50 in.; then for 75 ft the friction will be $0.75 \times 0.50 = 0.38$ in. In a like manner, any two variables may

To correct for pipe roughness multiply friction loss obtained from Figs. 2 and 3 by correction factor obtained from Fig. 5.

Fig. 5 .... Correction Factors for Pipe Roughness

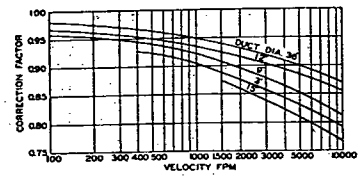

Fig. 6 .... Correction Factors for Aluminum Duct

be determined by the intersection of the lines representing the other two variables.

Example 2: If the duct in *Example 1* is very rough, instead of galvanized, with 40 joints per 100 ft, find the total friction.

Solution: On Fig. 5 find (by interpolation between 12-in. and 40-in. pipe) the intersection of the 24-in. *very rough pipe* line and the 3200 fpm velocity ordinate, and at the left margin read a correction factor of 2. The friction loss in the rough duct is therefore $2 \times 0.38 = 0.76$ in.

Example 3: If the duct in *Example 1* is made of aluminum, instead of galvanized iron, find the total friction.

Solution: On Fig. 6 find (by interpolation between 12-in. and 36-in. pipe) the intersection of the 24-in. line and the 3200-fpm velocity ordinate, and at the left margin read a correction factor of 0.91. The friction loss in the aluminum duct is therefore $0.91 \times 0.38 = 0.35$ in.

Example 4: Determine the friction loss in the duct of *Example 1*, if the temperature of the air transmitted through the duct is 200 F.

Solution: For $t = 200$ F, the density of the air is $\rho_s = 0.060$ lb per cu ft. Hence, the actual air-flow rate in the duct is

$$Q_s = \frac{10{,}000 \times 0.075}{0.060} = 12{,}500 \text{ cfm}$$

and the actual velocity

$$V = \frac{Q_s}{A} = \frac{12{,}500}{3.14} = 4{,}000 \text{ fpm}$$

With $Q_s = 12{,}500$ and $D = 24$ in., find $h_a = 0.77$ in. of water per 100 ft in Fig. 3 and $K = 0.835$ in Fig. 4. The friction loss under actual operating conditions is:

$$h_s = 0.835 \times 0.77 = 0.64 \text{ in. per 100 ft.}$$

The friction loss for 75 ft is then $0.75 \times 0.64 = 0.48$ in.

CIRCULAR EQUIVALENTS OF RECTANGULAR DUCTS

An air-handling system is usually sized first for round ducts. Then, if rectangular ducts are desired, their sizes are selected to provide flow rates equivalent to those of the round ducts originally selected.

A comprehensive study at the ASHAE Research Laboratory proved that for most practical purposes rectangular ducts of aspect ratios not exceeding 8:1 will have the same friction pressure loss for equal lengths and mean velocities of flow as a circular duct of the same hydraulic diameter. When duct sizes are expressed in terms of hydraulic diameter, and when equations for friction loss in round and rectangular ducts are equated for equal flow rate and equal length, Equation 6 giving the circular equivalent of a rectangular duct is obtained.[4]

Table 1 .... Values of Roughness ϵ for Different Pipes[a]

Pipe	Degree of Roughness	ϵ Roughness in Feet
Drawn Tubing	Very smooth	0.0000015
New Steel or Wrought Iron Pipe	Medium smooth	0.00015
Galvanized Iron	Average	0.0005
Average Concrete	Medium rough	0.003
Average Riveted Steel	Very rough	0.01

[a] Used in computing values for Fig. 5.

$$d_e = 1.30\frac{(ab)^{0.625}}{(a+b)^{0.250}} = 1.30\sqrt[8]{\frac{(ab)^5}{(a+b)^2}} \qquad (6)$$

where

a = length of one side of rectangular duct, inches.
b = length of adjacent side of rectangular duct, inches.
d_e = circular equivalent of a rectangular duct for equal friction and capacity, inches.

Table 2 gives the circular equivalents of rectangular ducts for equal friction and flow rate for aspect ratios not greater than 11.7:1 based on Equation 6.[4] Note that the mean velocity in a rectangular duct will be *less* than in its circular equivalent.

Multiplying or dividing the length of each side of a duct by a constant is the same as multiplying or dividing the equivalent round size by the same constant. Thus, if the circular equivalent of an 80 x 24 in. duct is required, it will be twice that of a 40 x 12 in. duct, or $2 \times 23.0 = 46.0$ in.

DYNAMIC LOSSES

Wherever eddying flow is present, brought about by sudden changes in the direction or magnitude of the velocity of the air flowing, a greater loss in pressure takes place than would occur in a steady flow through a similar length of straight duct having a uniform cross-section. The amount of this loss, in excess of straight-duct friction, is termed *dynamic loss*. Although dynamic losses may be assumed to be caused by changes in area actually occupied by the air flow, for convenience they are divided into two general classes: (1) those caused by *changes in direction* of the duct and (2) those caused by *changes in cross-sectional area* of the duct.

Dynamic losses vary substantially as the square of the mean velocity of the air, and are therefore conveniently expressed as a fraction of the velocity head:

$$H_d = C\left(\frac{V}{4005}\right)^2 \qquad (7)$$

where

H_d = dynamic pressure loss, inches of water.
V = mean velocity of air flow, feet per minute.
C = an experimentally determined constant (dynamic loss coefficient).

Where different areas are involved, subscripts are used to denote the area to which the coefficient applies, as C_1 for inlet area, C_2 for outlet area, and C_o for orifice area.

The dynamic loss coefficient C is dimensionless and represents the number of velocity heads lost at the conduit transition or bend. Values of the dynamic loss coefficient for elbows

Equation for Circular Equivalent of a Rectangular Duct[5]

$$d_e = 1.30\,\frac{(ab)^{0.625}}{(a+b)^{0.250}} = 1.30\,\sqrt[8]{\frac{(ab)^5}{(a+b)^2}}$$

where

a = length of one side of rectangular duct, inches.

b = length of adjacent side of rectangular duct, inches.

d_e = circular equivalent of a rectangular duct for equal friction and capacity, inches.

and other duct elements have been determined experimentally and are given in Tables 3 and 4. It should be noted, however, that absolutely reliable dynamic loss coefficients are not yet available for all duct elements and that the information available for pressure losses due to area changes is generally restricted to symmetrical area changes.

Fig. 7, which shows the relation of velocity pressure to velocity for standard air ($V = 4005\sqrt{H_v}$), can be conveniently used to find the total dynamic pressure loss for any duct element with known *dynamic loss coefficient* C.

PRESSURE LOSSES IN ELBOWS

Dynamic-loss coefficients are nearly independent of the air velocity and are affected by the roughness of the duct walls only in the case of bends, for which the dynamic losses are often grouped with the friction losses to facilitate design calculations. An ASHAE survey[6] of available data has indicated that the method of expressing the combined dynamic and friction losses due to an elbow as equivalent to the loss in a length L of similar straight duct is justified for design purposes, owing to the relation of the loss to the corresponding friction factor f.

Fig. 8 gives the *additional equivalent length* of duct in terms of widths W for elbows in rectangular ducts; Fig. 9 gives the *equivalent length* of duct in terms of diameters D for round ducts. When these curves for *additional equivalent length* are used, the straight lengths of duct between elbows should be measured to the intersection of their center lines.

Example 5: Use of Fig. 8 for the calculation of elbow losses.

Given the portion of a duct system shown in Fig. 10, it is required to determine the pressure loss between points A and D. Air at standard conditions is being supplied at the rate of 2000 cfm in a 6 by 24 in. galvanized duct of average construction. Elbows No. 1 and 2 have center line radii of 18 and 19 in., respectively.

Solution: For elbow No. 1 the radius ratio is $R_1/W_1 = 18/24 = 0.75$ and the aspect ratio is $H_1/W_1 = 6/24 = 0.25$. The additional equivalent length for elbow No. 1 in terms of W is obtained from Fig. 8; $(L/W)_1 = 11.5$. Thus $L_1 = 11.5 \times 24/12 = 23$ additional equivalent feet. Similarly for elbow No. 2, the ratio radius is $R_2/W_2 = 9/6 = 1.5$ and the aspect ratio is $H_2/W_2 = 24/6 = 4.0$; Fig. 8 gives $(L/W)_2 = 6$, so $L_2 = 6 \times 6/12 = 3$ additional equivalent feet.

The total length of the straight runs from A to D is $l = l_{A\text{-}1} + l_{1\text{-}2} + l_{2\text{-}D} = 7 + 20 + 5 = 32$ ft and the additional equivalent length due to the elbows is $L = L_1 + L_2 = 23 + 3 = 26$ ft. Thus the equivalent length of the system from A to D is $l + L = 32 + 26 = 58$ ft of 6 by 24 in. duct.

The diameter of a circular duct, equivalent in friction and capacity to this rectangular duct, is 12.4 in. as given by the table of circular equivalents, Table 2. At a delivery rate of

2000 cfm, the ASHAE FRICTION CHART, Fig. 3, gives a loss of 0.6 in. of water per 100 ft. of 12.4-in. diameter duct. Thus the loss from A to D is $0.6 \times 58/100 = 0.348$ in. of water.

The use of elbows of radius ratio, $R/W = 1.5$, is considered good practice with respect to both installation and operation. In a given rectangular duct 6 by 24 in., for example, the elbow loss will be greater for a flat bend where the aspect ratio, $H/W = 1/4$, than if the bend of the same radius ratio had been made in the plane of the narrow dimension giving an aspect ratio, $H/W = 4$.

Data now available for losses in compound bends,[7, 8] where two or more elbows are close together, do not warrant refinement of design calculations beyond use of the sum of the losses for the individual elbows. Actually, the losses are somewhat less than for two bends when they are placed to form a U bend, and somewhat more when they form a reversed, or S bend.

Where angles of other than 90-deg bend are encountered, the loss may be considered as directly proportional to the

angle of bend. Losses[9] for elbows discharging air directly into a large space are higher than those given for elbows within duct systems.

Turning vanes may be advantageously employed in elbows, both to reduce the pressure loss and to provide a more uniform velocity distribution downstream from the bend.[9, 10] Vanes and concentric splitters are particularly recommended where miter elbows are used, because even the simplest vane forms will produce a substantial saving in pressure loss.

PRESSURE LOSSES IN DIVIDED-FLOW FITTINGS

Analysis[11] of available data for losses at branch take-offs indicates that the loss in the straight-through section is about 35 percent of that for abrupt enlargement (1) involving the same ratios of velocities and (2) that the loss in the diverted-flow section depends on the ratio of the velocity of diverted flow to total flow and on the angle the take-off makes with the main, and is at a minimum for a natural relation that exists between these two variables. Some representative branch losses are given in Table 5.

LOSSES DUE TO AREA CHANGES

Area changes in ducts, generally unavoidable, are necessitated frequently by the building construction or changes in the volume of air carried. Experimental investigations[13, 23, 14, 12] of pressure changes, and pressure losses at changes of the area of duct cross-sections, indicate that the excess pressure loss over the normal friction loss is a dynamic loss due to a faster stream expanding into a slower stream, as determined by the actual areas occupied by the flow rather than the areas of the duct. No perceptible dynamic loss is due to the converging of the air stream itself where the flow is contracted, but the air stream continues to converge beyond the edge of the contraction and reaches a minimum at the *vena contracta*. For contraction, therefore, the dynamic loss is caused by expansion from the vena contracta to the full area following the contraction. Abrupt contraction in area may therefore be considered as a special condition of abrupt enlargement. Fig. 11 illustrates (*a*) abrupt enlargement and (*b*) abrupt contraction.

For a sudden symmetrical enlargement, a theoretical expression for the loss is

$$H_e = \left(\frac{V_1 - V_2}{4005}\right)^2 = \left(1 - \frac{A_1}{A_2}\right)^2 \left(\frac{V_1}{4005}\right)^2 = C_1 \left(\frac{V_1}{4005}\right)^2 - C_2 \left(\frac{V_2}{4005}\right)^2 \quad (8)$$

where

H_e = pressure loss due to sudden enlargement, based on standard air, inches of water.
V_1 = velocity of standard air in the inlet duct, feet per minute.

Fig. 11 .... Air Flow at Abrupt Enlargement or Contraction of Air Stream

V_2 = velocity of standard air in the outlet duct, feet per minute.
A_1 = area of the inlet duct, square feet.
A_2 = area of the outlet duct, square feet.
C_1 = loss coefficient based on area A_1.
C_2 = loss coefficient based on area A_2.

For a gradual symmetrical enlargement, Equation 8 changes to

$$H_{ge} = C_r\left(\frac{V_1 - V_2}{4005}\right)^2 = C_1C_1\left(\frac{V_1}{4005}\right)^2 = C_2C_2\left(\frac{V_2}{4005}\right)^2 \quad (9)$$

where

H_{ge} = pressure loss due to gradual enlargement, inches of water.
C_r = coefficient of loss, as ratio of loss to loss for abrupt expansion, dependent upon the total angle included between the sides of the duct.

The loss for a sudden symmetrical contraction can be expressed as

$$H_c = C_2\left(\frac{V_2}{4005}\right)^2 = C_1\left(\frac{V_1}{4005}\right)^2 = C_c\left(\frac{V_c}{4005}\right)^2 \quad (10)$$

where

H_c = pressure loss due to sudden contraction (Fig. 10b).
C_c = loss coefficient based or orifice area A_c.
V_c = velocity of air through orifice, feet per minute.

The loss for a gradual symmetrical contraction can be similarly expressed as

$$H_{gc} = C_2\left(\frac{V_2}{4005}\right)^2 \quad (11)$$

where the coefficient of loss C_2 depends on the included angle of the sides of the duct and the sharpness of the edges at the junction of taper to following duct section.

DUCT DESIGN

The following discussion refers to ducts for commercial and industrial heating, ventilating, and air-conditioning systems of the central station type. The design procedures given yield the static pressure required to overcome the resistance of the ductwork, including the supply outlets and return intakes. The fan selected for the duct system must not only produce this pressure but also the additional pressure required by the central equipment such as washers or spray chambers, heating or cooling coils, and filters. Pressure losses of these components should be obtained from the manufacturers' catalogs.

Special duct design procedures for heating ducts used in residences can be found in Chapter 18 Warm Air Heating Systems. The design of ducts in industrial exhaust systems is discussed in Chapter 52.

General rules which should be followed in the design of ducts are:

1. The air should be conveyed as directly as possible at the permissible velocities to obtain the desired results with minimum noise and greatest economy of power, material, and space.

2. Sudden changes in the direction or velocity of the air should be avoided. When sudden changes are necessary at bends, turning vanes should be used to minimize the pressure loss.

3. Diverging transition pieces should be made as gradual as practicable. As shown in the section on area changes, losses in abrupt enlargements are high and therefore such transitions should be avoided. The included angle of divergence for enlargement should not exceed 20 deg. Losses in contractions are low but the included angle of convergence should not be greater than 60 deg.

4. Where the greatest air carrying capacity per square foot of sheet metal is desired, rectangular ducts should be made as nearly square as possible. Aspect ratios (ratio of width to depth) greater than 8 to 1 should be avoided. Where possible, a ratio of 4 to 1 or less should be maintained.

5. Ducts should be constructed of smooth material, such as steel or aluminum sheet metal. For ducts made from other materials, proper allowance for the change in roughness should be made.[8]

6. Through the design procedures which follow, a reasonably precise estimate of the flow resistances offered by the system can be obtained. However, it should be recognized that in actual installations, resistances may vary considerably from the calculated values because of variation in the smoothness of materials, types of joints used, and the ability of workmen to fabricate the system in accordance with the design. Fans and motors should therefore be selected to provide at least a slight factor of safety, and dampers should be installed in each branch outlet for balancing the system.

Procedure for Duct Design

The general procedure is as follows:

1. Study the plan of the building and arrange the positions of the supply outlets to provide proper distribution of air within each space. Select outlet sizes from manufacturers' catalog data.

2. Draw a sketch of the most convenient system of ductwork, connecting the supply outlets and return intakes with the central station apparatus, taking cognizance of the building construction, avoiding all obstructions in steel work and equipment, and at the same time maintaining a simple design.

3. Calculate the sizes of all main and branch ducts by one of the procedures given in the following section.

4. Determine the total pressure requirement of the supply and return duct systems. Although the loss in total pressure of each duct run connecting the fan and each supply outlet (or return intake) should be calculated and made the same for all runs, ordinarily only the pressure loss of the duct run apparently having the greatest resistance is referred to as the pressure loss of the duct system. Dampers are relied upon for balancing the system.

Design Velocities

It is not possible to give specific rules for selecting duct velocities, but the velocities given in Table 6 have been found to give satisfactory results in designing conventional systems. Since the fan horsepower increases approximately as the square of the velocity, and noise generation increases with static pressure, velocities should be kept low for quiet and economical operation. On the other hand, as evident from Equation 3, at a given flow rate the duct size increases with decreasing velocity. For multistory buildings, it is sometimes possible to reduce the height between floors by using very small ducts, thereby effecting a considerable reduction in building investment cost. The various space-saving systems which are becoming increasingly numerous are discussed in the section High-Velocity Systems in Chapter 19 Central Systems for Air Conditioning. The design of high-velocity ducts is discussed briefly in a later section, Design of High-Velocity Ducts, in this chapter.

DESIGN METHODS

In the design of air duct systems, three methods are employed: (1) *velocity-reduction*, (2) *equal-friction*, and (3) *static-regain*. The three methods and their refinements represent different design levels of accuracy and complexity, and they should be selected, therefore, to suit the application. Simple duct systems may be designed as quickly and easily as possible, but for large installations the system static-

[a] These velocities are for total face area, not the net free area; other velocities in table are for net free area.

pressure requirement must be determined as precisely as possible, the most accurate method being recommended.

Velocity-Reduction Method

This method consists of selecting the velocity at the fan discharge and designing for progressively lower velocities in the main at each branch duct. With the selected velocities and known air-flow rates, the various duct diameters are read directly from Figs. 2 or 3, and the equivalent rectangular sizes are obtained from Table 2. The pressure loss of the run having apparently the highest resistance is determined by adding the straight pipe, elbow, and transition losses; this total value represents the fan static pressure required for the supply-duct system. The return-air system is sized similarly, starting with the lowest velocities at the return intakes and increasing them progressively in the direction of the fan inlet. Dampers are relied upon for balancing the system.

A refinement of this method is to size the several branch ducts to dissipate the pressure available at the entrance to each. The pressure loss of the ductwork between the fan and first branch take-off is subtracted from the now known fan static pressure to obtain the available pressure at each junction. By trial, a branch velocity is found that results in the branch pressure loss being equal to, or somewhat less than, that available. The procedure is repeated for each branch.

If the fan is specified so that the static pressure available for the ductwork is known, the method consists of finding, by trial, the velocities in the main duct that will result in a pressure loss equal to the pressure available. The branch ducts are then sized as previously explained if such a refinement is deemed necessary.

The merits of the *velocity-reduction* method are that (1) duct sizes are determined very easily, and (2) velocities can be limited to those known to be safe from causing noise problems. Its weaknesses are: (1) proper choice of velocities requires experience and judgment, and (2) the designer cannot always determine by inspection which run probably has the highest resistance.

Equal-Friction Method

The principle of this method is to make the pressure loss per foot of length the same for the entire system. With this method little balancing is required for symmetrical layouts in which all runs have about the same resistance. For layouts having both short and long runs, the shortest run will require considerable dampering.

Usual practice is to select the velocity in the main duct near the fan from the standpoint of noise for the particular application. Since the flow rate (cfm) is known, this establishes a value of friction loss per 100 ft of duct in Figs. 2 or 3. This same friction loss value is maintained throughout the design. For example, the flow rate in the main after the first branch take-off is reduced by that handled by the branch. Therefore, proceed vertically downward in Figs. 2 or 3 to the new flow rate value, and read the velocity and diameter. Note that the velocity is reduced by this procedure. An advantage of this method is that it *automatically* reduces the duct velocities in the direction of flow, thereby insuring that noise will not be a problem. The equivalent rectangular size of any diameter is obtained from Table 2. By continuing the procedure, all sections, including branch ducts, are sized from Figs. 2 and 3 at the same friction loss per foot of actual length.

After sizing the system the pressure loss of the run having apparently the highest resistance is calculated. In so doing, the pressure losses of all elbows and transitions are included, and are expressed in terms of *equivalent length* of straight pipe.

The principal limitation of the *equal-friction* method is that it does not differentiate between runs having several transitions, elbows, etc., and runs having none. Only the *actual length* of duct is considered; this and the flow rate fix the duct size. Moreover, when computing the system resistance, care must be exercised that the pressure losses of transitions, elbows, etc., are included and added to the straight pipe losses.

If the pressure available for the ductwork is known, as it is for packaged equipment, this pressure can be divided by the total equivalent length of the run apparently having the highest resistance to obtain a design friction loss value per foot, for use with Fig. 2 or Fig. 3. Hence, for these applications, it is not necessary to select an initial velocity. However, the method then has the weakness that the resistances of fittings must be expressed in terms of *equivalent length*. Since transitions, elbows, etc., have predominantly dynamic losses, the equivalent length of a particular fitting varies considerably with its actual size. Note, for example, the values for elbows in Fig. 7 of Chapter 18 are related to duct size, and note also, that the elbow losses in Fig. 9 of this chapter are given in terms of the number of *diameters*. Hence, when the available pressure is known, the method requires that the duct size be estimated in advance. The calculated duct size should therefore be compared with the initial estimate, and if considerably different, a recalculation should be made using the calculated size.

Less dampering is required if the method is modified so that only the main duct is sized by the equal-friction method. The fan is selected for this total duct resistance and the pressure available at each branch take-off is found in the

manner described for the *velocity-reduction* method. The pressure available at each branch is divided by its equivalent length, in hundreds of feet, to obtain a design friction loss value for use with Fig. 2 or Fig. 3 in conjunction with the branch flow rate. The branch ducts are therefore sized as nearly as possible to dissipate all of the available pressure.

When using this modified method, care should be exercised that the velocities in short branches do not become excessive from a noise standpoint. This is easily guarded against during the design process, because the velocity can be read directly from the friction chart. If it is excessive, move horizontally to the left on the chart and select a diameter which yields a reasonable velocity. The damper for this run will have to dissipate the excess pressure. Since ductwork attenuates noise to some extent, the damper should be located as close to the main as possible. Sound treatment for this branch should also be considered. An alternative solution may be to revise the duct layout to increase the resistance of the run, for example, by relocating the branch take-off so that the total duct length is increased.

Example 6: (Equal-Friction Method). A duct layout is shown in Fig. 12. Outlets Nos. 1 and 2 deliver 750 cfm each and outlet No. 3 delivers 1000 cfm. Selecting a velocity of 1600 cfm in Section *A*, size the duct system and determine its static-pressure requirement.

Solution: The total cfm to be handled is 2500 cfm. From Fig. 3, with 2500 cfm and 1600 fpm velocity, read a diameter of 17 in. and a friction loss of 0.2 in. of water per 100 ft. By subtraction, the flow rate in Section *B* is 1750 cfm. Along the 0.2 friction line in Fig. 3, all of the ducts can be sized immediately because the flow rates are known. Results are presented in Table 7.

The rectangular equivalents were selected from Table 2 with the objective of having the same duct depth for all three branch runs.

The duct run to outlet No. 3 has the highest apparent resistance. It is decided to fabricate the elbow in Section *C* with a radius ratio of 1.2; hence, from Fig. 8 with $H/W = 1.9$, $L/W = 8$. Since $W = 1.25$ ft (15 in.), the additional equivalent length due to the elbow L is 10 ft. The total equivalent length of the run is therefore $(20 + 10 + 15 + 10 + 15) = 70$ ft. Therefore, at 0.2 per 100 ft the duct resistance is $0.2 \times 0.70 = 0.14$ in. of water. Adding to this the outlet pressure of 0.12 in., the static-pressure requirement of the duct system is 0.26 in. of water. The design is now complete, and dampers will be relied upon for adjusting the outlets to the design flow rates.

If refinement is deemed necessary, the modified method can be applied to Sections *D* and *E*. First, the static pressures available at the junctions with the main of the Section *D* and *E* branch ducts are obtained. For Section *D* it is the system pressure of 0.26 minus the friction pressure loss in Section *A*. The latter is $0.20 \times (20/100) = 0.04$; hence, the pressure at the entrance of Section *B* is 0.22 in. of water. Deducting the outlet pressure loss of 0.12, that available for the ductwork is 0.10. Assume the equivalent lengths of the branch take-off and the elbow to be 10 ft each. The total equivalent length of Section *D* is then $(10 + 10 + 10 + 5) = 35$, and the friction loss per 100 ft required to dissipate 0.10 in. of water is $0.10 \times (100/35) = 0.29$. With this unit friction loss and a flow rate of 750 cfm, Fig. 2 yields a diameter of 10.0 in. and a velocity of 1380 fpm.

D	750	0.2	10.7	1190	12 × 8
E	750	0.2	10.7	1190	12 × 8

Section *E* is sized in a similar manner. The pressure available is 0.26 minus the friction loss in Sections *A* and *B*; hence, 0.20. With the outlet pressure loss of 0.12 deducted, the available ductwork pressure loss is 0.08 in. Assuming that the branch take-off loss is equivalent to 10 ft of duct, the total equivalent length is 20 ft. The required friction loss is $0.08 \times (100/20) = 0.40$. With this unit friction loss and a flow rate of 750 cfm, Fig. 2 yields a diameter of 9.4 in. and a velocity of 1580 fpm. An equivalent rectangular size is 9×8 in.

Comparing these results with those in Table 7, it is evident that the modified method has reduced the size of Section *D* somewhat and that of Section *E* considerably. The reduced sizes accomplish more economically what would otherwise have to be done with dampers.

Static-Regain Method

Consider a straight run of duct with several branch take-offs attached. The flow rate of air along the run is progressively reduced by the amount diverted into each successive take-off. If, for example, the size of the run were the same throughout its length, the velocity would become progressively less in accordance with Equation 3. When velocities are reduced, a conversion of velocity pressure into static pressure occurs (as well as a loss in total pressure). The principle of the *static-regain* method is to size a duct run so that the increase in static pressure (regain) at each take-off junction just offsets the pressure loss of the succeeding section of the run.

The method provides a convenient means of designing a long run of duct having several take-offs so that essentially the same static pressure exists at the entrance to each branch. If, instead of branch ducts, supply outlets are connected directly to the run, then essentially the same static pressure will exist behind each outlet. As a consequence, outlet selection and system balancing is simplified. The method is particularly suited to large installations having several long runs of duct, with each run having many take-offs or supply outlets attached. For this type of application, little or no dampering is ordinarily required to balance the system.

The initial velocity in the main duct is selected from noise and pressure loss considerations, and the branch ducts are sized by the modified equal-friction method.

If the distance between branch take-offs is either very small or very great, it may not be feasible or economically desirable to design for the same static pressure at each junction. In such cases, the method can be used to size the main for either a progressively lower static pressure (net static-pressure loss) or a progressively higher pressure (net static-pressure gain).

If no friction or dynamic losses occurred at the junction, there would be no loss in total pressure, and the change in velocity pressure would be completely converted into a regain (rise) in static pressure, which for standard air would be:

$$P_t = \left(\frac{V_1}{4005}\right)^2 - \left(\frac{V_2}{4005}\right)^2 \qquad (12)$$

where

P_t = theoretical static-pressure regain, inches of water.
V_1 = velocity in main upstream of branch, feet per minute.
V_2 = velocity in main downstream of branch, feet per minute.

Under the best practice, 0.7 to 0.8 of the change in velocity pressure is actually recovered, but for practical design an average recovery of 0.5 is assumed. Hence, the actual regain P_r is:

$$P_r = 0.5\left[\left(\frac{V_1}{4005}\right)^2 - \left(\frac{V_2}{4005}\right)^2\right] \qquad (13)$$

Design charts based on Equation 13 and rectangular ducts having aspect ratios of 3 to 1 or less are presented in Figs. 14 and 15.

The *duct length* of any section should include the equivalent length of any elbows or transitions within the section. The charts apply to constructions where regain takes place unaccompanied by radical change in direction; namely, to *straight-through sections* of divided-flow fittings.

Example 7: (Static-Regain Method). The duct shown in Fig. 13 handles 8000 cfm. Determine the duct sizes in Section *A*, *B*, *C*, *D*, *E*, *F*, and *G*, maintaining an operating pressure of 0.12 in. water in the duct behind each outlet. Find the total pressure loss of the system.

Solution: The following nine steps indicate the solution:

1. Assume the velocity in Section *A* to be 1500 fpm. This results in an initial duct size of 48 x 16 in. The 16-in. duct depth will be maintained throughout the system.

2. The circular equivalent of a 48 x 16-in. duct is 29.2 in. (from Table 2), and with 8000 cfm flowing in this duct, the friction loss from Fig. 3 is 0.13 in. per 100 ft.

3. To size the branch ducts, determine the shortest equivalent length of duct up to the first outlet. Section $B = 25$ ft; Section $F = 10$ + equivalent length of elbow. Assume the width of the duct in Section *F* to be 15 in.; therefore $H/W = 15/16 = 0.94$. Also the radius of the elbow should not be less than the width ($R/W = 1.00$), resulting in an equivalent length L, from Fig. 8, of $10 \times (15/12) = 12.5$ ft. Equivalent length of Section $F = 10 + 12.5 = 22.5$ ft. Therefore, Section *F* being shorter than Section *B*, size Section *F* first, using the same friction rate as in Section *A*, 0.13 in. per 100 ft. In Fig. 2, with 2000 cfm and a friction rate of 0.13 in., find an equivalent diameter of 17 in. for Section *F*. The rectangular equivalent of a 17-in. duct is 15 x 16 in. (from Table 2), resulting in a velocity of 1200 fpm.

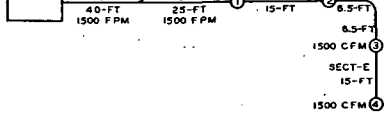

Fig. 13 .... Duct Layout for *Example 7*

Table 8 .... Tabulation of Results (*Example 7*)

Section	Air Volume Cfm	Equivalent Length Ft	Velocity Fpm	Rectangular Duct In.	Dia In.	Friction Per 100 ft In. H_2O	Net Pressure Loss In. H_2O
A	8000	40	1500	48 × 16	29.2	0.13	0.05
B	6000	25	1500	36 × 16	—	—	0.03
C	4500	15	1300	31 × 16	—	—	0
D	3000	26[a]	1040	26 × 16	—	—	0
E	1500	15	860	16 × 16	—	—	0
F	2000	22.5	1200	15 × 16	17	0.13	.03
G	1000	15	900	10 × 16	—	—	0

[a] Includes 13 equivalent ft for elbow (see Step 7 in *Example 7*).

Note: The shorter equivalent length line is sized first to prevent velocities in other branches from exceeding recommended values.

4. Loss in Section $F = 0.13 \times 0.225 = 0.03$ in. water.

5. Since the operating pressure of Outlet 1 is to be the same as that of Outlet 6, the loss in Section *B* must equal the loss in Section *F*. Using the Static-Regain Chart, Fig. 15, size Section *B* for a net loss of 0.03 in. water.

The procedure for using these charts is indicated by arrowheads and dashed lines on Fig. 15. Proceed as follows:

a. Locate the velocity of the preceding (upstream) duct section along the velocity scale on the left margin (1500 fpm).

b. Proceed horizontally to the air volume abscissa (6000 cfm).

c. Proceed parallel to the curved lines to intersect the diagonal base line.

d. Go vertically to the net loss desired (0.03 net loss).

e. Go horizontally to the air velocity base line.

f. Proceed parallel to the curved lines to intersect ordinate for 25-ft duct length.

g. Move horizontally to the air velocity scale and read the velocity in the downstream section of duct (1500 fpm).

6. This procedure is repeated for Section *C* except that the *no gain or loss* line is used in previous Step 5 d. Outlet No. 2 will then have the same static pressure behind it as Outlet No. 1, thus fulfilling the problem condition of the same operating pressure for all outlets.

7. At this point, the equivalent length of the elbow in Section *D* should be estimated. Its width will be somewhat less than that of Section *C*. Assume $W = 26$ in.; hence $H/W = 16/26 = 0.6$. With a typical radius ratio of 1.25, from Fig. 8, $L/W = 6$; therefore $L = 6 \times (26/12) = 13$ ft. Adding this to the actual length of Section *D* results in a total equivalent length of 26 ft.

8. Using the *no gain or loss* line in Fig. 14, size Sections *D*, *E*, and *G*. Results are listed in Table 8.

9. The total pressure loss of the system is the sum of the losses in Sections *A* and *B* (or *F*) and the outlet operating pressure:

Loss in Section *A*	= 0.13 × 0.40 = 0.05
Loss in Section *B* (or *F*)	= 0.03
Outlet Operating Pressure	= 0.12
Total Pressure Loss	= 0.20 in.

DESIGN OF HIGH-VELOCITY DUCTS

The transmission of air at high velocities, though common in industrial exhaust systems for many years, has gained wide acceptance in comfort air-conditioning and ventilation systems in the past few years only. This acceptance is due partly to the use of improved fans and of special sound-attenuation and control equipment, and partly to improved design and installation methods based upon a better understanding of the general problems connected with the design

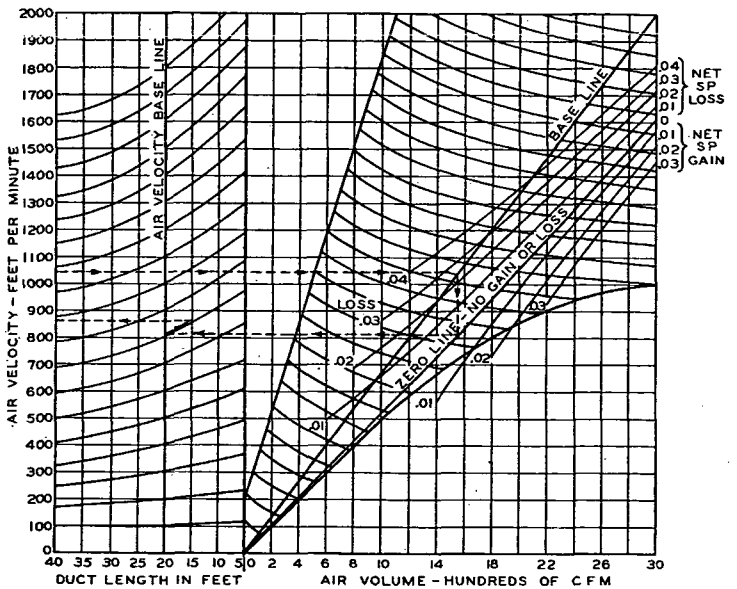

Fig. 14 .... Static-Regain Chart*-For Determining Velocity in Ducts Carrying 0 to 3000 Cfm

* Based on Equation 13.

and installation of high-velocity air-conditioning systems.[16-27] For general information on these systems, the reader is referred to Chapter 19—Central Systems for Air Conditioning.

The design of high-velocity duct systems involves a compromise between reduction of duct size and the consequent necessity for higher fan horsepower. While the size of the ducts and hence the air velocities are governed in large part by the available building space, the maximum velocities given later in this section should not be exceeded without careful examination of all factors involved.

The following *general rules* will prove helpful in designing high-velocity duct systems:

1. The same general rules which apply to conventional duct design also apply to high-velocity duct design. (See Section—Design Methods.)

2. When designing high-velocity systems, static regain must be accounted for. Latest data indicate that approximately 85 percent of the original velocity pressure can be regained. This may easily account for 1 in. water static pressure and, therefore, a method which does not take into consideration static regain will result in the selection of oversized fans and motors.

3. Proper sound control must be provided. To take care of low-frequency fan noise, a sound attenuator must usually be installed after the fan. When acoustic terminal devices are not used, attenuator chambers or sound-lined ducts must be installed after mixing valves, in order to attenuate duct and valve noise to acceptable levels.

4. Air velocities in main ducts may vary from 2500 fpm in some installations to over 6000 fpm in others. Corresponding maximum branch-duct velocities will then vary from 2000 fpm to 4500 fpm.

One general procedure for duct sizing used by many designers is to maintain velocities approximately constant in main riser and trunks until the friction loss reaches 1 in. per 100 feet. When further reductions in duct size take place, velocities are selected to maintain a constant friction loss of 1 in. per 100 feet. Final branches are generally designed with constant area so that decreasing capacity and velocity will allow full static regain. With this procedure the final velocity of an end branch duct may be 1000 fpm, or even lower.

The above procedure is not intended to be exclusive, since ducts may also be designed by other methods. (See foregoing section.)

5. Round ducts are used to a great extent in high-velocity systems, because they are easier to seal and do not require bracing or stiffening. However, it is commercially practicable to utilize rectangular ductwork in high-velocity systems. The duct aspect ratio should be kept low and should not exceed 4:1. The duct must be rigidly braced to withstand the static pressure of the system. All longitudinal seams and cross-seams must be made tight. Mastic sealing compounds and special tapes are available as less expensive substitutes for positive seals such as soldering or welding. (See Duct Construction Details.)

6. Low-loss take-offs and fittings should be used. Rigid turning vanes should be installed in all rectangular duct right-angle elbows. In round ducts, turning vanes should be avoided and long-radius elbows used instead. Both 90-deg and 45-deg duct take-offs are used. However, the use of conical take-offs or angular take-offs is recommended, in order to keep duct friction as low as possible.[28]

7. Duct dampers are not required in the inlet connections to an acoustic terminal device. Capacity dampering at each outlet can be adjusted by means of the acoustic terminal damper. A branch duct supplying air to a number of acoustic terminals may be equipped with a branch-line balancing damper as an aid in field balancing. In a single-duct system, the branch-line damper may be manually adjusted. In a dual-duct system, the branch-line balancing damper may be a static-pressure regulating damper controlling the pressure in the branch-line duct. In this manner the branch-duct capacity may be raised or lowered by adjusting the setting on the branch-duct damper. Face dampers on the two decks of a one-fan dual-duct system also may be used as static-pressure regulating dampers. An inlet-vane damper on the fan is usually effective for system capacity control.

Control

In primary-air high-velocity systems, it is not necessary to control static pressures in order to prevent static-pressure unbalance, because this system operates with constant air volume. In all-air high-velocity systems operating with variable air flow, some control of static pressures may be required in order to prevent *static-pressure unbalance*, which is a large deviation from design static pressure at the inlet of a terminal, caused by large deviations in air flow.

In single-duct high-velocity systems, operating with changing air volume, the variations in static pressures can be limited by:

a. Static-pressure controllers operating dampers in the air-distributing-system.

b. Static-pressure controllers operating inlet vane dampers on the fan.

c. Zoning and changing air-supply temperature in response to static-pressure changes.

In dual-duct systems, the daily and seasonal variations in heating and cooling loads produce constantly changing demands for cold and warm air, causing a wide variance in flow and consequently in duct static pressures. It is, therefore, necessary to control the total fan delivery and in some cases the duct static pressure to limit pressure at the terminals.

At present, there are three methods used by the industry to control static pressures in dual-duct systems:

a. By dampers operated by static-pressure regulators located at critical points in the air-distributing system. The number, arrangement, and location of such dampers and static taps are dictated entirely by the complexity of the air-distributing systems, the initial fan pressure, and the particular fan characteristics.

b. By static-pressure controllers, regulating cold and warm air temperatures in order to limit the variations in the air flow in individual ducts. This method is applicable to centrally zoned systems and may involve an increase in total fan capacity.

c. By volume regulators in each individual air-mixing valve or acoustic terminal device. When this method is used, fixed volumetric delivery is maintained at each outlet, and the system characteristics remain constant through the entire range of operation.

Performance and pressure-volume characteristics of dual-duct systems are discussed in the paper by N. S. Shataloff.[28] In the other papers, listed in the reference section of this chapter, may be found further discussions of the types of air-conditioning systems which use high-velocity ducts. (References 16–23 and 25–27.)

Longitudinal standing seams inside with 1 1/4 × 1 1/4 × 1/8 in. angles on 2 ft centers.
					Over 96	1 1/4 in. standing S cleat, bar slip, pocket lock reinforced with 2 × 2 × 1/4 in. angles, or companion angles on 4 ft centers. 1 1/4 in. standing S cleat, bar slip, pocket lock reinforced with 2 × 2 × 1/8 in. angles, or companion angles on 8 ft centers with 2 × 2 × 1/4 in. angles on 2 ft centers. 1 1/4 in. standing seams with 2 × 2 × 1/4 in. angles on 2 ft centers. Longitudinal standing seams inside with 2 × 2 × 1/4 in. angles on 2 ft centers.

Note: Where special rigidity or stiffness is required, ducts should be constructed of metal two gage numbers heavier e.g., use 22 gage instead of 24 gage. Ducts larger than 96 in. require special field study for hanging and supporting methods. Other joint construction of equivalent mechanical strength and airtightness may be used. Recommended methods of fastening bracing to ductwork include riveting, bolting, and tack welding. Bracing, stiffening members, or angle connections for copper ductwork, where exposed to the weather, should be of brass or aluminum, of suitable thickness for strength.

DUCT CONSTRUCTION DETAILS

The recommended gages for steel (or iron), aluminum, and copper sheet-metal rectangular ducts are given in Table 9. No general agreement has yet been reached as to the exact limits of the classifications *high pressure, medium pressure,* and *low pressure* shown in Table 9. Suggested ranges of static pressures *in the duct system* for these classifications are:

Low Pressure = up to 1½ in. water.
Medium Pressure = 1½ in. to 4 in. water.
High Pressure = 4 in. to 8 in. water.

It should be noted that these values are the pressures existing in the duct, not the total pressure at the fan.

Table 10 .... Recommended Duct Construction for Round and Flat-Oval Ducts[a, b]

Steel U.S. Std. Gage		Size Dia or Max Width	Bracing on Flat Surface
Round	Flat-oval		
24	22	To 10 in.	None
22	20	11 to 20 in.	1 1/4 × 1 1/4 × 1/8 in. angle or 1 1/2 × 1/2 × 1/8 in. channel on 4 ft centers.
20	18	21 to 40 in.	1 1/2 × 1 1/2 × 1/8 in. angle or 2 × 1/2 × 1/8 in. channel on 4 ft centers.
18	16	41 to 60 in.	2 × 2 × 1/8 in. angle or 2 1/2 × 5/8 × 3/16 in. channel on 2 ft centers.
16	14	61 in. and over	2 × 2 × 1/8 in. angle or 2 1/2 × 5/8 × 3/16 in. channel on 2 ft centers.

[a] All fittings should be of same gage as pipe or heavier.
[b] Satisfactory for pressure in duct up to 10 in. water.

The recommended gages for steel (or iron) sheet-metal round or flat-oval ducts are given in Table 10.

Steel or iron sheets are specified according to the manufacturers or U. S. Standard Gage System. Aluminum sheets are specified according to the American or Brown & Sharpe Gage System. Copper sheets are usually specified by the weight in ounces per square foot. Weights of black and galvanized-steel and -iron sheets per square foot of surface for various gages are given in Table 11. Similar data for 2S aluminum sheets will be found in Table 12. Weights of standard copper sheets are given in Table 13. In calculating the total weight of a given length of ductwork from these tables, it is customary to add 15 percent to the weight to cover hangers, slips, and scrap. Duct bracing or stiffening members should be calculated separately.

Rectangular ducts are generally constructed by breaking the corners and grooving the longitudinal seam, although some fabricators still use the standing seam. Elbows and transformation sections are generally formed with Pittsburgh corner seams because this seam is easier to lock in place than the double seam, but double seams are equally acceptable. The constructions of these various seams, as well as the types of girth connections, are shown in Fig. 16. The application of the various slips, connections, and bracing is outlined in Table 9. The end slip may be used wherever *S* slips are recommended.

Designs *M* to *P* of Fig. 16 are for flush-type seams on ductwork where joints are to be concealed. For smooth external appearance the seams may be filled with suitable filler. Screws or rivets used should be of oven-head type.

Round and flat-oval ducts should be fabricated in accordance with the recommendations given in Table 10. Sections may be assembled using beaded couplings, swaged ends, or beaded and crimped small ends. Sections are held in place, using suitable sealers, with sheet-metal screws or rivets, or are welded together.

Spiral conduit is acceptable in place of round or flat-oval duct, with recommended gages shown in the following table:

Diameter, Inches	Recommended U. S. Std. Gage
3 to 8	Not lighter than 26 gage
9 to 24	Not lighter than 24 gage

Aluminum sheets of the 2S- and 3S-type alloy and ¾ hard temper are readily workable, and can be used for practically all ductwork. The 2S type (commercially pure aluminum) is suitable for all, except very large ducts. For large ducts, where more strength is desired, the 3S alloy with ¾ or ½ hard temper is frequently used. The higher tempers, particularly full hard, do not have the formability of the lower tempers. Joints can be of any of the standard designs, and can be fabricated in the same manner as iron. Repeated sharp bending and rebending should be avoided, as aluminum has a tendency to crack under such treatment. Aluminum of 16 B. & S. gage or heavier can readily be welded by the metallic arc or acetylene process. Riveting is done in the same manner as in iron or steel sheet. Self-tapping screws tend to loosen because of the softness of aluminum.

The construction of elbows and changes of shape cannot be definitely outlined, because of the varied conditions en-

[a] Variations from these weights must be expected in practice.

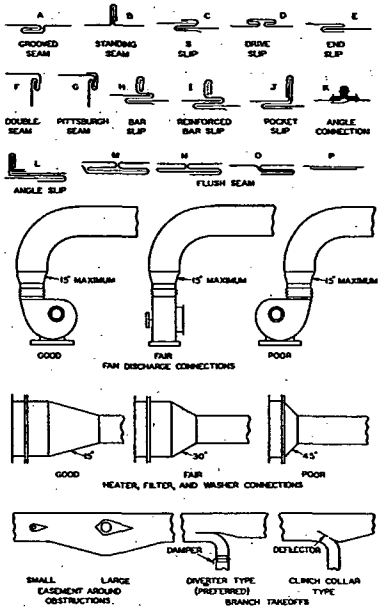

Fig. 16 .... Sheet-Metal Duct and Arrangement Details

countered in the field, but in general, long-radius elbows and gradual changes in shape tend to maintain uniform velocities accompanied by decreased turbulence, lower resistance, and a minimum of noise.

Heavy canvas connections are recommended on both the inlet and outlet to all fans. Self-vulcanising adhesive tapes are available for this purpose and for sealing joints in duct-work. Where a fire hazard exists, the material used must satisfy the requirements of any codes or authorities having jurisdiction. The fan discharge connections shown in Fig. 16 are marked *good*, *fair*, and *poor* in the order of the amount of turbulence produced. An inspection of the heater connections shown in Fig. 16 will readily show that uniform velocity through the heater cannot be expected in the diagram noted *poor*. When obstructions cannot be avoided, the duct area should never be decreased more than 10 percent, and then a *streamlined* collar should be used. Larger obstructions require an increase in the duct size in order to maintain as nearly uniform velocity as possible. Branch take-offs should always be arranged to cut or slice into the air stream in order to reduce as far as possible the losses in velocity head.

Wherever ducts pass through fire walls or connect two fire areas of a building, automatic fire dampers should be provided. For design of such dampers and other fire-protective details, see Pamphlet No. 90A of the National Board of Fire Underwriters.[29]

HEAT LOSSES FROM DUCTS

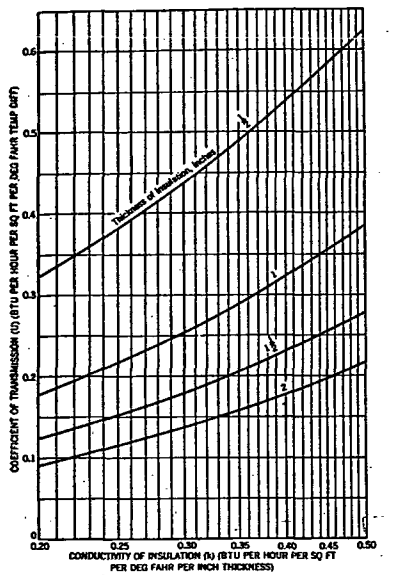
In designing duct systems, the heat gains or losses of the ducts can be quite considerable, not only if the duct passes through unconditioned space, but also on long duct runs within conditioned space. Proper insulation will remedy this situation considerably, but sometimes a redistribution of the supply air is necessary in order to compensate for the heat exchanges that occur.

The heat loss from a given length of duct can be expressed by:

$$Q_w = UPl\left[\left(\frac{t_1 + t_2}{2}\right) - t_3\right] \qquad (14)$$

where

Q_w = heat loss through duct walls, Btu per hour.
U = overall coefficient of heat transfer for the duct wall, Btu per (hour) (square foot) (Fahrenheit degree).
P = perimeter of duct, feet.
l = length of duct, feet.
t_1 = temperature of air entering duct, Fahrenheit.
t_2 = temperature of air leaving duct, Fahrenheit.
t_3 = temperature of air surrounding duct, Fahrenheit.



To obtain the temperature drop in warm air for a given distance of transmission, or the temperature rise if the duct carries air cooler than the room through which it passes, the following formulas can be used:

$$t_1 = \frac{t_3(y + 1) - 2t_3}{(y - 1)} \qquad (15)$$

$$t_2 = \frac{t_1(y - 1) + 2t_3}{(y + 1)} \qquad (16)$$

where

$$y = \frac{28.8AV\rho}{UPl} \text{ for rectangular ducts or,}$$

[a] *For round ducts less than 30 in. diameter, increase heat transmission values by the percentages shown below.*

Thickness of Insulation (Inches)	1/2	1	1 1/2	2
12- to 21-in. Duct Diameter	3%	5%	7%	9%
21- to 30-in. Duct Diameter	1%	2%	3%	4%

Fig. 17 .... Heat Loss Coefficients for Insulated Ducts[a]

$$y = \frac{7.2DV\rho}{Ul} \text{ for round ducts,}$$

A = cross-sectional area of duct, square feet.
ρ = density of air, pounds per cubic foot.
V = mean velocity of fluid, feet per minute.
D = diameter of round duct, feet.

In using Equations 15 and 16, one of the duct air temperatures will be unknown and will be obtained by substitution of the other known or assumed values.

Heat loss coefficients for insulated ducts with various conductivities are given in Fig. 17. The conductivities of various materials, which are based on mean temperatures, about 70 F, will be found in Table 4 of Chapter 9. For cases where the mean temperature is other than that at which the test was conducted, a correction should be made. However, in most cases the effect of this factor will be small and may be neglected.[a]

Example 8: Determine the entering air temperature and heat loss for a duct 24 x 36 in. cross-section and 70 ft in length, insulated with 1½-in. of a material having a conductivity of 0.35 Btu at 86 F mean temperature, carrying air at a velocity of 1200 fpm, measured at 70 F, to deliver air at 120 F with air surrounding the duct at 40 F.

Solution: Referring to Fig. 17, the overall heat transmission coefficient is found to be 0.49 Btu. From Table 2, Chapter 3, the density of air at 70 F and 29.921 in. Hg is found to be 1/13.348 = 0.0749 lb per cu ft. Substituting these and the other given values in Equation 16, y and t_1 will be as follows:

$$y = \frac{28.8 \times 6 \times 1200 \times 0.0749}{0.49 \times 10 \times 70} = 45.3$$

$$t_1 = \frac{120(45.3 + 1) - 80}{45.3 - 1} = 123.7 \text{ F}$$

Substituting in Equation 14:

$$Q_w = 0.49 \times 10 \times 70\left[\left(\frac{123.7 + 120}{2}\right) - 40\right]$$

$$= 28{,}100 \text{ Btu per hr.}$$

For special considerations which apply to insulation of ducts in marine installations see Chapter 48.

CHAPTER 22

FANS

Types, Fan Performance, Fan Laws, Fan Performance Curves, System Characteristics, Fan Arrangements, Fan Control, Motive Power, Fan Selection, Fan Installation, Fan Applications

IN HEATING, ventilating and air-conditioning practice, the devices used to produce air flow are variously known as fans, blowers, exhausters or propellers. The ASME Test Code[1] limits fans to those in which the fluid density change does not exceed 7 percent (one psi at atmospheric pressure) and labels as compressors those devices operating beyond that pressure range. Since air conditioning rarely requires pressures of over ½ psi, all such devices will be known as *fans* and the air will be considered non-compressible.

TYPES

Fans are divided into two general classifications: (1) *centrifugal or radial flow* in which the air flows radially through the impeller within a scroll type housing, and (2) *axial flow* in which the air flows axially through the impeller within a cylinder or ring.

Centrifugal fans are further subdivided into types denoted by the curvature or slope of the impeller blades, the angle of which largely determines the operating characteristics. For a given output, a forward inclination of blade indicates a relatively low speed of operation, and a backward inclination, a relatively high speed of operation. Many intermediate forms are also found.

Axial-flow fans are subdivided into types differentiated mainly by their enclosures and refinements of impellers and appurtenances. All types vary in shape, number and angles of blades; ratios of hub diameter to impeller diameter; materials and methods of fabrication, depending upon design and preference of manufacturer. *Tubeaxial* and *vaneaxial* fans, usually used against appreciable resistance, commonly have relatively large hubs and helical blades (the angle varies radially along the blade). The blades may be of uniform thickness, either flat or cambered, and either cast or made of plates; or they may be of air-foil sections, either cast or of double thickness sheet. Streamlining of both impeller and enclosure is common practice. *Vaneaxial* fans incorporate guide vanes to modify performance and increase efficiency. *Propeller* fans customarily used for free delivery, or against low resistance, also are found with a variety of blade conformations, but are simple in construction. They are merely mounted within a plate or ring.

The fan nomenclature in Fig. 1 has been standardized by the Air Moving and Conditioning Association.[2]

FAN PERFORMANCE

Fan performance is a statement of volume, total pressures, static pressures, speed, power input, mechanical efficiency, and static efficiency, at a stated density. These terms are defined by the Air Moving and Conditioning Association[3] as follows:

1. *Volume* handled by a fan is the number of cubic feet of air per minute expressed at fan outlet conditions.

2. *Total pressure* of a fan is the rise of pressure from fan inlet to fan outlet.

3. *Velocity pressure* of a fan is the pressure corresponding to the average velocity determination from the volume of air flow at the fan outlet area.

4. *Static pressure* of a fan is the total pressure diminished by the fan velocity pressure.

5. *Power output* of a fan is expressed in horsepower and is based on fan volume and the fan total pressure.

6. *Power input* to a fan is expressed in horsepower and is measured horsepower delivered to the fan shaft.

7. *Mechanical efficiency* of a fan is the ratio of power output to power input.

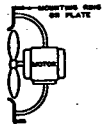
8. *Static efficiency* of a fan is the mechanical efficiency multiplied by the ratio of static pressure to the total pressure.

9. *Fan outlet area* is the inside area of the fan outlet.

10. *Fan inlet area* is the inside area of the inlet collar.

While the total pressure truly represents the actual pressure developed by the fan, the static pressure may best represent the useful pressure for overcoming resistance. In many installations, since the outlet velocity of the fan is greater than the duct velocity, some of the velocity pressure may be utilized by conversion to static pressure within the system. However, due to the uncertainty of the flow at the points of velocity change, the amount of conversion is seldom known and therefore, most fan tables list only the static pressure as available to overcome the system resistance.

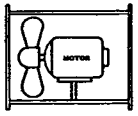
According to the Standard Test Code[4] the efficiencies may be determined by the formulas:



$$\text{Mechanical (total) Efficiency} = \frac{0.0001573 \times (\text{cfm}) \times \text{total pressure (inches water)}}{\text{horsepower input}}$$

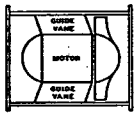
$$\text{Static Efficiency} = \frac{0.0001573 \times (\text{cfm}) \times \text{static pressure (inches water)}}{\text{horsepower input}}$$

As the static pressure is often more useful than total pressure, static efficiency is likewise many times more useful than



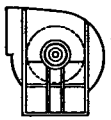
mechanical efficiency. However, where a high outlet velocity can be effectively utilized, the static efficiency fails to be a satisfactory measure of performance. Also when a fan operates against no resistance, the static efficiency becomes zero and is meaningless. Under such circumstances, many engineers prefer to use mechanical efficiency.

Sound developed by a fan is a characteristic which is becoming increasingly important. Unfortunately, no method has yet been devised for accurately measuring the sound actually discharged into a duct system. The ASHAE Research Laboratory, in cooperation with the U. S. Navy, has a program underway seeking to find a method. Many manufacturers list the average sound (for various fan operating



Propeller Fan

A propeller fan consists of a propeller or disc wheel within a mounting ring or plate.



Tubeaxial Fan

A tubeaxial fan consists of an axial-flow wheel within a cylinder.

Vaneaxial Fan

A vaneaxial fan consists of an axial-flow wheel within a cylinder, combined with a set of air guide vanes located either before or after the wheel.

Centrifugal Fan

A centrifugal fan consists of a fan rotor or wheel within a scroll type of housing.

Fig. 1. . . . Names and Definitions of Types of Fans

conditions) measured at seven stations near the fan. These stations, as specified in the AMCA Test Code,[4] are located in a horizontal plane passing through the fan shaft, and are at a distance of one wheel diameter (but not less than 5 ft) from the fan. Such values are useful in comparing the relative sound generated by various types and sizes of fans under comparable operating conditions.

FAN LAWS[5].

The performances of fans of all types follow certain laws which are useful in predicting the effect upon performance of changes in the conditions of operation, the duty required of the installation, or the size of the equipment due to the space, power, or speed limitations. In the following laws, groups 1 to 6, Q = air volume and P = static, velocity, or total pressure. The laws pertaining to fan size apply only to fans geometrically similar, i.e., those in which all dimensions are proportional to some linear dimension denoted as *size*. If the size number is also linearly proportional, it may be used; otherwise, wheel diameter is commonly used as a size criterion.

1. Variation in Fan Speed:
   Constant Air Density—Constant System
   (*a*) Q: Varies as fan speed.
   (*b*) P: Varies as square of fan speed.
   (*c*) Power: Varies as cube of fan speed.

2. Variation in Fan Size:
   Constant Tip Speed—Constant Air Density
   Constant Fan Proportions—Fixed Point of Rating
   (*a*) Q: Varies as square of wheel diameter.
   (*b*) P: Remains constant.
   (*c*) RPM: Varies inversely as wheel diameter.
   (*d*) Power: Varies as square of wheel diameter.

3. Variation in Fan Size:
   At Constant RPM—Constant Air Density
   Constant Fan Proportions—Fixed Point of Rating
   (*a*) Q: Varies as cube of wheel diameter.
   (*b*) P: Varies as square of wheel diameter.
   (*c*) Tip Speed: Varies as wheel diameter.
   (*d*) Power: Varies as fifth power of diameter.

4. Variation in Air Density:
   Constant Volume—Constant System
   Fixed Fan Size—Constant Fan Speed
   (*a*) Q: Constant.
   (*b*) P: Varies as density.
   (*c*) Power: Varies as density.

5. Variation in Air Density:
   Constant Pressure—Constant System
   Fixed Fan Size—Variable Fan Speed
   (*a*) Q: Varies inversely as square root of density.
   (*b*) P: Constant.
   (*c*) RPM: Varies inversely as square root of density.
   (*d*) Power: Varies inversely as square root of density.

6. Variation in Air Density:
   Constant Weight of Air—Constant System
   Fixed Fan Size—Variable Fan Speed
   (*a*) Q: Varies inversely as density.
   (*b*) P: Varies inversely as density.
   (*c*) RPM: Varies inversely as density.
   (*d*) Power: Varies inversely as square root of density.

Examples 1 to 4 illustrate the application of the preceding fan laws.

Example 1: A certain fan delivers 12,000 cfm at a static pressure of 1 in. of water when operating at a speed of 400 rpm and requires an input of 4 hp. If in the same installation 15,000 cfm are desired, what will be the speed, static pressure, and power?

$$\text{Speed} = 400 \times \frac{15{,}000}{12{,}000} = 500 \text{ rpm}$$

$$\text{Static pressure} = 1 \times \left(\frac{500}{400}\right)^2 = 1.56 \text{ in.}$$

$$\text{Power} = 4 \times \left(\frac{500}{400}\right)^3 = 7.81 \text{ hp}$$

Example 2: A certain fan delivers 12,000 cfm at 70 F and normal barometric pressure (density 0.075 lb per cubic foot) at a static pressure of 1 in. of water when operating at 400 rpm, and requires 4 hp. If the air temperature is increased to 200 F (density 0.0602 lb) and the speed of the fan remains the same, what will be the static pressure and power?

$$\text{Static pressure} = 1 \times \frac{0.0602}{0.075} = 0.80 \text{ in.}$$

$$\text{Power} = 4 \times \frac{0.0602}{0.075} = 3.20 \text{ hp}$$

Example 3: If the speed of the fan of *Example 2* is increased so as to produce a static pressure of 1 in. of water at at 200 F as at 70 F, what will be the speed, capacity, static power?

$$\text{Speed} = 400 \times \sqrt{\frac{0.075}{0.0602}} = 446 \text{ rpm}$$

$$\text{Capacity} = 12{,}000 \times \sqrt{\frac{0.075}{0.0602}}$$

$$= 13{,}392 \text{ cfm (measured at 200 F)}$$

$$\text{Power} = 4 \times \sqrt{\frac{0.075}{0.0602}} = 4.46 \text{ hp}$$

Example 4: If the speed of the fan of the previous examples is increased so as to deliver the same weight of air at 200 F as at 70 F, what will be the speed, capacity, static pressure, and power?

$$\text{Speed} = 400 \times \frac{0.075}{0.0602} = 498 \text{ rpm}$$

$$\text{Capacity} = 12{,}000 \times \frac{0.075}{0.0602} = 14{,}945 \text{ cfm (measured at 200 F)}$$

$$\text{Static pressure} = 1 \times \frac{0.075}{0.0602} = 1.25 \text{ in.}$$

$$\text{Power} = 4 \times \left(\frac{0.075}{0.0602}\right)^3 = 6.20 \text{ hp}$$

The fan laws stated may be combined to give other overall values. One useful combination is the product of Laws 1 and 3 which gives the following relations:

Capacity varies as the ratio of size cubed, times the ratio of the rpm.

Pressure varies as the ratio of size squared, times the ratio of the rpm squared.

Horsepower varies as the ratio of the size to fifth power, times the ratio of the rpm cubed.

Example 5: Assuming that a fan with a 36 in. diameter blast wheel will deliver 12,000 cfm at 70 F at 1 in. static pressure, requiring 4.0 brake hp when operating at 400 rpm, what is the capacity, pressure, and horsepower of a homologous fan having a 45 in. wheel at the same speed?

$$\text{Capacity} = \left(\frac{45}{36}\right)^3 \times \left(\frac{400}{400}\right) \times 12{,}000 = 23{,}400 \text{ cfm}$$

$$\text{Static pressure} = \left(\frac{45}{36}\right)^2 \times \left(\frac{400}{400}\right)^2 \times 1 = 1.56 \text{ in.}$$

$$\text{Horsepower} = \left(\frac{45}{36}\right)^5 \times \left(\frac{400}{400}\right)^3 \times 4 = 12.2 \text{ hp}$$

FAN PERFORMANCE CURVES

Fan performance curves are the graphical presentation (for constant speed and air density) of the relation of total pressure, static pressure, power input, and mechanical efficiency, and static efficiency, to actual volume, for the desired range of volumes. Figs. 2, 3 and 4 illustrate performance (sometimes called characteristic) curves of various types of fans.

Centrifugal fans[6] may be roughly divided into three classes: (1) those with the tip of the blades curved forward in the direction of rotation; (2) those with straight radial blades; and (3) those with the tip of the blades inclined backward away from direction of rotation. They are also characterized as slow speed, moderate speed, and high speed types, respectively, although the actual speed range of each may be wide and overlapping. The highest speed type may operate as high as 200 percent of the speed of the lowest speed type, to deliver the same volume of air at the same pressure. The differentiating curvature is always the tip of the blade, since the inlet edge, if inclined, is always curved forward to minimize the shock loss at entrance. Straight radial blades are most frequently found in pressure fans and material-handling fans.

Centrifugal fans produce pressure from two independent sources: (1) from the centrifugal force created by rotating the enclosed air column, and (2) from the kinetic energy imparted to the air by virtue of its velocity leaving the impeller. This velocity in turn is a combination of rotative velocity of the impeller and air speed relative to the impeller. When the blades tip forward, these two velocities are cumulative, and when backward, oppositional. Thus a fan with forward-curved blades depends less on centrifugal force for its pressure, and more on velocity pressure conversion in the scroll, with the result that it may run at relatively low speed. Conversely, a fan having backward-curved blades builds up more of its pressure by centrifugal force (a more efficient form of energy transfer) and less by velocity conversion and, therefore, must run at a higher speed. Likewise, a fan having forward-curved blades will produce the greatest capacity of any type of the same size when operating against no resistance.

Since the energy imparted to the air depends on the velocities,[7] and since the velocities are cumulative with a fan having forward-curved blades, the theoretical energy per pound of air rises rapidly with an increase of air delivery. With the velocities oppositional in the fan having backward-curved blades, the energy per pound of air may decrease, and in a fan having straight blades it is roughly constant. Thus the shape of the horsepower curve definitely identifies the blade angle.

Performance curves of a typical *forward-curved* blade centrifugal fan are shown in Fig. 2. The pressure rises from free delivery toward no delivery, with a characteristic drop at low capacities, because a large share of the pressure is being generated by conversion of velocity, which is small at low capacity. The maximum efficiency occurs at approximately maximum pressure. The horsepower curve reflects the increase in energy by rising rapidly from no delivery to free delivery. The sound is a minimum at maximum efficiency, and rises toward free delivery as the velocities increase.

Performance curves of a typical *backward-curved* blade centrifugal fan are shown in Fig. 3. The pressure is constantly rising from free delivery nearly to point of no de-

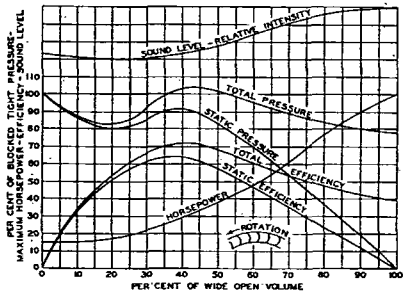


Fig. 2.... Percentage Performance Curves of a Forward-Curved Blade Centrifugal Fan

livery. The horsepower reflects the energy-velocity relationship by rising to a maximum value as the capacity increases, and then decreasing with further increase in capacity to give a self-limiting horsepower characteristic. The maximum horsepower coincides approximately with the maximum efficiency. The sound is again a minimum near maximum efficiency, but is little or no higher at free delivery than at low capacities.

Between the extremes of forward and full-backward-curved blades, there exists a number of intermediate designs which show varying degrees of similarity to the curves in Figs. 2 and 3. A common variation is a fan having modified backward, single, or double-curved blades and equipped with fixed inlet vanes. Such vanes applied to a partially backward-curved impeller give the steep, constantly rising pressure characteristic, and the self-limiting horsepower feature of the full-backward-curve impeller. They also stabilize the flow entering the impeller when adverse flow conditions exist in the approach to the inlet.

Axial-flow fans develop none of their static pressure by centrifugal force, but all from the change in velocity in passing through the impeller, and its conversion into static pressure. They are thus inherently high-velocity fans, and are very dependent on blade conformation for good characteristics. For that reason, an air-foil section, such as developed in wind tunnels for aircraft work[2] is frequently used. Since any shape of blade can only be correct for a narrow range of capacity at constant speed, the performance curves for any blade show definite characteristics. To absorb energy, the air must be given a tangential motion in passing the impeller,[1] and when operating against higher pressures, must have guide vanes (see vaneaxial fans) to obtain best efficiencies.

While *axial-flow fans* are inherently a higher capacity type than centrifugal fans, they, too, may be designed with widely varying characteristics. As with a centrifugal fan, the pressure rises generally from free delivery to no delivery, but tubeaxial and vaneaxial fans may have a drop in pressure when the capacity decreases below a certain volume, a condition also found in the case of the centrifugal fan having forward-curved blades. The pressure drop is caused by the same condition for both fans, i.e., the static pressure is largely dependent on conversion of velocity pressure, and velocity pressure is small at low capacity. Tubeaxial and vaneaxial fans may also have performance curves resembling somewhat those of a centrifugal fan with backward-curved blades. Fig. 4 shows the performance curves for a typical design.

The horsepower curve may be flat with a self-limiting characteristic as in a backward-curved blade centrifugal fan, or it may have a generally downward trend from no delivery to free delivery with the maximum at no delivery, contrary to that of a centrifugal fan. The type of guide vanes in a vaneaxial fan has a distinct bearing on the shape of the horsepower curve. The maximum efficiency tends to occur at a percentage of free delivery capacity higher than for a centrifugal fan.

The sound curve, which may have a minimum value comparable to centrifugal fans, is again lowest near maximum efficiency, but has a characteristic rise when the fan is operating at low capacities and the *stall* point of the blade section is reached.

Since *propeller fans* are designed for operation near free delivery, less attention is given the regaining of velocity to static pressure, and the pressure curve rises constantly from free delivery to no delivery. The horsepower is highest at no delivery, and decreases toward free delivery, in contrast to a centrifugal fan. Maximum total efficiency is obtained at a higher percentage of free delivery than for other types.

SYSTEM CHARACTERISTICS

Any ventilating system consisting of ductwork, heaters, air washers, filters, etc., has a system characteristic which is individual to that system, and is independent of any fan which may be applied to the system. This characteristic may be expressed in curve form in exactly the same manner that fan characteristics may be shown. Typical system characteristic curves are shown as *A*, *B*, and *C* in Fig. 5. These curves are drawn to follow the simple parabolic law in which the static pressure or resistance to flow of air varies as the square of the volume flowing through the system. Heating and ventilating systems follow this law very closely and no serious error is introduced by its use.

When the characteristic curve of a constant-speed fan of a given size is superimposed upon a system characteristic curve, the relation between the two is at once apparent. The only point common to the two curves is the point at the intersection of the system characteristic curve and the fan characteristic curve, and it is at this point that the combination will operate. In Fig. 5, system characteristic curves *A*, *B*, and *C* cross the fan characteristic curve at points *X*, *Y*, and *Z*. The fan whose curve is shown, when applied to systems having characteristic curves *A*, *B*, and *C*, will deliver 10,000, 13,000 or 16,400 cfm, respectively.

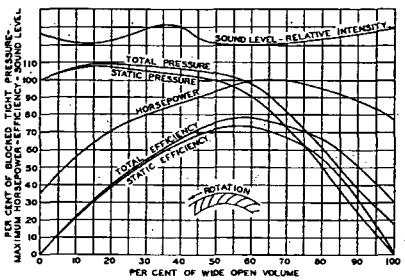

Fig. 3.... Percentage Performance Curves of a Backward-Curved Blade Centrifugal Fan

The curves in Fig. 5 also illustrate the effect of errors that may be made in calculating the resistance of a ventilating system. For instance, if a given system requires 13,000 cfm, and the resistance to flow of the system has been computed as 1.25 in. static pressure, such a system would be represented by system characteristic curve *B* in Fig. 5. If a 100 percent error had been made and the resistance were 2.5 in. instead of 1.25 in., then the system characteristic would be as shown in curve *A*, and would cross the fan curve at 10,000 cfm. Such an error would cause the flow of air to be decreased from a design volume of 13,000 cfm to 10,000 cfm. If the resistance to flow had been overestimated and the resistance actually were 0.625 in., the system characteristic curve would be as shown in curve *C*, and the fan would deliver 16,400 cfm to the system instead of the design volume of 13,000 cfm.

In this example, extreme errors have been selected to emphasize the effect the square function of the system characteristic has in maintaining the fan performance within comparatively narrow limits. In the first example, a system estimated at half what it should have been, resulted in a drop of 23 percent in volume; and in the second example, a system estimated at twice what it should have been resulted in an increase of 26 percent in volume.

In some instances fans may be applied to variable-flow systems. In such cases, the limiting systems may be plotted and the effect on fan performance examined. For instance, a system might have a characteristic curve between *A*, shown in Fig. 5, as one limit, and *B* as the other limit. The fan performance will then fall between points *X* and *Y* on the fan curve at a point determined by the system characteristics at that particular time. If *A* and *B* are the limiting characteristic curves of the systems, the fan performance will never be outside the points *X* or *Y*.

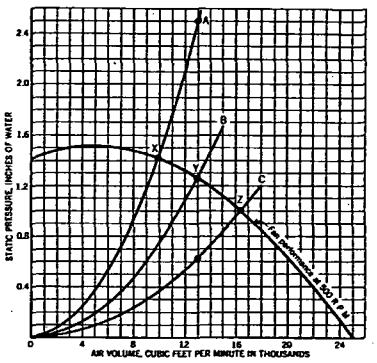

Fig. 5.... Parabolic System Characteristic Curves

FAN ARRANGEMENTS

Centrifugal fan arrangements have been standardized by the Air Moving and Conditioning Association. Figs. 6, 7, and 8 show the accepted designation as to arrangement of drive, rotation, discharge, and motor position, for belt drive. Axial-flow fans are either belt driven or direct connected, in accordance with individual manufacturer's arrangements. Usually a choice of antifriction or sleeve bearings is available.

FAN CONTROL

In some heating and ventilating systems it is desirable to vary the volume of air handled by the fan. This may be accomplished by a number of methods. Where the change is made infrequently, the pulley or sheave on the driving motor or fan may be changed to vary the speed of the fan and alter the air volume. Dampers may be placed in the duct system to vary the volume. Variable-speed pulleys or transmissions, such as fan belt change boxes, or electric or hydraulic couplings, may be used to vary the fan speed. Variable-speed motors and variable inlet vanes on fans may also be used to adjust the fan volume. All of these methods will give control. From a power consumption consideration, a reduction of fan speed is most efficient. Inlet vanes save some power, while dampers save the least. From consideration of first cost, dampers usually are the lowest in cost. In some installations, adjustments of volume are desirable at various times during the day, or continuously. In others, an increased supply of air in summer, over that needed in winter, is demanded. The demands in each case will dictate which type of control is most desirable. Where noise is a factor, a lowering of fan speed, if possible, is preferred as a control means, because of the resulting reduction in sound level.

In addition to the above types of control, *tubeaxial* and *vaneaxial* fans are sometimes made with adjustable blades to permit balancing of the fan against the system, or making seasonal adjustment.

MOTIVE POWER

Heating, ventilating, and air-conditioning fans are usually driven by electric motors, although other prime movers may be used. The small sizes of fans, and especially those operating in the higher speed range, are equipped with direct-connected motors. For larger size fans, and those operating at lower speed, V-belt drives are generally used.

In selecting the size of motor for operating a fan, it is advisable to select at least the standard size next larger than the fan requirements. Direct-connected motors do not require so great a safety factor as belted units. Justification for liberal power provision exists only in systems where it is possible that larger volumes of air may be required at intervals, and made available by use of bypass dampers, thus greatly reducing the system resistance. If such a system includes a fan with forward-curved blades, it would be necessary that the motor be sized for the maximum volume and duty. If such a system includes fans with backward-curved blades, the volume peak would not make it necessary to provide additional motor power. In selecting fans for such a system, sound ratings should be given careful consideration.

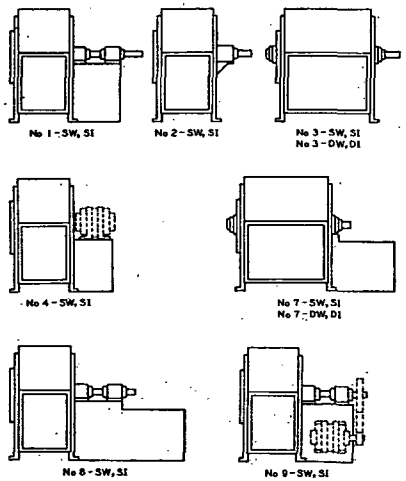

Fig. 6 .... Arrangement of Fan Drives

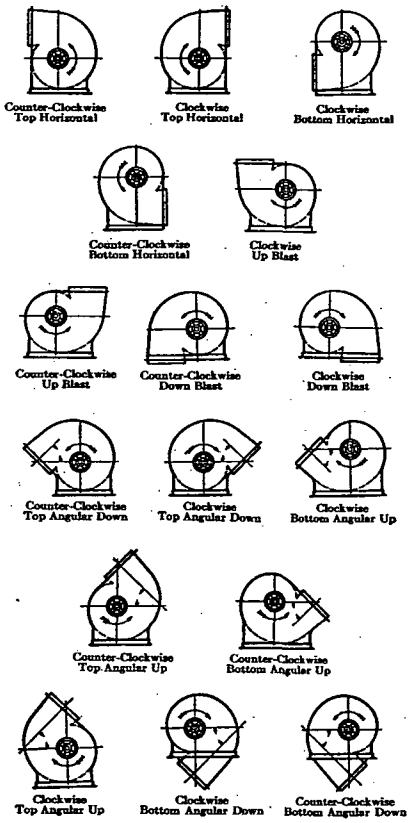
Arr. 1, SW, SI. For belt drive or direct connection. Wheel overhung. Two bearings on base.

Arr. 2, SW, SI. For belt drive or direct connection. Wheel overhung. Bearings in bracket supported by fan housing.

Arr. 3, SW, SI. For belt drive or direct connection. One bearing on each side and supported by fan housing. Not recommended in sizes 27 in. diameter wheel and smaller.

Arr. 3, DW, DI. For belt drive or direct connection. One bearing on each side and supported by fan housing.



Arr. 4, SW, SI. For direct drive. Wheel overhung on prime mover shaft. No bearings on fan. Base or equivalent for prime mover.

Arr. 7, SW, SI. For belt drive or direct connection. Arrangement No. 3 plus base for prime mover. Not recommended in sizes 27 in. diameter and smaller.

Arr. 7, DW, DI. For belt drive or direct connection. Arrangement No. 3 plus base for prime mover.

Arr. 8, SW, SI. For belt drive or direct connection. Arrangement No. 1 plus base for prime mover.

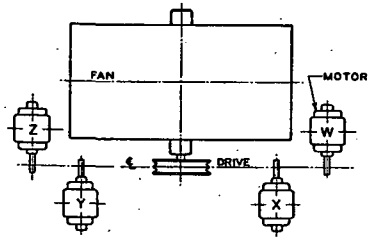
Arr. 9, SW, SI. For belt drive. Arrangement No. 1 designed for mounting prime mover on side of base.

Note: Direction of Rotation is determined from the drive side for either single or double width or single or double inlet fans. (The driving side of a single inlet fan is considered to be the side opposite the inlet regardless of the actual location of the drive.) For fan inverted for ceiling suspension, direction of rotation and discharge is determined when fan is resting on floor.

Fig. 7 .... Designation of Direction of Rotation and Discharge

Where a system is constant, and has no provision for volume change that would materially reduce the resistance, and when the resistance calculations are reasonably precise, there is no necessity for too liberal a motor allowance (even where fans with forward-curved blades are used) if the fan has been properly selected. Fig. 5 shows that the system resistance varies as the square of the volume, and that the fan static pressure varies approximately inversely as the volume, thus greatly offsetting the trend toward both increase in air delivery and motor load. Reference to Fig. 5 indicates that there is no justification for allowing large spare motor capacity. It is generally more economical to operate motors well loaded.

Since the power consumption of fans varies as the cube of the speed, very little starting torque is required of the motor. Refer to Chapter 45 for characteristics of various types of motors.



FAN SELECTION

The following information is required to select the proper *type and size of fan*:

1. Capacity in cubic feet per minute.
2. Static pressure or system resistance.
3. Air density if other than standard.
4. Type of application or service.
5. Arrangement of system.
6. Prevailing sound level or use of space served.
7. Nature of load.
8. Type of motive power available.

In order to facilitate the choice of apparatus, the various fan manufacturers supply fan tables or curves which usually show the following factors for each size of fan operating against a wide range of static pressures: (1) volume of air in cubic feet per minute (68 F, 50 percent relative humidity, 0.075 lb per cubic foot); (2) outlet velocity; (3) revolutions per minute; (4) brake horsepower; (5) tip or peripheral speed; and (6) static pressure. The most efficient operating point is usually shown by either boldface or italicized figures in the capacity tables.

Often the service determines the type of fan. When operation occurs with little or no resistance, and particularly without a duct system, the propeller fan is indicated for convenience and low cost. When resistance is low the power required is low, and efficiency becomes of secondary importance. When a duct system is involved the choice is usually made between a centrifugal fan and a tubeaxial or vaneaxial. At times the capacity-pressure-speed relationship (specific speed)[9] dictates a choice. Usually, space, efficiency, sound, cost, and serviceability must all be considered.[10] In general, centrifugal and axial fans are comparable in efficiency and sound, but the latter are lighter and require considerably less space, especially if arranged for straight-through operation. The comparison cannot be made on the cost of fans only, but the difference in cost of ductwork, mounting, and servicing must be included. A vaneaxial is more efficient and quieter than a tubeaxial, but is more expensive, and frequently requires more space. While requiring less space than the centrifugal, the axial flow fan is inherently less accessible for service. When high-temperature air or air containing corrosive elements is being conveyed, motors and bearings should be located outside of the air stream. This requirement may determine the type of fan to be used. Where the system resistance is indefinite or variable, the pressure, horsepower, and noise characteristics of centrifugal fans usually indicate their selection. Under such conditions, a steep and constantly rising pressure curve permits less variation in air delivery when the resistance varies. Likewise, a flat sound curve minimizes the change of moving into a region of increased noise. A fan having a high effi-

Location of motor is determined by facing the drive side of fan or blower and designating the motor position by letters W, X, Y, or Z as the case may be.

10	4000–6400	8200–9450	4000–6400	15000–18500	

ciency over a wide range is more desirable than one which reaches an even higher maximum efficiency, but decreases more rapidly on either side of a narrow range. A self-limiting horsepower curve may permit more accurate selection of motor size.

The selection of size of fan usually involves balancing cost and space against sound and efficiency. Unless the pressure involved is so high that a smaller fan running at greater speed requires a higher class[2] of construction, the smallest fan is the cheapest in first cost of the fan only. However, as the cost of the driving equipment is also involved in the total installation cost, fan efficiency must be considered for that reason as well as its bearing on the cost of operation. In some cases where large fans operate long hours per year, selection at absolute maximum efficiency is indicated. Generally, however, the power saving by selecting for optimum efficiency does not justify the extra cost, and a slightly smaller fan gives the best balance of cost and efficiency. Reference to Figs. 2 to 4 shows that all types tend to have a minimum sound near maximum efficiency. When noise is a consideration, therefore, selection approaching maximum efficiency is indicated. Too large a fan may not only cause an unnecessary investment and an increased power consumption and sound, but may also give faulty performance if it is of a type having an unstable pressure characteristic at low capacity.

Table 1 shows the outlet velocities and impeller tip speeds recognized as good practice for various static pressures for centrifugal, tubeaxial, and vaneaxial fans applied to average heating, ventilating, and air-conditioning applications. Fans for churches, schools, residences, and other buildings having a low prevailing noise level should be selected for lower than average outlet velocities.

FAN INSTALLATION

In designing heating, ventilating, and air-conditioning systems, the characteristics of the fans available for use therewith should not be ignored. If double inlet fans or multiple fans in parallel are used, care must be taken that both inlets have the same free area and general approach conditions.

The dimensions of the ductwork and the size of the various devices whose individual resistances determine the static pressure, dictate the fan selection. Often a minor modification of the system may permit use of a smaller motor, and even a lower class[2] of fan, with considerable saving of cost. Invariably, the sound generated is affected, as fans operating at high pressure produce more noise than at lower pressure (see Chapter 25). Minimizing the resistance may be the best insurance against noise. On the other hand, sometimes the lowest overall cost results from selecting the minimum size of system equipment, and then installing adequate acoustical and vibration treatment.

All ducts should be connected to fan outlets and inlets by means of unpainted canvas or other flexible material. Access should be provided in the connections for periodic removal of any accumulations tending to unbalance the rotor. When operating against high resistance, or when ambient noise levels are low, it is preferable to locate the fan in a room removed from occupied areas or acoustically treated to prevent sound transmission. The lighter building constructions which are common today, make it desirable to mount fans and driving motors on resilient bases designed to prevent transmission of vibrations through floors to the building structure. Conduits, pipes, and other rigid members should not be attached to fans. Noises due to high velocities, abrupt turns, grilles, and other items not connected with the fan, may be present. Treatment of such problems, as well as the design of sound and vibration absorbents, are covered in Chapter 25.

FAN APPLICATIONS

Many fan applications and the corresponding types of fan commonly used are listed in the following paragraphs. Reference is also made to the chapters where the applications are discussed.

Central-system supply fans (Chapter 19) are usually of the centrifugal type, since this application requires a wide range of satisfactory and quiet operation against high pressures. They can readily be connected to apparatus of large cross-section on the inlet side, and to relatively small ducts on the outlet side.

Comparative sizes have been standardized among manufacturers,[3] and most rating tables cover a range of 700 to 500,000 cfm, and static pressures from ¼ to 15 in. of water.

Central-system exhaust fans are predominately centrifugal, but the space conservation of the axial is being increasingly utilized. Tubeaxial and vaneaxial fan sizes are not yet standardized, but several manufacturers list capacities from 2000 to 125,000 cfm, and static pressures up to 3 in. of water.

Exhaust fans are found in all types. *Wall fans* are predominantly of the propeller type, since they operate against little or no resistance. They are listed in capacities from 1000 to 75,000 cfm. They are sometimes incorporated in factory-built penthouses or roof caps, or are provided with matching automatic louvers. *Hood-exhaust fans* (Chapter 52) involving ductwork, are predominantly centrifugal, especially if handling hot, corrosive, or erosive fumes, where it is best to keep the bearings and drive remote from the air stream. Otherwise, axial fans are applicable, and where little or no ductwork is involved, propeller fans are suitable. *Spraybooth-exhaust fans* (Chapter 52) are frequently centrifugal, especially if built into self-contained booths. Tubeaxial fans lend themselves particularly well to this application, where ease of cleaning and of suspension in a section of ductwork are advantageous. For such application built-in cleanout doors are desirable. *Material handling fans* (Chapter 52) are always straight radial (or modified) blade centrifugal type. They are of heavier construction, and have fewer blades and greater clearances than ventilating fans. Many characteristics are compromised to provide wear resistance and ease of maintenance. They are commonly listed in capacities from 600 to 125,000 cfm, and static pressures up to 18 in. water.

Mine-fan applications[11] vary greatly and require fans ranging from small portable units for local ventilation, to immense slow speed centrifugal fans, often steam-engine-driven, for general or emergency ventilation. Vaneaxial fans are well suited to mine ventilation. For underground location, their compactness saves on cost of excavations, and above ground, their ready reversibility is valuable in emergencies, even if reversal causes a reduction in capacity.

Marine fans (Chapter 48) are both centrifugal and vaneaxial types. The latter are particularly well adapted to both combatant and noncombatant ships, where compactness and light weight are invaluable.

Unitary systems, i.e., unit heaters, unit ventilators, unit humidifiers, unit air conditioners, unit air coolers, and unit evaporative condensers are equipped with centrifugal or propeller fans, the latter usually being limited to the relatively small suspended type where no ductwork is involved. Fans for units having considerable internal or possible external resistance, are mostly of the forward-curved blade, or so-called mixed-flow centrifugal type. The latter is really a centrifugal type with axial inlets, having a pressure curve resembling a backward-curved-blade centrifugal fan. Both of these types have the high capacities (in relation to displacement) requisite for a compact unit. Ratings are frequently given for these units as separate fans, as well as in conjunction with the various internal resistances. In multiple units on a common shaft they are listed up to 40,000 cfm capacities.

Cooling tower fans (Chapter 40) are predominantly of the propeller type, but axial types are also used for packed towers, and occasionally a centrifugal fan is used to supply forced draft.

Circulating fans are invariably of propeller or disk type, and are made in a vast variety of blade shapes and arrangements. They are designed for pleasing appearance, as well as utility.

General purpose fans are centrifugal fans of conventional design, built for service in the lower capacity ranges. They are built with the fan wheel mounted on the motor shaft, or connected to a self-contained belt-driven arrangement. They are listed in capacities from 100 to 20,000 cfm, and static pressures up to 1½ in. water.

Kitchen fans for domestic use are small propeller fans arranged for window or wall mounting, and with various useful fixtures. Their capacities range from 300 to 1200 cfm.

Attic fans are used during the warm seasons to draw large volumes of outdoor air through a house or other building whenever the indoor temperature exceeds the outdoor, and thereby utilize the cooling effect of the relatively cool evening or night air. Research by the ASHAE[12] indicates that a two to three-minute air change is desirable in the North while in the South, a one-minute change is recommended to provide the additional cooling effect of air motion.

Fans may be centrally located in an attic or other unused space, or in a hallway, and arranged to draw proportionately from several rooms; or local window units may be installed in a single room. Central units draw from the living quarters and discharge into the attic, whence the air escapes through windows or grilles; or the air may be drawn through grilles into the attic with the fan discharging directly outdoors. Discharge openings on the lee side are preferred.

Attic fans are usually of propeller type, and should be selected to operate at low velocities to minimize noise. Noise is more of a problem on local units, but care should be taken to prevent transmission of noise or vibration on all installations, because they operate during sleeping hours. Central units are available in sizes from 3,000 to 30,000 cfm, and window units up to 8,000 cfm.

Fans For Special Applications

Fans are used to handle many gases other than air at normal temperature. These range from heated air to many types of fumes, vapors, and industrial gases which may be corrosive, explosive, toxic, radio active, or merely noxious.

For handling corrosive gases fans should be constructed of a material suitable for the particular gas being handled, although at times it is economical to plan on replacing a unit of standard material at more frequent intervals. Explosive combinations usually dictate a non-sparking fan in which either the fan, or only those parts which might strike together if not adjusted, are built of non-sparking materials. Noxious, toxic, radio-active, or pure or valuable gases call for special construction to prevent leakage. This usually consists of a welded gas-tight housing, using flanged inlet and outlet, and some form of shaft seal.

In most of these special applications, since it is desirable to keep all bearings, drives and motors outside the gas stream, centrifugal fans are usually used and in arrangements 1, 2, 4, or 8 (Fig. 6). The exception is in the case of fans handling explosive mixtures, where propeller or axial fans are permissible when built with explosion-proof motors and non-ferrous wheels.

Fans handling hot air or gas are generally of the centrifugal types and follow arrangements 1 or 8 so that bearings, drives and motors are remote from the heat. If of double-inlet type, they have inlet boxes and long shafts to keep the bearings outside the stream. Propeller or axial types are rare when the temperature exceeds 150 F. With temperatures above 600 F special heat-resistant materials may be required for the rotors. In addition to a remote location for the bearings, external cooling is frequently required when the temperature exceeds 200 to 250 F. This is often obtained by use of air-cooled or water-cooled jackets. With anti-friction bearings a head-radiating disc or a small circulating impeller between the fan and the nearest bearing is sometimes sufficient. Oil lubrication rather than grease lubrication is commonly recommended.

CHAPTER 23

AIR HEATING AND COOLING COILS

Uses for Coils; Coil Construction and Arrangement: Steam Coils, Water Coils, Direct-Expansion Coils, Flow Arrangement, Applications; Coil Selection: Heating, Cooling, and Dehumidifying Coils; Heat Transfer and Air-Flow Resistance; Performance of Heating and Dry Cooling Coils; Overall Coefficient of Heat Transfer; Performance of Dehumidifying Coils; Determining Refrigeration Load

COILS described in this chapter are used for heating or cooling an air stream under forced convection. Surface-coil equipment may be made up of a number of banks assembled in the field, or the entire assembly may be factory constructed. The applications of each type of coil are limited to the field within which it is rated. Other limitations are imposed by code regulations, by proper choice of materials for the fluids used and the condition of the air handled, or by an economic analysis of the possible alternates for each installation.

USES FOR COILS

For *heating service*, coils are used as tempering coils, preheaters, reheaters, or booster heaters. The function of the coils is air heating only, but the apparatus assembly may include means for humidification and air cleaning. Steam or hot water are the usual heating media, although others are used in special cases, such as reheating by means of discharge gas from a refrigerating system.

Coils are used for *air cooling* with or without accompanying dehumidification. Examples of cooling applications without dehumidification are precooling coils using well water or other relatively high temperature water to reduce the load on the refrigerating machinery, or water-cooled coils removing sensible heat in connection with chemical moisture-absorption apparatus. A major portion of coil equipment is designed to handle both sensible cooling and dehumidification. The assembly usually includes air cleaning means to protect the coil from accumulation of dirt, and to keep dust and foreign matter out of the conditioned space. Although cooling and dehumidification are the usual functions, cooling coils are additionally and purposely wetted to aid in air cleaning and odor absorption.

The usual cooling media used in *surface coils* are cold water or Group I (ASA Classification) refrigerants, but others are used in special cases. Brines are seldom required for the range of applications covered by this chapter, although there are cases where low entering-air temperatures with large latent heat loads require a refrigerant temperature so low that use of water becomes impracticable. Sometimes, also, brine from an industrial system already installed is the only convenient source of refrigeration.

For combined cooling and dehumidifying, surface coils present an alternate to spray dehumidifiers. For many applications it is possible, by proper selection of apparatus, choice of air velocities, refrigerant temperatures, etc., to perform the same duty with either. In a few cases both sprays and coils are used. The coils may then be installed within the spray chamber, either in series with the sprays or below them. In making the selection between spray and surface dehumidifiers, certain advantages of each should be considered. The fact that a spray dehumidifier is usually designed to deliver nearly saturated air, tends to simplify the control problem. In this case the dry-bulb temperature is also the dew point, and hence, a dew-point control can be arranged by using a simple duct thermostat. Spray dehumidifiers have an advantage over unwetted coils of obtaining more air cleaning and odor absorption. On the other hand, coils make possible a closed and balanced cooling-water circuit, obviating the unbalanced pumping head, the complication of water-level control, and danger from possible floods incidental to multiple-spray dehumidifiers, especially if located on different levels. The use of coils often makes it possible for the same surface to serve for summer cooling and winter heating by circulating cold water in one season and hot water in the other, with consequent saving in apparatus and piping. Another advantage is that where the surface-coil system can be used with direct expansion of refrigerant, it is comparatively low in initial and operating costs. For comfort-conditioning applications, the regulations of the applicable national and local safety codes should be consulted by the design engineer.

COIL CONSTRUCTION AND ARRANGEMENT

Coils are basically of two types, those consisting of plain tubes or pipe, and those having *extended surfaces*. The former are little used for the applications covered by this chapter, but are often employed where conditions cause frost accumulation, and for cooling within spray dehumidifiers.

The heat transmission from air passing over a tube to a fluid flowing within it is impeded by three resistances. The first is that from the air to the surface of the tube and is usually called the outside surface resistance or air-film resistance. The second is the resistance to the conduction of heat through the metal itself. Finally there is another surface or film resistance to the flow of heat between the inside surface of the metal and the fluid in the tube. For the applications under consideration both the resistance of the metal wall to heat conduction, and the inside surface or film resistance are usually low as compared with the air-side surface resistance. Economy in space, weight, and cost makes it advantageous to decrease the external surface resistance, where it is proportionately large, to approach that of the tube wall, and that from the tube to refrigerant. This may be accomplished by increasing the external surface by means of fins. Sometimes water spray is applied to the same type surface as would have been used without it. The overall heat transfer is not necessarily

increased much, but the water spray may serve other purposes than to increase the flow of heat, such as air and coil cleaning.

In fin or *extended-surface* coils the external surface of the tubes is known as *primary*, and the fin surface is called *secondary*. The primary surface consists generally of round tubes or pipes which may be staggered, or in some cases placed in line with respect to the air flow. The staggered arrangement is usually preferred because it obtains a somewhat higher heat transfer value. Numerous types of fin arrangement are used, the most common of which are spiral, flat, and flat-crinkled or corrugated, all as shown in Fig. 1. While

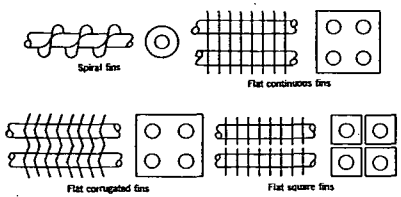

Fig. 1 . . . . Types of Fin-Coil Arrangement

the spiral fin surrounds each tube individually in all cases, the flat types may be continuous (including several rows of tubes), or they may be round or square, with individual fins for each tube. All of these, as well as other less common types, are in use, the selection for a particular installation being based on economic considerations, space requirements, and resistances of individual designs of coils. A most important factor in the performance of extended-surface coils is the bond between the fin and the tube. An intimate contact between the tube and the fin must be maintained permanently in order to assure a continuation of rated performance after the heating units have been in service for a period of time. In some coils, fins are wound on the tubes under pressure, in order to upset the metal slightly at the fin root, and are then given a coating of solder while the fin and tube are still revolving, for the purpose of assuring a uniform coating of solder. In other types, the spiral fin may be knurled into a shallow groove on the exterior of the tube. The tube may be expanded after the fins are assembled, or the tube-hole flanges of a flat or corrugated fin may be made to override those in the preceding fin and so compress them upon the tube. There are also types of construction where the fin is formed out of the material of the tube itself.

For *heating coils*, materials most generally used are copper and aluminum. Steel is occasionally used where sodium or calcium chloride brine is circulated in the tubes. Aluminum fins on copper tubes are common construction. Generally speaking, brass does not serve as a satisfactory fin material because of corrosion difficulties. *Cooling coils* for water or for volatile refrigerants most frequently have aluminum fins and copper tubes, although copper fins on copper tubes are also used. There are many makes of heating and cooling coils of the light-weight extended-surface type for both heating and cooling with tubes commonly ⅜, ½, ⅝, ¾, and 1 in. outside diameter, and with fins spaced three per inch up to fourteen per inch. The tube spacing generally varies from about 1 to 2½ in. on centers, depending upon the width of individual fins and on other considerations of performance. Fin spacing should be chosen for the duty to be performed, with special attention being paid to possibility of lint accumulation and, especially in lower temperature dehumidifying, the consideration of frost accumulation.

Steam Coils

For proper performance of steam heating coils, condensate and air must be continuously eliminated and the steam must be evenly distributed to the individual tubes. This distribution is usually accomplished by individual orifices in the tubes, by distributing plates and orifices in the steam header, or by perforated internal steam-distributing pipes extending into the individual tubes. The latter arrangement has the advantage of distributing the steam throughout the length of each tube, and is conducive to uniform temperature of delivered air. The tendency of condensate to freeze at the bottom of the coil with cold entering air and light heating loads, is also minimized. This is especially valuable for outdoor air preheaters.

Water Coils

The performance of water coils, for heating or cooling, depends on the elimination of air from the system and proper distribution of water. Air elimination is taken care of in the system piping as described in Chapter 28. To assure a pressure drop sufficient for adequate distribution, but at the same time to provide against excessive pumping head where large water quantities are handled, water coils are provided with various water-circuit arrangements. For instance, a typical coil 18 tubes high and 6 tubes deep in the direction of air flow can be arranged for 6, 9, 18, 24, or 36 parallel water circuits, as conditions may require. Orifices in individual tubes are occasionally employed, but are usually unnecessary as the resistance of individual water circuits is generally sufficient to effect a satisfactory distribution. In precooling coils using well water, where there

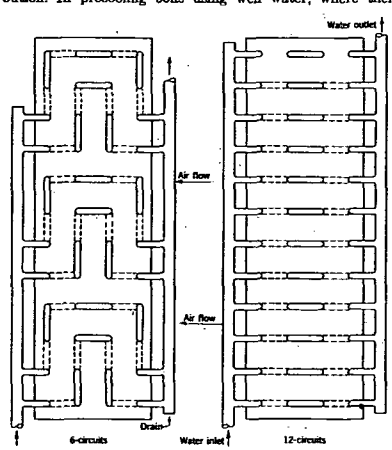

Fig. 2 . . . . Various Water Circuit Arrangements

may be considerable sand and other foreign matter in the water, provision for cleaning of individual tubes is of advantage. It is important to arrange water coils for complete drainage (see Fig. 2). The drains are usually provided in the water piping at the coil header.

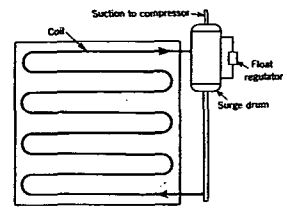

Fig. 3 . . . . Direct-Expansion Coil with Flooded System

Direct-Expansion Coils

Coils for volatile refrigerants present more complex problems of fluid distribution than water, brine, or steam coils. It is desirable that the coil be effectively and uniformly cooled throughout, and necessary that the compressor be protected from entrained, unevaporated refrigerant. There are two types, namely, flooded systems, and thermal-expansion-valve systems, as shown in Figs. 3 and 4. In a flooded coil, the circulation is similar to that in a water tube boiler. The liquid is maintained at the proper level by the action of a float regulator as shown in Fig. 3. The thermal-expansion-valve system depends upon the thermal valve to feed automatically just as much liquid to the coils as is required to maintain the superheat at the coil-suction outlet within predetermined limits, which vary from about 6 to 15 deg. The thermal-valve arrangement is in common use for the type of coils covered by this chapter, while the flooded system is rarely used.

With the flooded system the refrigerant distribution through the tubes depends on properly selecting the length of the feeds, and the head of liquid imposed upon the liquid inlets. The flow of refrigerant from the liquid inlets must be horizontal and upward. The possibility of gas trapping must be avoided. No auxiliary distributing devices are required.

In the thermal-valve system, the path of each refrigerant feed from the distributor to the suction header is called a circuit. The length of each circuit should be chosen to provide good heat transfer and return of oil, as well as a reasonable pressure drop across the circuit. The external loading conditions, the tube size, and other factors, influence the practical length of a circuit. Because of the various factors involved, the practical length and the arrangement of the circuits is developed from laboratory tests and the design of coils for units produced in volume are usually verified by additional tests. It is general practice to obtain superheat by suitable design of the coil rather than by use of external heat exchangers or other auxiliary devices.

To insure reasonably uniform refrigerant distribution in multi-circuit coils, it is common practice to provide a distributing means, between valve and coil liquid inlets, to divide the refrigerant equally among the feeds. Such a distributor must be effective for distributing both liquid and vapor, because the entering refrigerant is a mixture of the two. Fig. 5 shows three typical types of distributors. In distributor A the liquid and gas mixture from the thermal valve is led tangentially into a chamber. The coil feed connections extend outward radially at the top of this chamber. In distributor B the refrigerant is discharged at a high velocity through a central jet against the end plate, forming a uniform mixture of gas and liquid within the distributor, from which individual connections are led as shown. In type C the refrigerant enters at high velocity from the thermal valve and is discharged against the end plug in which the individual liquid feeds are closely arranged. These distributors can be used in either vertical or horizontal position. There are also other types of headers such as the centrifugal and weir type. The individual liquid connections from the distributor to the coil inlet are commonly made of small diameter tubing, and are all of the same length and diameter in order to impose the same friction between the distributor and the coil. Since the thermal valves act in response to the superheat at the coil outlet, this superheat should be produced with the least possible sacrifice of active evaporating surface. Sometimes a single thermal valve is used per coil. In other cases, multiple valves are used, with the coil divided across the air flow or parallel to the air flow as shown in Fig. 6. The arrangement of Fig. 7 should be avoided, since it offers the disadvantage of unequal load on the two parallel circuits.

Control of Coils

Chapter 43 discusses methods of controlling air-heating and cooling coils to meet system or space requirements, and factors that should be considered in sizing automatic valves for steam and water coils.

Flow Arrangement

In all heat transfer processes, the relative directions of flow of the fluids influence the performance of the heat-transfer surface. In air-heating and cooling coils, the air usually flows at right angles to the tubes. In a coil having only one row in the direction of air flow, the relative directions of flow would all be at right angles. In coils having more than one row in the direction of air flow, the media in the tubes may be variously circuited as illustrated for

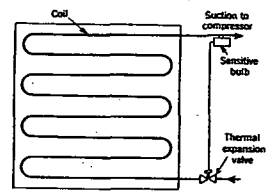

Fig. 4 . . . . Direct-Expansion Coil with Thermal Valve System

water or steam coils in Fig. 8. It is the usual practice to designate a coil that is circuited and employed as in Fig. 8A, as a *parallel-flow* coil. Figs. 8B and 8C show the general arrangements that are termed *counter-flow* and *cross-flow* respectively. Cross flow is common in steam

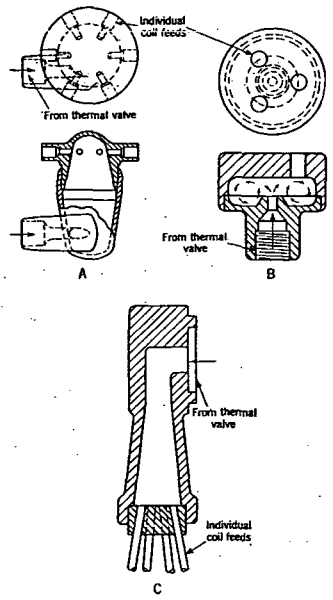

Fig. 5 .... Refrigerant Feed Distributing Heads

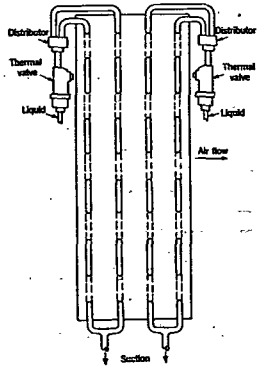

Fig. 7 .... Arrangement for Depth Control

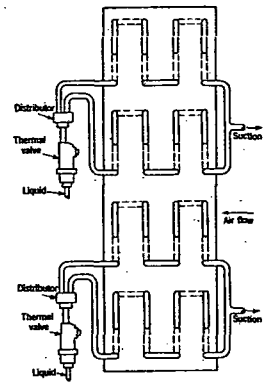

Fig. 6 .... Arrangement for Face Control

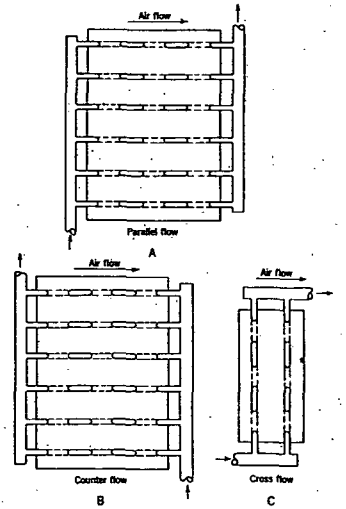

Fig. 8 .... Flow of Media in Tubes in Relation to Air Flow

heating coils, the temperature within the tubes being substantially uniform, and the mean temperature difference the same whatever the direction of flow, relative to the air. The parallel and counter-flow arrangements as illustrated in Figs. 8A and 8B are common in brine or water coils, with the counter-flow arrangement being the preferred arrangement to secure the advantage of highest possible mean temperature difference. Most direct-expansion coils also follow the general scheme of counter flow but the circuiting requirements for proper loading sometimes result in a combination of the other flow arrangements with counter flow in the same coil. Cross flow is generally avoided in the volatile refrigerant coils because of the unequal loading of the parallel circuits.

Applications

Heating coils in field-assembled banks are used for a number of purposes as described in Chapter 19. They may be arranged with the air flow vertical or horizontal, although the latter is more common. For steam heating, the coils may be set with the tubes vertical or horizontal. In the latter case the coil should be sloped to provide for condensate drainage. Because of the multi-circuit feed arrangement and the necessity for avoiding air and water pockets, water heating coils are generally arranged with the tubes horizontal. Certain precautions must be taken against freezing. Where steam coils are used with entering air below freezing temperature, throttling the steam supply may cause freezing of the condensate in the bottom of the coil, if the tubes are of the variety not provided with internal distributing pipes or an equivalent arrangement.

Some coils have inner distributing tubes, and also have supply and return headers cast in one piece. In this type of coil the condensate that forms in the outer tube has resulted from steam fed from the inner tube orifices. This condensate flowing back along the warm inner tube is prevented from freezing. A wide range of modulation at very low temperatures without danger of freezing, is therefore obtained. As an added precaution, with both steam and water coils, the outdoor air inlet dampers are often closed automatically when the fan is stopped to avoid trouble caused by very cold outdoor air drifting in during *off* periods.

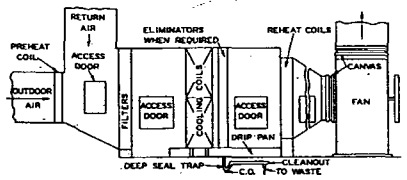

Fig. 9 .... Typical Arrangement of Cooling Coils in a Central System

A typical arrangement of coils is shown in Fig. 9. All of the air should be filtered to prevent dirt, insects, and foreign matter from accumulating on the coils. The cooling coil and humidifier must be provided with a drip pan to catch the condensate formed during the cooling cycle and the excess water from the humidifier. The drain connection should be on the downstream side of the coils, made of ample size (not less than 1¼-in. pipe), provided with accessible clean-outs, a deep-seal trap, and discharge to an indirect waste or storm sewer, so that there will be no possibility that sewer gas may enter the system. Precautions against freezing must be taken with the humidifier piping and drain connections as well as with steam or water coils.

Face and bypass dampers have proven to be satisfactory means of capacity reduction for cooling coils using non-volatile refrigerants. The use of such face and bypass damper

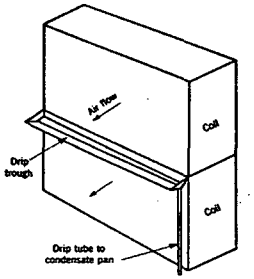

Fig. 10 .... Coil Arranged with Drip Trough

arrangements on volatile refrigerant coils poses difficult refrigerant control problems which are most severe when a change of setting at the thermostat imposes a rapid change in the dampers at the coils. On many installations, the coil bank is divided into 2, 3, or 4 sections and each section is connected to an individual compressor, or connected to a modulating compressor or compressors which will adjust to the load as each succeeding coil section is cut out by the thermostat.

The design features of the coil (fin spacing and type of fins, whether circular fins or plate) determine at what air velocity condensed moisture will be blown off the coil. Water blows off some coils below 400 fpm *face* velocity, while this does not occur on others at *face* velocities in excess of 500 fpm. Where there is a likelihood of water being blown off the coil face, eliminator plates should be placed on the downstream side of the coil. Plate coils are most frequently installed without eliminator plates. When a number of coil sections are stacked one above another, there is a tendency for the condensate to be carried out into the air stream as it drips from one coil to the next one. In such cases, drip troughs as shown in Fig. 10 are used to collect the water and conduct it to the drain pan.

The enclosure around a coil or filter bank should be corrosion resistant and should have adequate access doors to provide for changing of air filters, cleaning of coils, adjusting expansion valves, oiling motors, etc.

Sometimes cooling and dehumidifying coils are sprayed with water to increase the rate of heat transfer and to provide outlet air approaching saturation. This arrangement requires a collecting tank and recirculating pump to maintain water circulation whenever the apparatus is in operation. Fig. 11 illustrates this arrangement with a bypass around the coil. This bypass is often used to facilitate

thermostatic control. It is advantageous to direct only return air through the bypass rather than a mixture of return and outdoor air in order to hold the humidity ratio under thermostatic control.

Although both heating and cooling coils are made of sufficient strength to take up expansion and contraction arising within themselves, care should be taken to avoid imposing strains from the piping on the coil connections. (See Chapter 26.)

COIL SELECTION

In the selection of a coil it is necessary to consider various factors:

1. The duty required: heating, cooling, dehumidifying, and the capacity required to maintain balance with other system components such as compressor equipment in the case of direct expansion coils.
2. Temperature of entering air—dry-bulb only if there is no dehumidification; dry- and wet-bulb if moisture is to be removed.
3. Available heating and cooling media.
4. Space and dimensional limitations.
5. Air quantity limitations.

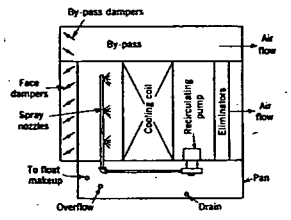

Fig. 11 .... Recirculating Spray System for Cleaning Coils

6. Allowable resistances in air circuit and through tubes.
7. Allowable resistance between the inlet and the outlet of the tube circuits of the coil.
8. Characteristics of individual coil designs.
9. Individual installation requirements, such as, for example, the type of automatic control to be used.

The duties required may be determined from information in Chapter 9, 11, 12, 13, and 19. There may, or may not, be a choice of cooling and heating media, as well as operating temperatures, depending upon whether the installation is new or is in combination with present sources of heating or cooling. Space limitations are dictated by the requirements of individual cases. The air quantity is influenced by a number of considerations. The air quantity through heating coils is often made the same as that necessary to handle the summer cooling load. The air handled may be limited by the use of installed ventilating ducts for air distribution or may be determined by requirements for satisfactory air distribution or ventilation. The resistance through the air circuit influences the fan horsepower and speed. This resistance may be limited to allow the use of a given size of fan motor, or to keep the operating expense low, or it may be limited because of sound-level requirements. The allowable friction through the water or brine circuit may be dictated by the head available from a given size of pump and pump motor. The performance of a surface heating or cooling coil depends upon correct choice of the original equipment, and upon proper application and maintenance.

Coil ratings are based on a uniform *face* velocity. Interference with uniform air flow through the coil will affect performance. Such air flow interference may be caused by air entrance at odd angles or by inadvertent blocking of a portion of the coil face. To obtain rated performance it is necessary that the air quantity be adjusted on the job to that used when selecting the coil, and that it be kept at this value. The most common cause of a reduction of air quantity are the fouling of the filters and collection of dirt on the coils. These difficulties can be avoided by proper design and regular servicing. There are a number of ways in which coils may be cleaned. A common method is to wash them with water. They can sometimes be brushed and cleaned with a vacuum cleaner. In bad cases of neglect, especially on restaurant jobs where grease and dirt have accumulated, it is sometimes necessary to remove the coils and wash off the accumulation with steam, compressed air and water, or hot water. The best practice, however, is to keep the filters serviced, and to inspect and wash the coils at regular intervals.

The proper selection of coils requires an understanding of the requirements of each case, and should be based on an economic analysis of the plant design as a whole. While no general rule can be established for the selection of heating or cooling coils, it is possible, nevertheless, to point out the limits of usual practice and to indicate the influence of the variables involved in the coil selection.

Heating Coils

Steam and *hot water heating coils* are usually *rated* within these limits:

Air Face Velocity—200 to 1200 fpm, sometimes up to 1500 fpm.
Steam Pressure—2 to 200 psig, sometimes up to 350 psig.
Hot Water Temperature—150 to 225 F.
Water Velocity—2 to 6 fps.

Individual cases may deviate widely, but the tabulation given herewith will serve as a guide to usual *heating installation practice*:

Air Face Velocity—500 to 800 fpm face, 500 being a common figure.
Delivered Air Temperature—varies from about 72 F for ventilation only, to about 150 F for complete heating.
Steam Pressure—2 to 10 psig, 5 psig being common.
Hot Water Temperature—150 to 225 F.
Water Velocity—2 to 6 fps.
Water Quantity—Based on about 20 deg temperature drop through a hot-water coil.
Air Resistance—The total resistance through heating coils is usually limited to from ⅜ to ⅝ in. of water for public buildings, to about 1 in. for factories.

The selection of heating coils is relatively simple as it involves dry-bulb temperatures and sensible heat only, without the complication of simultaneous latent heat loads, as in cooling coils. For a given duty, entering air temperature, and steam pressure, it is possible to select several arrangements of the same design of coil depending upon the relative importance of space, cross-sectional area, and air resistance.

Cooling Coils

Cooling and *dehumidifying coils* are usually *rated* within these limits:

Entering Air Dry-Bulb—60 to 100 F.
Entering Air Wet-Bulb—50 to 80 F.
Air Face Velocities—300 to 800 fpm (sometimes as low as 200 and as high as 1200).
Volatile Refrigerant Temperatures—25 to 55 F, at coil suction outlet.
Water Temperatures—40 to 65 F.
Water Quantities—2 to 6 gpm per ton, or equivalent to a water temperature rise of from 4 to 12 deg.
Water Velocity—2 to 6 fps.

The ratio of total to sensible heat removed varies in practice from 1.00 to about 1.65, i.e., sensible heat is from 60 to 100 percent of total, depending on the application. (See Chapter 19.) Since required ratios may demand wide variations in air velocities, refrigerant temperatures, and coil depth, general rules as to their values may be misleading. On most comfort installations air face velocities between 400 and 600 fpm are frequent, 500 being a common value. Refrigerant temperatures ordinarily vary between 35 and 50 F where cooling is accompanied by dehumidification. Water velocities range from 2 to about 6 fps.

When no dehumidification is desired, for which condition the dew point of the entering air is equal to or lower than the cooling coil surface temperature, the coil selection is made on the basis of dry-bulb temperatures and sensible-heat transfer only, the same as with heating coils. It is possible also to choose various arrangements of face area, depth, air velocity, etc., for the same duty.

Dehumidifying Coils

The performance of coils accomplishing both cooling and dehumidification is determined by a series of tests carried on under laboratory conditions. Coil ratings can be prepared from such laboratory test data to facilitate the selection of coils for cooling and dehumidifying duty. The coil capacity should be in balance with the capacity of related equipment, such as compressors, and the temperature of the circulating medium.

The selection of cooling coils for factory-assembled self-contained air conditioners is generally accomplished in conjunction with laboratory testing. The current industry standards call for ratings at 33.4 cfm per thousand Btu of cooling capacity and this is approximately 400 cfm per ton of refrigeration. The use of an entering air condition of 80 F dry-bulb and 67 F wet-bulb is representative of the entering air conditions actually encountered in many comfort operations because, while the indoor conditions are usually lower than 67 wet-bulb, the introduction of outdoor air will usually bring the mixture of air to the cooling coil up to an approximation of the 67 wet-bulb entering air condition at design conditions.

The selection of cooling coils for field assembled projects is usually accomplished by the use of coil rating tables. The practice of selecting coils from the load division indicated by the load calculation has worked out satisfactorily for the usual human comfort applications. Additional design precautions and refinements are being used for more exacting industrial applications and for improved results on all types of air conditioning in the more humid areas. One of these refinements is the use of a separate cooling coil to cool and dehumidify the ventilation air before admixture with recirculated air. This procedure takes care of one of the main sources of moisture in the usual application. Provision for reheat is required for some industrial applications, and is used for better results on very special commercial applications.

In checking the operating results obtained from cooling coils in various air-conditioning installations, it is necessary to keep in mind the influence of the climatic conditions of the various areas encountered. The majority of problems are encountered at *light-load* conditions when the cooling requirement is considerably less than at design conditions. In the hot, dry climates, where the outdoor dew points are so constantly low that dehumidifying is not generally a problem, the *light-load* condition does not pose any special problems. In the hot, humid climates, where the outdoor dew points are generally high and close to the dry-bulb temperatures, the *light-load* condition has a higher proportion of moisture and a correspondingly lower proportion of sensible heat. These climatic conditions result in higher dew points in the conditioned spaces during the *light-load* conditions unless some of the special means for controlling the inside dew points are used. In the geographic locations where warm weather occurs with both high and low dew points, such as around the Great Lakes, the *light-load* operating conditions with the higher percentage of moisture loading will be encountered less frequently and consistently than in the south coastal areas.

Care should be taken to avoid freezing at light loads. In general, freezing occurs when the coil surface temperature falls to 32 F. With usual coils for comfort installations, this does not occur unless the evaporating temperature at the coil outlet is about 20 to 25 F. The exact value depends on the design of the coil and the amount of loading. Although it is not customary to choose coil and condensing units to balance at low temperatures at peak loads, there is danger of this occurring when the load decreases. This is further aggravated if a bypass is used so that less air is passed through the coil at light loads.

HEAT TRANSFER AND AIR FLOW RESISTANCE

The transfer of heat between the heating or cooling medium and the air stream is influenced by several variables:

1. The temperature difference.
2. The design and surface arrangement of the coil.
3. The velocity and character of the air stream.
4. The velocity and character of the medium in the tubes.

The driving force is usually taken as the logarithmic mean temperature difference for heating or cooling without dehumidification. The rating of cooling coils for combined cooling and dehumidification is discussed later in this chapter. With volatile refrigerants there is often an appreciable pressure drop and corresponding change in evaporating temperature through the refrigerant circuit. The problem is further complicated by the fact that the refrigerant is evaporating in part of the circuit, and superheating in the remainder. In the case of volatile refrigerants, a cooling coil is tested and rated in conjunction with a specific distributing and liquid-metering device, and the capacities are stated for a given superheat condition of leaving vapor.

The design and surface arrangement of the coil include

such items as materials, type, thickness, height, and spacing of the fins, and the ratio of this surface to that of the tube, the use of the staggered or in-line tube arrangement, and provisions to increase the air turbulence such as the use of corrugated instead of flat fins. Staggered tubes increase the total heat transfer, as against the in-line arrangement, and corrugated fins may be more effective than flat. This design and surface arrangement has a large effect on the air-film heat-transfer resistance.

The velocity of the air usually considered is the coil *face* velocity. This bears a *varied relation to the actual velocity* over the surface, depending upon the individual coil design. As long as a fixed design of coil is under consideration face velocities may be used, but they may be unsatisfactory in comparing different designs, as it is the *actual surface velocity that is significant*. The air volume is usually based on standard air at 70 F and a barometric pressure of 29.92 in. mercury.

At the same mass air velocity, varying performance can be obtained depending upon the turbulence of the air flow into the coil, and upon the uniformity of distribution of air over the coil face. The latter is very important in obtaining reliable test ratings, and in realizing rated performance in actual installations. The air resistance through the coils will assist in distributing the air properly, but where the inlet duct connections are brought in at sharp angles to the coil face, the effect is frequently bad and there may even be reverse air currents through a portion of the coils. This reduces the capacity, but can be avoided by proper layout or by the use of vanes or baffles.

Heat-transfer information on plain pipe coils has been developed and verified through many tests. In the case of finned coils, the heat transfer from the cooling or heating medium to the air stream is dependent on so many factors that reliable rating and performance information for any design of coil must be based upon actual tests of the specific coil. Mathematical comparisons of different designs of coils on a square foot of surface and face area basis may be misleading. The selection of finned coils should be made from curves or tables of coil performance prepared from a series of adequate and reliable tests. There are cases in which the engineer must extend available data or design for a single unique installation. For such purposes the following coil calculations will be useful.

PERFORMANCE OF HEATING AND DRY COOLING COILS

The performance of heating and dry cooling coils depends in general upon:

1. The overall coefficient of heat transfer from the fluid within the coil to the air it heats or cools.
2. The mean temperature difference between the fluid within the coil and the air flowing over the coil.
3. The physical dimensions of the coil.

Thus, for any one definite operating condition, the heating or cooling capacity of a given coil is expressed by the following basic formula:

$$q_t = U \times (\Delta t_m) \times A \times N \qquad (1)$$

where

q_t = total heat transfer of the coil, Btu per (hour) (square foot of coil face area).

U = overall coefficient of heat transfer, Btu per (hour) (square foot of external coil surface) (Fahrenheit degree temperature difference between the fluid within the coil and the air flowing over the coil).

Δt_m = mean temperature difference, Fahrenheit degrees, between the fluid within the coil and the air passing over it. (This is commonly taken as the logarithmic mean temperature difference.)

A = external surface area of the given coil, square feet per (square foot of coil face area) (row of coil depth).

N = number of rows of coil depth.

Overall Coefficient of Heat Transfer

While the overall coefficients of heat transfer for plain pipe coils have been defined by numerous tests within close limits, the verification of a plain coil design by a series of tests is an accepted commercial practice. The overall coefficients of heat transfer for finned coils should always be obtained from tests. The data from a series of tests may be used for purposes of extending coil data beyond test range but such data should later be verified by test.

Considering any coil, whether of bare pipe or of finned type, the overall heat-transfer coefficient for a given size and design of coil can always be considered as a combined effect of three individual heat-transfer coefficients, namely:

1. The film coefficient of heat transfer between air and the external surface of the coil, usually given in Btu per (hour) (square foot external surface) (Fahrenheit degree mean temperature difference).
2. The conductivity of the coil material—tube wall, fins, ribs, etc., usually given in Btu per (hour) (square foot of surface) (Fahrenheit degree per inch).
3. The film coefficient of heat transfer between the internal surface of the coil and the fluid flowing within the coil, usually given in Btu per (hour) (square foot internal surface) (Fahrenheit degree mean temperature difference).

These three individual coefficients acting in series result in an overall coefficient of heat transfer in accordance with the basic laws given in Chapters 5 and 9. For a *bare-pipe* coil the overall coefficient of heat transfer, whether for heating or for cooling (without dehumidification), can be expressed by a simplified basic formula as follows:

$$U = \frac{1}{\frac{R}{f_i} + \frac{L}{k} + \frac{1}{f_o}}. \qquad (2)$$

where

U = overall coefficient of heat transfer, Btu per (hour) (square foot external surface) (Fahrenheit degree mean temperature difference between air and fluid within the coil).

f_i = film coefficient of heat transfer between the internal surface of the coil and the fluid flowing within the coil, Btu per (hour) (square foot internal surface) (Fahrenheit degree mean temperature difference between that surface and the average fluid temperature).

f_o = film coefficient of heat transfer between air and the external surface of the coil, Btu per (hour) (square foot external surface) (Fahrenheit degree mean temperature difference between the mass of air and the external surface).

k = conductivity of material from which the bare pipe is constructed, Btu per (hour) (square foot) (Fahrenheit degree per inch thickness).

L = thickness of tube wall inches.

R = ratio between external and internal surface of the bare tube, usually varying from 1.03 to 1.15 for the tube used in typical heating or cooling coils. This ratio R is inserted in the formula in order to place internal fluid coefficient of heat transfer on the basis of external surface.

Frequently, when pipe or tube walls are thin and of material having high conductivity (as is the case in construction of typical heating and cooling coils) the term L/k in Equation 2 becomes negligible and is generally disregarded. (The effect of the term L/k in typical bare-pipe heating or cooling coils seldom exceeds 1 to 2 percent of the overall coefficient.) Thus, in its simplest form, for bare pipe:

$$U = \frac{1}{\frac{R}{f_i} + \frac{1}{f_o}}. \qquad (3)$$

For finned coils the formula* for the overall coefficient of heat transfer can be conveniently written:

$$U = \frac{1}{\frac{R}{f_i} + \frac{1}{\eta f_o}} \qquad (4)$$

in which the term η, called the *fin efficiency*, is introduced to allow for the resistance to heat flow encountered in the fins.

The term R, in this case, is the ratio of *total* external surface to internal surface. For typical designs of finned coils for heating or cooling, this ratio varies from 10 to 30. Term R is again introduced to place the internal surface coefficient of heat transfer on a basis of external surface.

The performances of all heating and dry cooling coils are influenced by these same factors. But, when cooling coils operate wet or act as dehumidifying coils, the performance cannot be predicted on the basis of overall coefficients.

PERFORMANCE OF DEHUMIDIFYING COILS

When the dew point of the air leaving a cooling coil is lower than the dew point of the air entering the coil, some moisture removal has been accomplished. A coil that normally accomplishes (or is designed to accomplish) moisture removal in addition to sensible-heat cooling is termed a dehumidifying coil.

In most air-conditioning processes, the air may be considered as a mixture of water vapor and the dry components. Both dry components and the water vapor enter an air-conditioning coil at the same dry-bulb temperature; both the dry components and the water vapor lose sensible heat during the contact with the first portion of the cooling coil in the same manner as in a dry cooling coil. As the dry-bulb temperature of the mixture approaches the dew point of the water-vapor components, moisture removal starts.

The psychrometric path of air through a cooling coil is generally assumed to follow a path similar to that shown in Fig. 12. When the dry-bulb temperature of the air mixture in the coil falls below the entering dew-point temperature, moisture removal proceeds. The indications are that the lower the leaving dry-bulb temperature below the entering dew-point temperature, the less will be the difference between the leaving dry-bulb temperature and the leaving dew-point temperature.

The first portion of a cooling coil (in the direction of air flow) may function in the same manner as a dry cooling coil. Where the moisture removal starts, the cooling surfaces also

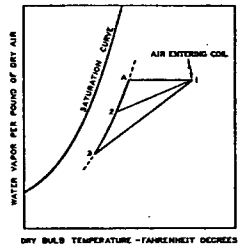

Fig. 12 .... Performance of Dehumidifying Coil

continue the removal of sensible heat, thereby carrying the load due to both. As saturation is approached in the cooling coil, each degree of sensible cooling is approximately matched by a corresponding degree of dew-point decrease. However, while the sensible heat removal from the dry air remains approximately constant per degree change, the amount of latent heat removal per degree of dew-point change varies considerably because moisture content varies widely at different temperatures.

For example, the following tabulation compares the amount of moisture removal involved in a reduction of one degree of dew point from 60 to 59 F with the removal from 50 to 49 F:

Dew Point	$W_s \times 10^3$ lb/(lb)	Dew Point	$W_s \times 10^3$ lb/(lb)
60	11.080	50	7.658
59	10.690	49	7.374
Difference	0.390	Difference	0.284

The above values are given in Table 2, Chapter 3.

When cooling coils act as dehumidifying coils, the performance can be predicted accurately only from tests at a sufficient number of points to establish the definite performance characteristics of the coil under varying conditions of loading and of entering air. Dehumidifying coils employing volatile refrigerants are generally rated in conjunction with specific refrigerant distributing and flow control equipment. The combination of the coil with its refrigerant control equipment (such as distributor and expansion valve, and capillary tube or float valve) must be tested at both the higher and lower capacities of its rated range. The lower capacities impose a test on the distributor to provide equal distribution and on the control to modulate without *hunting* at the lower capacities. The higher capacities result in a greater pressure drop through the coil system and a test of the maximum feeding capacity of the flow control device at various *head pressures*.

Most coil manufacturers have their own methods of producing performance rating tables from a suitable number of coil-performance tests. A method of testing and rating coils,

* Rational development and rating of extended air cooling surface, by H. B. Pownall (*Refrigerating Engineering*, October 1935, p. 211).

titled *Joint ASRE-ASHAE Standard Method of Testing and Rating Forced-Circulation Air-Cooling and Air-Heating Coils*, has been adopted (1958).

DETERMINING REFRIGERATION LOAD

The following determination of the refrigeration load shows a division of the true *sensible* and *latent heat* loss of the air, which is accurate within the limitations of the data. These divisions will not correspond to load determination obtained from approximate factors or constants.

The total refrigeration load q_t of a cooling and dehumidifying coil (or air washer) is indicated on Fig. 13 and consists of the following components:

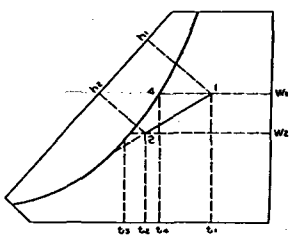

Fig. 13 .... Psychrometric Performance of Cooling Coil in Central System

1. The *sensible heat* q_s removed from the dry air and moisture in cooling from entering temperature t_1 to leaving temperature t_2.

2. The *latent heat* q_s removed to condense the moisture at the dew-point temperature t_4 of the entering air.

3. The heat of *subcooling* q_w removed from the condensate in cooling it from the condensing temperature t_4 to the leaving condensate temperature t_3.

Items 1, 2, and 3 may be related by

$$q_t = q_s + q_s + q_w \tag{5}$$

If only the *total heat* value is desired, it may be computed by

$$q_t = (h_1 - h_2) - (w_1 - w_2)h_{w3} \tag{6}$$

where

h_1 and h_2 = enthalpy at points 1 and 2 respectively.
w_1 and w_2 = humidity ratio at points 1 and 2 respectively.
h_{w3} = enthalpy of saturated liquid at the final temperature, t_3.

If a breakdown into *latent* and *sensible heat* components is desired, the following relations may be used:

The *latent heat* may be found from

$$q_s = (w_1 - w_2)h_{fs4} \tag{7}$$

where

h_{fs4} = enthalpy at the condensing temperature, t_4.

The *sensible heat* may be shown to be

$$q_s + q_w = (h_1 - h_2) - (w_1 - w_2)h_{s4} + (w_1 - w_2)(h_{w4} - h_{w3}) \tag{8}$$

where

h_{s4} = enthalpy at the condensing temperature, t_4.
h_{w4} = enthalpy of saturated liquid at condensing temperature, t_4.

The last term in Equation 8 is the heat of *subcooling* the condensate from the condensing temperature t_4 to its final temperature t_3. Then,

$$q_w = (w_1 - w_2)(h_{w4} - h_{w3}) \tag{9}$$

All values for solving the foregoing equations may be found on the ASHAE Psychrometric Chart and Tables 2 and 3 of Chapter 3.

Example 1: Air enters a coil at 90 F dry-bulb, 75 F wet-bulb; it leaves at 61 F dry-bulb, 58 F wet-bulb; leaving water is assumed to leave at a temperature between the leaving air dew point and coil surface temperature of 54 F. Find the total, latent, and sensible cooling loads on the coil.

Solution: From the ASHAE Psychrometric Chart, find the following:

h_1 = 38.42 Btu per lb of dry air.
h_2 = 25.10 Btu per lb of dry air.
t_4 = 69 F wet-bulb of entering air.
w_1 = 0.01525 lb per lb of dry air.
w_2 = 0.00960 lb per lb of dry air.

From Table 3, find:

h_{w4} = 37.11 Btu per lb.
h_{w3} = 22.12 Btu per lb.
h_{fs4} = 1054.27 Btu per lb.
h_{s4} = 1091.34 Btu per lb.

The total heat from Equation 6 is

$$q_t = (38.42 - 25.10) - (0.01525 - 0.00960) \times 22.12$$
$$= 13.32 - (0.00565 \times 22.12)$$
$$= 13.32 - 0.12 = 13.20 \text{ Btu per lb dry air.}$$

The *latent heat* from Equation 7 is

$$q_s = 0.00565 \times 1054.27 = 5.96 \text{ Btu per lb of dry air.}$$

The *sensible heat* by difference, is

$$q_s + q_w = q_t - q_s = 13.20 - 5.96 = 7.24 \text{ Btu per lb of dry air.}$$

Or the *sensible heat* may be computed from Equation 8 as

$$q_s + q_w = (38.42 - 25.10) - (0.00565 \times 1091.34) + 0.00565\,(37.11 - 22.12)$$
$$= 13.32 - 6.16 + 0.00565 \times 14.99$$
$$= 13.32 - 6.16 + 0.08 = 7.24 \text{ Btu per lb of dry air.}$$

The *subcooling* of the condensate as a part of the sensible heat is indicated by the last term of the equation, 0.08 Btu per lb of dry air.

CHAPTER 24

AIR CLEANING

Atmospheric Air Cleaners: Airborne Particulate Matter, Viscous-Impingement Filters, Dry Air Filters, Electronic Air Cleaners, Air Filter Performance, Selection, Maintenance, Installation, Adsorption of Vapors; Industrial Air and Gas Cleaners: Degree of Cleaning, Selection, Types, Application, Inertial Separators, Scrubbers, Wet Collectors, Filters, Electrostatic Precipitators, Adsorbers, Absorbers, Combustion Devices

AIR cleaning devices remove contaminants from an air or gas stream. They are available in a wide range of designs to meet various air cleaning requirements. Degree of removal required, quantity and characteristics of the contaminant to be removed, and conditions of the air or gas stream will have a bearing on the device selected for a given application. Definitions and a discussion of contaminant characteristics are given in Chapter 7, together with some consideration of their origin.

Air cleaning devices are divided in this chapter into two basic groups: Atmospheric Air Cleaners, described in Part I, and Industrial Air and Gas Cleaners, described in Part II.

Atmospheric Air Cleaners are ordinarily used to remove particulates such as are found in outdoor air, and are employed in ventilation, air conditioning, and heating systems where dust content seldom exceeds 4 grains per 1000 cu ft of air.

Industrial Air and Gas Cleaners are ordinarily used for the heavier concentrations encountered in local exhaust ventilation where the particulate content (loading) ranges from 100 to 20,000 grains per 1000 cu ft of air. Because of these heavier loadings, atmospheric air cleaners can seldom be used for the control of process aerosols in industrial applications.

PART I—ATMOSPHERIC AIR CLEANERS

Conventional air filters and electronic air cleaners are installed in air handling systems to remove dusts. These dusts constitute a mixture of particle sizes within the classification of temporary and permanent impurities listed in Fig. 1, Chapter 7, including bacteria, pollens, house dusts, and similar allergens which motivate attacks on persons of allergic sensitivity.[1,2]

Since the purpose of the filter or cleaner is to free the air of as much existing contamination as practicable, the degree of air cleanliness required should influence the choice of apparatus. Atmospheric dusts are mixtures of particles in all sizes. The removal of these particles and fractions becomes progressively difficult as the particle size decreases. Smoke particles are of major importance in many applications. Air cleaners will justify their cost through a reduction in housekeeping expense in the ventilated space, by the protection of the equipment in the ventilation system itself, and by providing relatively dust-free air for critical manufacturing processes.

Cleaning devices for atmospheric air are classified by the principle employed to collect dirt particles such as impingement on viscous coated media, filtration through porous media, or electronic air cleaning. In some cases a filter may display a combination of these principles. Each type of air cleaner has certain advantages. There are applications where it is desirable to pass air through a series of two or more different types to obtain optimum results.

AIRBORNE PARTICULATE MATTER

Suspensions of particulate matter in the air are called aerosols and consist of smokes, dusts, mists, and fumes. The characteristics of the aerosols which affect the performance of an air cleaner include particle size, concentration, shape, density, velocity, and surface characteristics. One of the most important of these is size.

The rate of settling of particles varies approximately as the square of the diameter. Particles larger than 10 microns in diameter settle so rapidly that the concentration of such particles decreases rapidly as the distance from the source increases. Particles less than 1 micron in size settle so slowly that the ordinary convection currents prevent sustained downward motion, and consequently such particles remain in the air for long periods.

If particles could be examined through a super microscope having a magnification of 250,000 diameters, a tobacco smoke particle of 0.1 micron would appear to be 1 in. in diameter, or approximately the size of a golf ball; a soft coal smoke particle 0.3 micron in diameter would appear like a baseball; a ragweed pollen grain of 20 microns in diameter would appear 16.5 ft in diameter, while the 50 micron particle (just visible to the naked eye and able to pass through a 270 mesh screen) would appear to be 50 ft in diameter. Consideration of this range in particle size from a golf ball to a sphere 50 ft in diameter will emphasize the difficulty of devising any single test to measure adequately the performance of air cleaning devices under all conditions of service.

The particles in the atmosphere can range in size from less than 0.01 micron up to things which are caught by an ordinary fly screen, such as lint, feathers, and insects. Almost all conceivable shapes and sizes are represented. The material is very commonly soot, ash, soil, lint, smoke, and fumes, but may include particles of almost any inorganic or organic material and even such living organisms as virus, bacteria,[3] and fungus spores.

This wide variety makes it impossible to design one type of cleaner which will be best for all applications. Mechanical filters of the low-pressure type can remove large particles effectively. Other mechanical filters can remove extremely fine particles, but may be handicapped somewhat by high-pressure drop and cost. Electronic air cleaners have the ability to give high effectiveness on normal atmospheric contamination, with a low operating-pressure drop.

As a general rule, the removal of the coarser dust particles and lint from the ventilating air produces tangible results in

so far as cleanliness in a house or building is concerned, because much of the finer dust remains suspended in the air and is removed from the building by the circulating air. However, since some of the fine dusts, especially smoke and fume particles, are undoubtedly deposited by means other than settling, such as electrical or thermal precipitation[4, 5] and by contact, the ability to remove small particles is desirable in an air cleaner if it can be obtained at a reasonable cost.

VISCOUS-IMPINGEMENT TYPE FILTERS

The viscous-impingement type of filters consist of relatively coarse media constructed of a suitable fiber, screen, wire, mesh, metal stamping or plates, or a combination of media. The filter may be of the unit type manually-cleaned, the replaceable type, or the automatic moving-curtain type.

The medium in a viscous-impingement type filter is usually a fiber pack for non-automatic types, or a series of metal plates for automatic self-cleaning types. In either case, the medium is treated with a viscous substance, often an oil or grease, called the *adhesive* or the *saturant*, intended to retain dust particles which come in contact with it. Also, in either case, the arrangement is such that the air stream is broken up into many small air streams, and these are caused to change direction abruptly a number of times in order to throw the dust particles, by momentum, against the adhesive. Several desirable characteristics of an adhesive for air cleaners of this type are: (1) its surface tension should be such as to produce a homogeneous film or coating on the filter medium; (2) the viscosity should vary only slightly with normal changes of temperature; (3) it should prevent the development of mold spores and bacteria on the filter medium; (4) the liquid should have high capillarity, or ability to wet and retain the dust at all operating temperatures; (5) evaporation should be slight; (6) it should be fire resistant; (7) it should be odorless.

Various fibrous materials have been used as filtering media in unit filters of the viscous-impingement type. These include glass fiber, steel wool, similar *wool* of non-ferrous metals, wire screen, animal hair, hemp fibers, and other materials. In such filters, the medium is often packed more densely on the discharge than on the approach side, in order to increase the dust-holding capacity. This results in a selective arrestance of dust with the larger particles nearer the approach face. The arrangement also permits some penetration of lint into (but not through) the filter, so that the amount of lint which can be tolerated on the filter is also increased. Due to plane surface area the viscous-impingement type filter, however, may be inferior to some dry types if the air carries a high percentage of lint.

The resistance of air filters obviously increases with the rate of air flow through them. Face velocities of about 300 fpm, and resistances in the range from 0.1 to 0.2 in. water, when the device is new and clean, are usual for ventilation system filters.

Filters designated as high-velocity units are also available. In most instances these filters employ a uniform media pack and give best performance at velocities about 500 fpm. Impingement type air filters should hold a substantial amount of adhesive so that the dirt collected by the filter will be retained. The design and construction should also provide a goodly proportion of free space through the media so that high velocities can be used without excessive resistances. The design should assure that the media throughout the thickness of the filter will be effectively utilized and therefore, the filter should be designed to minimize the formation of a clogging dirt mat on the filter face. High-velocity filters are apt to be adversely affected if the amount of lint in the air to be cleaned is excessive.

The resistance of filters increases with dust or lint loading, and it is the resistance due to this cause that ordinarily necessitates servicing. The rate of loading obviously depends upon the amount as well as the kind of dust in the air, and for this reason, periods between servicing cannot be predicted with certainty. Manometers are often installed to measure the pressure drop across filter banks and thereby indicate when the filter requires cleaning. The pressure drop tolerated differs between operators and system designs. The resistance of a filter bank can be kept desirably low by periodically servicing some, but not all, of the units in the bank at one time. It is to be noted that a decline in efficiency may be the limiting factor in filter life rather than increased resistance due to load.

The method of cleaning viscous-impingement unit filters differs for different types of filters and kinds of dust. Much dry dust or lint can often be removed by rapping the filter.

Throw-away filters are constructed of inexpensive materials, and are designed to be discarded after one period of use. The frame is frequently a combination of cardboard and wire.

Cleanable filters usually have metal frames. Various cleaning methods have been recommended including: air jet, water jet, steam jet, washing in kerosene, and dipping in an oil. The last may serve both to clean the filter and add the necessary adhesive.

It is not mandatory that unit filters be removed from their metal frames for cleaning outside of the system. Cleaning of unit filters in place is feasible by means of hot water sprayed from a hose or by means of fixed nozzles to accomplish washing and adhesive application. Where filters are cleaned in place, provision should be made to collect and drain the water so as to prevent leakage from the filter housing.

Moving-Curtain Viscous Filters

Moving-curtain air filters are available in two main types. In one type the filtering medium making up the curtain is considered "permanent" and means are provided to remove the dust from the curtain mechanically. In the other type the curtain consists of a roll of viscous-coated fibrous filter medium which is not permanent but which is replaced after accumulating its dust load. Filters with moving cloth media, not viscous coated, are available essentially for lint removal.

The medium in the permanent, mechanically cleaned, moving-curtain type consists of a series of specially formed metal plates mounted on a pair of chains. The chains are mounted on sprockets located at the top and bottom of the filter housing, so that the filter medium can be moved as a continuous curtain up one side and down the other side of the sprockets. The arrangement is such that, at the bottom, the medium passes through a bath of special oil which both serves to remove the dirt from the plates, and acts as an adhesive when the cleaned plates next pass through the air stream. The plates forming the filtering medium or curtain usually overlap each other, and due to their special shape, form many small air passages between them. These air passages turn abruptly one or more times in order to give the impingement effect.

The medium in the replaceable moving-curtain type filter is supplied in roll form, one roll being sufficient for one to two years of operation in typical applications. The medium forming the moving curtain is unrolled from the supply roll

at the top, is moved down across the air stream where its dust load is accumulated, and then is rewound on a roll at the bottom. Replacement is accomplished by inserting a clean roll of medium at the top and disposing of the loaded dirty roll. In typical replacement medium, moving-curtain filters a signal is provided to indicate the end of the medium roll has reached the airstream. Usually provision is also made to stop the automatic curtain-moving mechanism before the end of the curtain is reached.

An electrically driven rotating device is usually supplied with a moving-curtain filter. The device may be set to move the curtain periodically, or a special switch, actuated by pressure drop, may be used to govern its motion. In operation, the resistance of an automatic filter will remain approximately constant as long as proper operation is obtained. A resistance of ½ in. water at a face velocity of 500 fpm is typical of this class.

DRY AIR FILTERS

The media in dry filters are usually fabrics or fabric-like materials. Media of wool felt, cotton batting (both glazed and unglazed), cellulose fiber, and other materials have been used commercially. The medium in a filter of this class is usually supported by a wire frame in the form of pockets or V-shaped pleats in order to increase the area exposed to the passage of air. A 2-ft-square unit may contain from 15 to 30 sq ft of medium.

Dry air filters, by virtue of the large area of medium used, have a comparatively high lint-holding capacity. The efficiency of dry type filters is usually higher than that of viscous impingement filters, while the life of the former based on dust-holding capacity, may be lower. Dust tends to clog the fine pores or openings of dry filters more quickly, thereby causing a higher rate of resistance rise than for viscous impingement filters. Efficiency with very fine particles equivalent to that of electronic air cleaners is not uncommon with certain types of dry filters. A comparatively deep bed, ½ to 1 in. thick, of filtering media having individual fibers in the order of 1 micron in diameter, is required for such high efficiency.

Dry filters may consist of a cleanable medium held in permanent frames, or a throw-away or replaceable filtering medium held in permanent frames, or the entire filter may be of the throw-away type. Usually the filtering medium alone is replaced after having collected its full dust load.

ELECTRONIC AIR CLEANERS

Two principal types of electronic air cleaners are available for air filter application: (1) ionizing type collectors where particles are given a definite charge by passing through an ionization zone, and (2) charged-media type collectors where the energized collecting medium induces a charge on the particles.

Ionizing Type Electronic Air Cleaners

Electronic air cleaners use electrostatic precipitation principles to collect particulate matter (see Fig. 1) but operate on much lower voltages than the type commonly used on industrial stacks. The *designation* Electronic Air Cleaner has been standardized to distinguish the class of electrostatic precipitator which alone is suitable for cleaning ventilating air.

In a typical case, a potential of 12,000 volts may be used to create the ionizing field, and some 6000 volts between the plates upon which the precipitation of dust occurs. These voltages, which are capable of momentary shock to personnel similar to that of a spark plug, necessitate some safety measures. A typical arrangement provides means for making the equipment inoperative when any door affording access to high-voltage parts is opened. Operation can be resumed only after all doors are closed. The voltages necessary for operation of the equipment are usually obtained by means of electronic high-voltage direct-current power packs operating from a 110–120 volt, 60-cycle, single-phase building service. Electric power consumption is about 10 watts per 1000 cfm, plus the approximately 40 watts required to energize the rectifier tube heaters.

Air cleaners of this type offer negligible resistance to air flow and, therefore, care must be exercised in arranging the duct approaches on the entering and leaving sides of the cleaners in order that the air flow may be distributed uniformly over the cross-sectional area. The efficiency of the electronic air cleaner is sensitive to air velocity, and the device itself has much less tendency to rectify the air stream than filters which have higher resistances. In most systems, resistance is deliberately added in the form of a perforated plate, pre-filters, or after-filters for the purpose of obtaining a uniform distribution of air. The resistance, including the baffles or after-filters, is constant and generally ranges from 0.15 to 0.25 in. of water at the usual velocities of 300 to 400 fpm. Such plates or filters, however, cannot compensate for defects in the duct layout ahead of the cleaner. Suitable screens of no coarser than 16 mesh should be installed across all outdoor air entrances to prevent insects, leaves, bits of paper, and similar material from entering the cleaner. Where lint is present in appreciable quantities, devices for lint removal should be installed ahead of the cleaner.

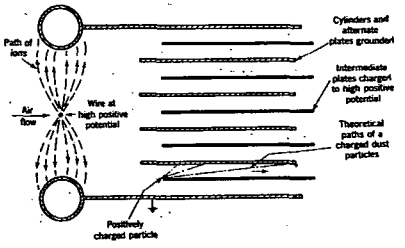

Fig. 1 . . . . Diagrammatic Cross-Section of Ionizing Type Electronic Air Cleaner

Electronic air cleaners of the ionizing type are efficient, low-pressure-drop devices for removing fine dust and smoke particles. They are available in fixed collector-plate and moving collector-plate types. The fixed collector plates are often coated with a special oil as an adhesive. Cleaning is generally accomplished by washing the cells in place with hot water from a water hose or by means of fixed or moving nozzle systems. The bottom of the equipment is made water tight and provided with a drain. In one moving-plate type, the grounded elements on which the dirt collects are mounted

on chains, and are alternately dipped in oil and exposed to the air stream.

Charged-Media Electronic Air Cleaners

The charged-media type air cleaner consists of a dielectric filtering medium, usually arranged in pleats as in typical dry filters. No ionization means are employed. The dielectric filtering medium may consist of glass fiber mat, cellulose mat,

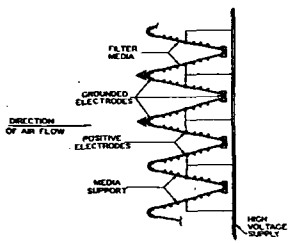

Fig. 2 .... Cross-Section Diagram of Charged Media Type Electronic Air Cleaner

or other similar material, and is supported on or in contact with a gridwork consisting of alternately grounded and charged members, the latter usually being held at a potential of 12,000 volts d-c. An intense and non-uniform electrostatic field is thus created through the dielectric medium. Airborne particles approaching the field are polarized and drawn toward filaments or fibers of the media. The general arrangement illustrating this type of filter is shown in Fig. 2.

The precipitator of this type offers resistance to air flow, when clean, on the order of 0.10 in. of water at 250 fpm velocity and, unlike the ionizing type, the resistance of the charged-media type electronic cleaner rises as dust is accumulated on the media. Because of these characteristics the filter tends to equalize the air distribution over the face of the filter. Like typical replaceable-media mechanical filters, the charged-media precipitator is serviced by replacing the filtering medium. The dielectric properties of the media are impaired when the relative humidity exceeds 70 percent.

AIR CLEANER PERFORMANCE AND TESTING

Atmospheric air cleaners are generally rated in terms of the three more critical factors in performance; namely, (1) resistance vs air flow, (2) efficiency or arrestance vs dust load at design air flow, and, (3) resistance vs dust load at design air flow.

Air flow is expressed in cubic feet per minute and is therefore a function of face velocity and filter size. Face velocity is defined as the average velocity of the air entering the effective face area of the cleaner and may be expressed by the equation:

$$V = Q/A \qquad (1)$$

where

V = face velocity, feet per minute.
Q = air flow, cubic feet per minute.
A = effective face area, square feet.

Effective face area is further defined as that area of the filter face inside the enclosing frame, flanges, or seals, but not corrected for any area occupied by any bracing, and retaining or strengthening grid members, located within the enclosing frame.

The rated capacity of general ventilation filters is often based on face velocities in the range of 250 to 520 fpm. Resistance to air flow, measured in inches of water column, at rated capacity, is generally available from the manufacturer (see Catalog Data Section). A suitable allowance must be made in the system design for increase in resistance as the filter becomes loaded with dust. Fig. 3 indicates the range of resistance to air flow found on tests of four unit filters. Type A is a dense pack used in bacterium control; Type B is a medium pack used for general ventilation work; Type C is a low-resistance unit, for use where low resistance is the important factor and maximum cleaning efficiencies are not essential; and Type D is a high-velocity viscous-impingement filter.

The effectiveness of air cleaners in removing a given dust from the air is called efficiency or arrestance. If the efficiency is denoted by E, then algebraically E is given by:

$$E = \frac{D_1 - D_2}{D_1} \qquad (2)$$

where

D_1 = amount of dust per unit volume in uncleaned air.
D_2 = amount of dust per unit volume in cleaned air.

A number of procedures for evaluating air cleaner efficiency have been proposed and are in use. These procedures differ principally in the type of test dust that is used and in the method of measuring the dust content of the entering and leaving air. The numerical value of the arrestance or efficiency of an air cleaner may be different for different methods of test even when the same test dust is used, and is generally different for different test dusts using the same test method. Caution is to be exercised in interpreting published arrestance data, since the test efficiency may be different from that obtained in an actual installation, or in the space being supplied with air.

The two most common methods for evaluating efficiency are: (1) the weight method, in which the weight concentration of dust in the air entering and leaving the filter is measured by some suitable means, and (2) the dust spot test in which the dust content of the entering and leaving air is measured in terms of its ability to stain filter paper. The particle count method is not used for efficiency evaluation, except in investigation of filter performance on specific par-

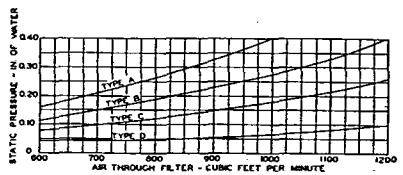

Fig. 3 .... Resistance to Air Flow of Four Unit Air Filters

ticles such as pollen, or on certain industrial dusts harmful to health. Dust particles can be captured on microscope slides by means of one of the various kinds of impingement devices. The process is useful if inspection and analysis of dust are desired, but particle counting is not sufficiently precise for evaluating the efficiency of a cleaner operating on a heterogeneous dust.

Among the weight methods that have been used are the Air Filter Institute Code[6] and modifications of the former ASHVE Code.[7] By the latter test method, a known weight of a prepared dust is injected into air supplied to the filter, and the quantity of dust in the cleaned air is determined by extracting and weighing the dust from a known volume of cleaned air. Dust extraction from the air is accomplished by drawing the air through a porous crucible or thimble by means of a high vacuum. The test dust specified in the ASHVE Code is a mixture of coal ash and carbon black.

The Air Filter Institute Code, Section I, specifies a test dust as follows:

"The test dust mixture consists of 72 percent standardized air cleaner test dust, fine (Arizona road dust, fine); 25 percent K-1 carbon black; and 3 percent No. 7 cotton linters (percentages by weight)."

As in the ASHVE Code, the entering concentration (D_1) is determined by feeding a known weight of the prepared test dust. The concentration of dust in the air leaving the filter (D_2) is determined by passing the entire air flow through a high-efficiency filtering blanket known as an absolute filter, the gain in weight of which is measured. Test data and results are presented on standardized forms made available by the Air Filter Institute.

The dust-spot or discoloration method of test for air-cleaner efficiency was developed at the National Bureau of Standards.[8] In effect, this method is based on a comparison of the volumes of air before and after cleaning by the filter that must be drawn through unit areas of suitable filter paper to yield dust spots of equal opacity to transmitted light as determined by means of a photometer. For example, if equal opacities are obtained when the amount of air sampled, per unit area of dust spot, is four times as great for the downstream paper as for the upstream paper, the efficiency of the filter is considered to be 75 percent, since the dustiness of the cleaned air, as measured by change in opacity, is one-fourth that of the uncleaned air. To obtain equal opacities, samples may be drawn at equal rates for equal times through unequal spot areas, or at equal rates through equal areas for unequal times, as best suits the circumstances. Tests may be made with atmospheric air, or with an artificial dust dispersed in the air stream.

Dust-holding capacity is defined as the amount of dust which a filter can retain and have a resistance less than some arbitrary value. The term applies only to fixed-type air cleaners. Under the AFI[6] and the former ASHVE[7] procedures dust-holding capacity is defined as the product of the weight of dust reaching the filter and the average efficiency at a specified resistance and air flow. Dust loading and arrestance determinations are made simultaneously, arrestance and resistance being determined for each increment of feed with the results plotted against weight of dust fed or against accumulated load in the filter.

Dirt-loading measurements are made at the National Bureau of Standards[9] by feeding a mixture of 4 percent cotton linters and 96 percent Cottrell precipitate (by weight) to the test filter. The two ingredients are separately dispersed into the air stream, using two aspirating-type injectors. The measurements show the relationship between the pressure drop and the weight of dirt mixture received at the filter. The curves in Fig. 4 illustrate the difference in the dirt-loading characteristics of two filters, one a viscous-impingement type and the other a dry filter with an extended-surface cellulose-fiber medium, with dust and with lint.

SELECTION AND MAINTENANCE

To evaluate filters and air cleaners properly for a particular application, two factors should be carefully weighed: (1) the degree of air cleanliness required and (2) disposal of the dirt after it is removed from the air. These factors affect initial costs, operating costs, and the extent of maintenance that will be required. Savings that accrue through reduction in housekeeping expenses, protection of valuable property and equipment, ability to carry on dust-free manufacturing processes, improved working conditions, and even health benefits should be credited against the cost of installing and operating an adequate system. The capacity and physical size of the unit required may emphasize the need for self-cleaning features. Operating costs, predicted life, and efficiency are more important than first cost, because air cleaning is a continuing process.

While electronic air cleaners have a higher first cost, they exhibit very high efficiencies in cleaning atmospheric air, due largely to their ability to remove fine dust which shows no gravitational effect. They are equally effective on coolant oil mists from high-speed cutting and grinding machines. System resistance remains unchanged as dirt is being collected, and the resulting residue is disposed of directly to prepare the equipment for further duty. The charged-media type cleaners are less effective than the ionizing type, but are appreciably better than mechanical filters in the matter of small particle collection.

The advantage of the moving-curtain impingement type filter consists in the small amount of attention which it requires. Such devices are therefore to be recommended where labor is scarce, or where reliable and frequent attention to filters cannot be assumed. The constant pressure drop of this type of filter is an advantage. The first cost is substantially greater than that of unit filters, and the dust arrestance may not be any higher.

Unit filters constitute the majority of air cleaners now in use, and some choice is possible between the types avail-

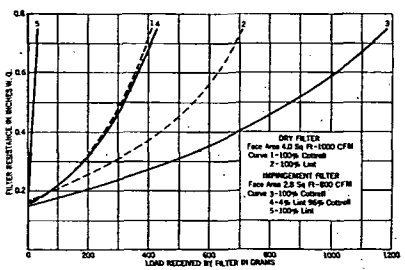

Fig. 4 .... Dust and Lint Holding Capacity of Two Filters

able. Where lint in an eminently dry state predominates, a dry filter obviously may be preferable to other types because of its lint-holding capacity. If the lint is greasy, or if oil vapor exists in the air, the dry filter, if it is of the cleanable type, may be troublesome, since grease tends to make it difficult to clean. Most dry types, however, employ a throw-away type of medium which is held in permanent metal frames so that the difficulty of cleaning the medium is avoided. Some dry filters are capable of high efficiencies, compared to other unit filters on fine particles, but their dust-holding capacity for such dust may be inferior to that of the viscous-impingement type.

Viscous-impingement unit filters are practically standard in size, and their overall dimensions are small when compared with their ratings.

Throw-away units are often installed in series so that the one in front, which usually becomes plugged with lint, can be discarded, after which the downstream unit is moved to the front and replaced by a new unit.

Viscous-impingement unit filters do not have efficiencies as high as can be expected with some other types of unit filters, but their first cost and upkeep are generally lower, whether of the cleanable or the throw-away type. They require more careful attention than the moving-curtain type if the resistance is to be maintained within reasonable limits.

FILTER INSTALLATION

Many air cleaners are available in units of convenient size for handling when installing, cleaning, or replacing. Such units are usually designated as filters or unit filters. A typical unit filter may be 20 in. square and from one to several inches thick, depending on the manufacture and proposed use. In large systems, a number of such units are installed adjacent to each other and collectively called a bank of filters.

Air cleaners are commonly installed in the outdoor-air intake ducts of buildings, and generally in the recirculating and bypass air ducts as well. Cleaners are logically placed ahead of heating or cooling coils and other air-conditioning equipment in the system to protect them from dust. The character of the dust arrested by the filters in an air-intake duct is likely to be mostly particulate matter of a greasy nature, while lint may predominate in dust from within the building.

The published performance data for all air filters are based on *straight-through* unrestricted air flow. Filters should be installed so that the face area is at right angles to the air flow whenever possible. Eddy currents and dead air spaces should be avoided, and air should be distributed uniformly over the entire filter surface, using baffles or diffusers if necessary.

Failure of air-filter installations to give satisfactory results can, in most cases, be traced to faulty installation or improper maintenance or both.

The most important requirements of a satisfactory and efficiently operating air filter installation are:

1. The filter must be of ample size for the amount of air it is expected to handle. An overload of 10 to 15 percent is regarded as the maximum allowable. When air volume is subject to increase, a larger filter should be installed.
2. The filter must be suited to the operating conditions, such as degree of air cleanliness required, amount of dust in the entering air, type of duty, allowable pressure drop, operating temperatures, and maintenance facilities.
3. The filter type should be the most economical for the specific application. The first cost of the installation should be balanced against efficiency and depreciation as well as expense and convenience of maintenance.

The following recommendations apply to filters installed with central fan systems:

1. Duct connections to and from the filter should change size or shape gradually to insure even air distribution over the entire filter area.
2. Sufficient space should be provided in front as well as behind the filter to make it accessible for inspection and service. A distance of two feet may be regarded as the minimum.
3. Access doors of convenient size should be provided in the sheet-metal connections leading to and from the filters.
4. All doors on the clean-air side should be lined with felt to prevent infiltration of unclean air. All connections and seams of the sheet-metal ducts on the clean-air side should be as airtight as possible.
5. Electric lights should be installed in the chamber in front of and behind the air filter.
6. Filters installed close to an air inlet should be protected from the weather by suitable louvers, in front of which a large mesh wire screen should be provided.
7. Filters, other than electronic air cleaners, should have permanent indicators to give a warning when the filter resistance reaches too high a value.

Safety Requirements

An investigation of safety ordinances should be made by the engineer when the installation of an air cleaner of any considerable size is contemplated. It is possible that combustible filtering media may not be permitted in accordance with some existing local regulations. Combustion of dust and lint on a filtering medium is possible, though the medium itself may not burn.

ADSORPTION OF VAPORS OTHER THAN WATER

Many of the foreign gases in the atmosphere are selectively adsorbed by charcoal. Included are many of the organic gases, such as those emanating from animals and people, some of the gaseous constituents of combustion, alcohols, ketones, esters, and gaseous products of putrefaction.

Charcoals differ widely in their adsorptive capacity. Those which have marked adsorption characteristics, such as properly prepared coconut shell charcoals, are sometimes called *activated charcoals* or *activated carbon*.* These materials can adsorb approximately 50 percent of their own weight of many organic gases at 70 F. The charcoal may be used for a long time by reactivation at high temperatures, under which condition it gives up the adsorbed gases. Temperatures of approximately 1000 F are desirable for reactivation. Charcoals for use in air handling systems should be able to stand physical handling, including reactivation, without excessive loss by breakage or dusting.

As applied in air handling systems, the charcoal is placed in perforated metal containers which are grouped in frames and set in the air stream. The percentage removal of an organic gas, such as carbon tetrachloride, is 95 percent or above, when placed in intimate contact with the carbon at 70 F. In commercial apparatus there may be a bypass effect which depends on the physical arrangement of the charcoal containers. This bypassing reduces the percentage removed in the total gas passing through the adsorber. Resistance to air flow is usually selected within the general range of resistance of impingement filters.

The required quantity of recirculated air to be treated is determined by dividing the requirements for contaminant-free air, *minus the outdoor air*, by the fraction denoting the percentage removal of the gas in question in the adsorber bank which is to be used.

Adsorbers may be applied to reduce objectionable gases entering through the outdoor air inlet. They may also be used to reduce the odors caused by exhausts from processing. Adsorber beds, in all cases, should be protected from dust, free oil, and grease.

PART II—INDUSTRIAL AIR AND GAS CLEANERS

Industrial development and growth of industrial areas have had a cumulative effect upon the problem of controlling contaminants. Not only has the atmosphere in many cities become more polluted, but the intensity of pollution at the points of control has increased. Accompanying this increase in pollution there has been a growing consciousness of the need for more effective air cleaning among housewives, store managers, industrialists, and legal inspectors, and this has resulted in increasing severity of regulations pertaining to collection of dust and contaminants.

Air cleaning for the supply system is usually accomplished by means of some type of air filter. To prevent escape of industrial dust into the atmosphere, some type of collector is required. An industrial air-cleaning installation is designed to perform one or more of the following 6 functions:

1. Prevent a nuisance or physical damage to an individual, a plant, or adjacent property.
2. Prevent re-entry of contaminants to working spaces.
3. Reclaim usable material.
4. Reduce fire, explosion, or other hazards.
5. Permit recirculation of cleaned air to working spaces.
6. Allow utilization of cleaned gases for processes.

DEGREE OF AIR CLEANING REQUIRED

The amount of material which can be discharged to the atmosphere is established by local or state regulations prepared by pollution control, labor, or health departments. Standards are established to prevent injury to persons or property. The need for control within the plant is often of prime interest to the industrialist for protecting his equipment, improving his product, and providing a clean working environment. The re-entry of contaminants to working spaces is prevented by effective air-cleaning devices since only a clean effluent is discharged to the ambient atmosphere. Public nuisance complaints often occur even when the effluent concentration discharged to the atmosphere is below the permissible limits of concentration and visibility. Plant location, contaminants involved, and meteorological condition of the areas must be evaluated in addition to existing regulations or codes of good practice.

Fire and explosion hazards are created by combustible dusts, vapors, or gases. Safety may be affected by loss of visibility, settlement, or accumulation of various materials. The cleaning device can prevent these hazards by providing an effluent below the inflammation limit, visibility index, and point where settlement or accumulation will occur.

The degree of air cleaning for the recovery of usable material is a matter of economic evaluation which will vary with such factors as quantity and value of material collected, capital cost, and operating cost.

Air cleanliness must be of the highest order where toxic materials are involved and the cleaned air is recirculated to the workroom. Such recirculation is considered poor practice and is prohibited by many regulations where toxic materials are involved, except for those cases where discharge to atmosphere is impossible or decidely impracticable. Where air is recirculated, its contamination must not exceed the established maximum allowable concentrations listed in Chapter 7. Usual requirements are a fraction, often 1/5 to 1/2, of this standard, depending on: regulation involved, air quantities recirculated in relation to the cubical content of working space, and the presence of other exhaust systems discharging to the atmosphere.

Cleaning requirements for the utilization of cleaned gases are dependent on the process and are generally of the highest order (usually comparable to atmospheric air cleanliness).

Regardless of standards it is good practice to install the most effective collection equipment available in the light of practical operation features, installation, and equipment costs. This is warranted because the required degree of cleaning is increasing continually.

FACTORS AFFECTING SELECTION

Selection of an industrial air cleaner for a given application requires an evaluation of the following 5 considerations:

1. Concentration, particle size, and size distribution of the contaminant.
2. Degree of cleaning required.
3. Conditions of air or gas stream with reference to temperature, moisture content, and chemical composition.
4. Characteristics of the contaminant, corrosiveness, solubility, adhesion, or packing, and its specific gravity, surface, and shape.
5. Methods of disposal or salvage that meet the conditions imposed by material, process, or plant location.

In view of the range of these variables, all available test data, application experience, and manufacturers' performance data should be considered.

TYPES AND APPLICATION

There are a number of principles involved in the operation of industrial air and gas cleaners. They are illustrated by the following types of cleaners:

1. *Inertial Separators* (Gravitational or inertial force principle): Baffle Chambers, Centrifugal Collectors.
2. *Scrubbers and other Wet Collectors:* Air Washers, Wet Filters or Packed Towers, Spray Towers, Centrifugal or Inertial Scrubbers, Venturi Scrubbers.
3. *Filters:* Fabric Filters, Ultra or Absolute Filters.
4. *Electrostatic Precipitators.*
5. *Adsorbers, Absorbers, and Combustion Devices.*

Units employing these principles may apply them singly or in combination. The important characteristics of any unit are: its collection efficiency, resistance to air or gas flow (power requirements), ability to maintain specified air or gas flow during its operating cycle, and maintenance requirements.

In relation to industrial air cleaners, efficiency of collection is generally presented on a basis of weight removal. In many instances, collection efficiency is expressed in terms of weight removal in specific particle size ranges. Occasionally efficiencies are given in terms of visibility or photometric evaluation. Under other circumstances efficiencies are stated by particle count. For most process recovery problems and air pollution control, the weight basis has been adequate. When loss of visibility is the major problem, light opacity measurements may be required.

From a hygienic viewpoint where air is to be recirculated, only the contaminant concentration in the recirculated air stream, rather than the collection efficiency, should be considered.

Correlation between the various efficiencies is poor due to the wide variation in particle size, size distribution, and shape.

Resistance or pressure drop through any given collector is related to the operating principle, and varies about as follows: low resistance collectors—up to 2 in. water; medium resistance collectors—2 to 8 in. water; high resistance collectors—8 to 25 in. water.

In mechanical centrifugal collectors of the wet or dry type (power driven impellers or rotors) resistance alone is not of significance since these devices are also air movers and therefore the factor of paramount importance is the overall power consumption of the unit. This is also true of certain types of wet collectors which require auxiliary pumping power.

The ability of any unit to maintain specified air or gas flow during its operating cycle is also a function of its operating principle. For example, inertial collectors of the simple and centrifugal type are able to maintain constant resistance regardless of concentration and particle size. However, adhesive materials may collect at the entry, throughout the unit, and at the exit, and thus cause a reduction in air flow and serious maintenance problems. With the exception of packed towers and wet filters, wet collectors operate at constant resistance throughout their operating cycles. However they may also be adversely affected by adhesive or corrosive materials. Wet filters or packed towers will eventually become clogged because of retention of inert dusts. Units employing fabric or other filter media will have resistance influenced by the concentration, particle size, shape, and packing characteristics of the aerosol. Their overall resistance during the operating cycle may increase gradually over a known or determined period. Auxiliary cleaning devices such as separate compartments, alternately shaken, reverse air flow, or reverse jet air flow may maintain constant or nearly constant resistance or insure only small fluctuations in air or gas flow. Electrostatic precipitators have the outstanding characteristic of maintaining a constant air flow with an accompanying low resistance. Adsorbers behave similarly to packed towers in that they provide constant resistance until the voids become seriously plugged with inert dusts. This generally requires a matter of several months on normal applications.

It has been found that inertial separators require the least maintenance. Simple wet collectors rank next in this respect. Complex wet collectors and fabric arrestors require maintenance on a definitely scheduled basis. Electrostatic precipitators require the usual maintenance connected with high-voltage equipment and may vary widely. The maintenance of adsorber type units is minimal and is based primarily on the amount of inert material encountered.

INERTIAL SEPARATORS

There are many types in this group. These range from simple settling chambers utilizing gravitational forces, to complex centrifugal devices using abrupt directional changes or motor driven rotors. They all have the desirable features of constant resistance during their operating cycle and do not require any special construction for temperatures under 750 F. Usually they require less maintenance than other types of collectors.

Table 1 . . . . Inertial Separator Characteristics

Kind	Efficiency Particle Size Range In Microns			Resistance (Pressure Drop)	Description and Remarks
	>100	100–10	<10		
Settling and baffle chambers	Medium	Low	Low	Low	A large chamber to reduce velocity to permit settling. Auxiliary baffles are sometimes used to improve performance. Requires large space.
Large diameter cyclones	High	Medium to low	Low	Low	Considered as single body over 3 ft in diameter. Gases and material must be dry. Air-tight dust bins or continuous removal of material must be provided. Space requirements moderate.
Refined design centrifugals	High	High	Medium to low	Medium	Available as multiple small-diameter tubes, scroll-shaped bodies, and multiple louvers. Gases and material must be dry. Air-tight dust bins or continuous removal of material must be provided. Space requirements moderate.
Integral rotor type	High	High	Medium to low	See remarks	Rotor acts as air mover and separating element. Usually limited to dry granular materials and dry gases. Low space requirements. No external pressure loss involved but power requirements are higher than usual exhauster.
Slotted scroll fan	High	Medium to low	Low	See remarks	Separation takes place in fan scroll. No external loss involved but power requirements are higher than usual exhauster.

On the basis of their important characteristics inertial separators may be classified according to Table 1.

SCRUBBERS AND OTHER WET COLLECTORS

In these collectors many methods are used to wet the contaminant and remove it from the air stream. A number of wet collectors are similar in design to dry collectors with the addition of sprays or liquid contactors. The mechanism of separation in wet collectors depends on inertial forces such as impaction and impingement, and in some cases, diffusion.

Wet collectors do not require any special construction for high temperatures. They are suitable for use on mixed contaminants such as gases and solid or liquid particles. The collection of dust in a wetted form eliminates a secondary dust problem in disposal of collected material. Protection against corrosion and freezing may be necessary and disposal of waste liquids may become a problem. With the exception of the packed towers and wetted filters they all have a constant resistance during their operation.

Table 2 . . . . Characteristics of Wet Collectors

Kind	Efficiency Particle size range in microns			Resistance In. Water	Water Rate In Gallons Per 1000 Cu Ft Gas	Maintenance	Description and Remarks
	>10	10–1	<1				
Air washers	High	Medium	Low	Low (less than 1)	5–15	Medium	Composed of one or more banks of low-pressure sprays and flooded eliminator plates. Space requirements are large. Water is usually recirculated.
Wet filters	High	High	Medium	Low (less than 1)	3–8	Medium	Composed of one or more banks of low-pressure sprays flooding packed cells of glass or other fibers. Space requirements are large. Limited to low loadings of solid particles.
Packed towers	High	High	Medium	High	5–10	High	Composed of granular or ceramic packing. Space requirements large. Generally limited to gas absorption.
Spray towers	High	Medium	Low	Low	5–10	Low	Usually a vertical chamber equipped with low-pressure water sprays at the top or along the walls. Baffle plates may be provided for contacting. Space requirements medium. Usually applied for hot gases.
Centrifugal or inertial scrubbers	High	High	Medium to high	Medium (see remarks)	½–40	See remarks	This classification includes most of the commercial wet collectors. They may utilize singly or in combination, low- or high-pressure sprays, wetted plates, rotating members, liquid gas contact by induction or centrifugal action. Some of these units (disintegrators) have high overall power requirements for driving the rotor while others have high power consumption for raising water pressures for spray nozzles. Maintenance varies from low to high depending on component parts. Simple gas liquid contact units would be classified as low. Units having rotating members may vary from medium to high depending on the type of service.
Venturi scrubber	High	High	High	High (12–25)	5–10	Medium	Consists of a simple venturi with low-pressure sprays at throat followed by a cyclonic type separator. Space requirements are low. Unit functions independent of grain loadings. High velocity at venturi throat may cause erosion problems.

On the basis of their important characteristics wet collectors may be classified according to Table 2.

FILTERS

Filters for industrial air and gas cleaning consist primarily of cloth dust collectors and the ultra or absolute type of filter.

Cloth dust collectors are generally constructed in the form of housings with cloth envelopes drawn over wire screen frames or with vertical cloth bags or tubes. Cloth filters depend to a great extent on the accumulated dust

Table 3 . . . . Characteristics of Fabric Filters

Kind	Efficiency, Particle size range in microns: >10	10 to 1	<1	Resistance	Filtering Velocity fpm	Maintenance
Cloth collector (shaken or rapped)[a]	High	High	Moderate to high	Medium	1–6	Medium to high (periodic)
Cloth collectors (reverse air or jet cleaning)[b]	High	High	Moderate to high	Medium to high	10–35	Medium to low
Absolute type[c]	High	High	High	Medium	3–14	None (see remarks)[c]

[a] Space requirements large. Requires scheduled cleaning.
[b] Space requirements medium. Cleaning constant during operating cycle. Added horsepower used for reverse jet action.
[c] Space requirements small. Requires replacement of unit when predetermined resistance is attained. Ordinary cleaning not possible.

layer for their effectiveness. Their basic or initial efficiency depends upon the type of fabric employed; felted media such as wool gives higher initial removal than woven fabrics. The increase in resistance to air flow, resulting from the accumulated dust layer, is related to rate of flow, concentration, and characteristics of the contaminant. Removal of the collected material is accomplished through periodic shaking by single mechanisms or combinations of them employing rapping, or through reversal of air flow, or by means of high-velocity reverse air jets. With shaking or rapping, air flow is not constant and filtering velocities are usually held under 6 fpm. With reverse jets or reverse air flow, substantially constant air flow is maintained and filtering velocities are generally higher (up to 35 fpm). Filtering velocities in all fabric collectors are highly dependent upon the aerosol, fume, or dust being collected.

The ultra or absolute type of filter[2] may consist of pleated cellulose asbestos paper, deep sand beds, composite glass wool layers, compressed glass fiber in the form of paper, or batts and resin wool. The use of this type of filter is limited to concentrations in the range of outdoor air where very high efficiencies, greater than 99.95 percent are required.

Fabric filters are not suitable for high temperatures, above 300 F, acid mists or vapors, or mixed contaminants such as wet corrosive gases and solid or liquid particles. Cotton fabrics are limited to 180 F, whereas wool is limited to temperatures under 200 F. A wide variety of natural and synthetic filter media are available for various temperature and corrosion conditions but caution must be exercised relative to rupture, high temperatures, and corrosive gases. When properly selected, efficiencies are often high enough to permit recirculation of air except, possibly, when handling toxic contaminants. On the basis of their important characteristics, fabric filters may be classified according to Table 3.

ELECTROSTATIC PRECIPITATORS

Electrostatic precipitators for industrial air and gas cleaning differ materially from the low-voltage designs described in Part I of this chapter, although the principles of operation are similar. For industrial concentrations, it is obvious that more severe demands are made upon methods of cleaning the collector, disposal of collected material, and servicing practices. Low-voltage cleaners for industrial loadings to date do not have sufficient inherent dust-holding capacity. One exception in the field of exhaust systems is that of the oil-mist collector, which functions satisfactorily on a liquid aerosol with the conventional low-voltage type (2 stage) electrostatic precipitator.

Industrial precipitators employ an assembly of parallel collector electrodes of various constructions, including corrugated plate, rod curtains, or perforated plate. Air flow is usually horizontal, although special construction may permit vertical air flow. High-voltage collectors were made in the form of vertical pipes, and are used for high operating pressures and for *wet-collector* designs where water continuously flows downward inside the pipe walls of the collector electrode. The negative discharge electrodes or rods are accurately centered between the usual 9 in. collector electrode spacing, the latter being of positive charge. Precipitation occurs in a single stage wherein ionization and collection are carried on simultaneously throughout the unit, and depend on high potentials of 25,000 to 75,000 volts. The high-voltage direct current is supplied by either mechanical or electronic rectifiers.

High efficiencies are obtained by allowing suitable time for contact in the collector zone, and by proper ratio of air flow velocity to that of transverse velocity of the negatively charged particles toward the positively charged collector plates.

Air velocities vary from 240 fpm to 480 fpm with a constant pressure drop of less than ½ in. water. Since the maximum efficiency is obtained with the finer particles at low concentrations, and the precipitation is not effective for large particles, inertial separators are frequently used in series with these units.

Attention should be directed to the prohibition of air recirculation to occupied spaces. High-voltage cleaning equipment produces ozone and nitrogen oxides in excessive quantities. The major source of maintenance usually will be in conjunction with the high-voltage rectifying equipment rather than the collector. Although usually used for elevated temperature work, unless the gases are preconditioned, temperatures in excess of 700 F should be avoided.

Collector electrode cleaning is accomplished by a rapping device, either electrical or pneumatic, without interrupting operation. The dry plate surfaces release the dust into hoppers below the plates. Some wet cleaning methods are also used.

Electronic precipitators require large spaces, maintenance may vary widely, and initial costs are high. Efficiency is a function of the aerosol encountered and usually ranges above 90 percent.

ABSORBERS, ADSORBERS, AND COMBUSTION DEVICES

One of the important problems in industrial air and gas cleaning is the removal of soluble, insoluble, or combustible gases and vapors from fluid streams before their discharge to the atmosphere. These contaminants may create problems which are distinct from the particulate removal discussed previously. It has been pointed out that scrubbers and other wet collectors may remove gases and particulate matter from contaminated air streams. However, the units

described are intended primarily for particulate removal with the exception of the spray or packed towers or wet cell devices.

Absorption devices are intended primarily for the removal of readily soluble gases which can be removed by simple absorbing agents such as water or alkali; for example, the removal of hydrochloric acid gas by a caustic spray.

Adsorption apparatus is intended primarily for removal of organic vapors in either high concentration (solvent recovery) or low concentration (odor removal). The first process is usually carried on as a matter of economic recovery. In the second process, the concentration of the contaminant must be low enough so that the adsorbent will have a reasonable life before replacement or reactivation.

Combustion, either total or catalytic, may be used to destroy organic compounds, either gaseous or particulate, which create odor problems. The use of catalysts to reduce the temperature needed for combustion is comparatively recent in this field. In some instances the heat of combustion may be recovered for utilization. The temperature necessary for destruction of compounds varies with the nature of the contaminant. However, partial combustion may alter the compound to render it innocuous. The temperature required for complete destruction is usually above 1100 F. Catalysts may only require heating to 500 F or may operate without heating if the gas temperature is above 500 F.

Absorbers

These may consist of spray chambers, packed towers, or wet-cell washers through which an absorbing agent is recirculated. The gases collected may be converted to insoluble salts or usable acids and other compounds. The performance of these devices depends upon several factors such as the solubility of the gas, its vapor pressure, its rate of reaction with the absorbent, the velocity through the collector, and area of the absorbing surface either as spray droplets or wetted media. These are generally designed for the specific purpose intended. They usually are intended to collect over 95 percent of the contaminant. Resistance depends upon the particular design and ranges from 1 to 10 in. of water in most installations. Their resistance during their operating interval is constant unless serious plugging of packing occurs. Spray units are seldom affected by plugging. Packed absorption devices require a precleaner to remove particulates if long trouble-free service is desired. Maintenance of spray nozzles is a function of the degree of atomization used and of conditions encountered, such as purity of spray liquids.

Protection against corrosion and freezing may be necessary and disposal of waste liquids may create secondary problems.

Adsorbers

These units consist of a chamber filled with a granular adsorbent. The adsorbent may be activated charcoal, silica gel, alumina, and other treated solids. Activated charcoal is the most common and has the highest retention per unit weight for organic solvents. Performance of adsorbent beds depends upon their thickness, velocity of the gas passing, mesh size (surface area) of adsorbent, and temperature of the vapor being removed. They can be designed to obtain almost complete removal of organic vapors and some inorganic gases. They may be reactivated by the use of steam or heat. Resistance depends upon the adsorbent mesh size, depth, and velocity. It may range from less than one inch of water to several inches of mercury.

Adsorbent beds are usually limited, because of their cost, to applications where recovery may be economically feasible. Removal of particulate matter by use of precleaners is necessary if significant loadings are involved as the adsorbent voids are readily plugged. They are not suitable for high temperature conditions. Silica gel and alumina exhibit a strong preference for water vapor whereas charcoal does not.

Combustion Devices

This group of industrial air cleaners entails the use of high temperatures or catalysis combined with some elevation in temperature to destory or decompose organic and some inorganic gases which create obnoxious odors. The devices are divided into those in which combustion is obtained by use of liquid or gaseous fuels and the secondary air for combustion is provided by the contaminated air. In essence, the simplest form involves passing the contaminated air through the combustion chamber of a boiler or fire box. Special fire boxes or brick checkerwork may also be employed. Catalytic devices consist of noble metal packed into frames in the form of ribbons or screens or may be ceramic granules coated with noble metal catalysts. The frames or packing are placed in a housing over which the gas stream to be decontaminated is passed. The contaminants break down and are reduced to elemental gases of an innocuous nature. Catalysts reduce the amount of heat necessary but may become contaminated by sulfur or other elements.

The performance of a combustion device is dependent upon the retention period of the contaminant in the high temperature zone. Removal or destruction is thus dependent on velocity and surface area of the heat-transfer device. If properly designed, obnoxious odors are removed.

The resistance of the direct combustion unit is negligible since it is an integral part of the fuel-combustion system. Catalytic devices behave in a manner comparable to packed beds or filters except that they are not plugged by organic particulates but may be affected by inorganic solids.

Maintenance of these types of units is essentially dependent upon the contaminants encountered. The direct-combustion system requires little care other than that required by ordinary fuel-burning equipment. Catalytic units become contaminated slowly and will require removal for reactivation at certain intervals depending upon the application.

Economic factors may limit the use of direct-combustion methods unless there is a demand for the heat generated. They may best be applied to processes employing combustion. Catalytic units require temperatures of at least 500 F and consequently it may be necessary to preheat the contaminated air to this value.

CHAPTER 25

SOUND CONTROL

Acoustical Terminology; Apparatus for Measuring Sound; Approaches to the General Problem of Noise Control; Criteria for Noise Control; Kinds of Noise; Noise Generated by Fans, Grilles, and other Sources; Sound Attenuation in Ducts; Determination of Room Levels; Cross Transmission between Rooms and through Duct Walls; Controlling Vibration from Machine Mountings

THE NOISE created by heating, ventilating, and air-conditioning equipment has become an important factor in modern building design. Related to this, and of equal importance, is the problem of the transmission of speech or music from one part of the building to another through ventilating and air-conditioning ducts. The architect and the acoustical engineer cooperate to produce rooms that are satisfactory for speech, music, or other intended uses. The ventilation and acoustical engineers cooperate to ventilate and air condition these rooms to be physically comfortable without adding noise in excess of established requirements. This chapter is planned to supply part of the information needed to achieve adequate quietness in rooms that are ventilated and air conditioned through supply ducts. The quieting of unit heaters and coolers is assumed to be the job of the manufacturers and is not covered here. Remaining information on cost, availability, durability, and ease of installation can come only through experience with practical installations.

ACOUSTICAL TERMINOLOGY[1]

Sound Power W is the power in watts produced by a source of sound. This power may be (*a*) the total power radiated by the source over its entire frequency range, (*b*) the power radiated in a limited frequency range, or (*c*) the power radiated in each of a series of contiguous frequency bands. The frequency range or frequency band should be clearly stated.

Sound Intensity I is the power radiated in a specified direction through unit area normal to this direction, e.g., watts per square meter, watts per square foot, or watts per square centimeter.

Sound Pressure p is the root-mean-square incremental pressure produced when a sound wave passes through an otherwise undisturbed medium. The unit is the microbar (1 dyne per sq cm or 0.1 newton per sq m).

Frequency f is the rate of repetition of a periodic phenomenon. The frequency is the reciprocal of the period, or the time necessary for the phenomenon to repeat. The frequency f of a single tone sound wave is equal to the ratio of the speed of sound c to the wavelength λ of the tone. $f = c/\lambda$, or $c = f\lambda$. The unit is the cycle per second, or cps.

Decibel db is a dimensionless unit for expressing the ratio of two numerical values (usually electrical or mechanical power) on a logarithmic scale. The number of decibels is ten times the logarithm to the base 10 of the numerical ratio of the two quantities. For example, let W_1 and W_2 designate two powers; or I_1 and I_2 designate two sound intensities, and let M designate the number of corresponding decibels, then

$$M = 10 \log_{10} \frac{W_1}{W_2} \text{ decibels} \quad (1)$$

or,

$$M = 10 \log_{10} \frac{I_1}{I_2} \text{ decibels} \quad (2)$$

Alternatively, the ratio of two sound pressures squared is expressed in the same units,

$$M = 10 \log_{10} \frac{p_1^2}{p_2^2} = 20 \log_{10} \frac{p_1}{p_2} \text{ decibels} \quad (3)$$

These relations tacitly assume that: $W = p^2/Z$, which means that Z, the acoustic impedance, is real, and that for p_1 and p_2, $Z_1 = Z_2$. This is not usually the case, but because sound pressure is the easiest variable to measure in a sound field, the relation:

$$M = 20 \log_{10} \frac{p_1}{p_2} \text{ decibels} \quad (4)$$

is commonly used. Thus, in a sense when used in this way, the decibel is redefined on the basis of a pressure squared ratio rather than a power ratio.

Octave Frequency Bands. The frequency range of a noise is frequently broken up into octave frequency bands where, in principle, the upper frequency is twice the lower frequency of the band as shown in the following table.

Band Number	Usual Frequency Limits	Approximate Geometric Mean Frequency
1	20 to 75 cps*	40
2	75 to 150	105
3	150 to 300	210
4	300 to 600	425
5	600 to 1200	850
6	1200 to 2400	1700
7	2400 to 4800	3400
8	4800 to 10,000*	6900

* The highest and lowest bands as usually used, contain somewhat more than one octave as indicated.

Sound Power Level PWL is ten times the logarithm to the base 10 of the ratio of the sound power to the reference power of 10^{-13} watt. Thus, Power Level in the English system[2]

$$\text{PWL} = 10 \log_{10} \frac{W}{10^{-13}} \text{ dbe} \quad (5)$$

where

W = sound power, watts.

The unit is the *dbe*. The symbol *dbe* means that the sound

power level is convenient to use in the English system and that 10^{-13} watt is the reference power.

Sound Intensity Level (L_I) is ten times the logarithm to the base ten of the ratio of the sound intensity I to the reference intensity of 10^{-16} watt per sq cm (or its equivalent of 1 picowatt per sq m). Thus

$$L_I = 10 \log_{10} \frac{I}{10^{-16}} \text{ dbi} \quad (6)$$

where

I = watts per square centimeter

or

$$L_I = 10 \log_{10} \frac{I}{10^{-12}} \text{ dbi} \quad (7)$$

where

I = watts per square meter.

The unit is the *dbi*. Either formula gives the same result.

Sound Pressure Level L_p is twenty times the logarithm to the base 10 of the ratio of the sound pressure p to the reference sound pressure of 0.0002 microbar, i.e.,

$$L_p = 20 \log_{10} \frac{p}{0.0002} \text{ dbc} \quad (8)$$

where

p = sound pressure, microbars (dynes per square centimeter).

The unit is the *dbc*, where *c* stands for the C scale or flat scale on the sound level meter.

Loudness N is the intensive subjective attribute of an auditory sensation, in terms of which sounds may be ordered on a scale extending from soft to loud. The unit is the sone. The number of sones is directly proportional to the loudness. By definition, a 1000 cps pure tone with a sound pressure level of 40 dbc has a loudness of 1.0 sone.

Loudness Level (L_N) of a sound is numerically equal to the sound pressure level L_p of a simple tone of frequency 1000 cps that is judged by the listeners to be equivalent in loudness. The unit is the phon. In this text, for a 1000 cps tone, L_N in phons is assumed to be related to N in sones by the formula

$$L_N = 33 \log_{10} N + 40 \text{ phons} \quad (9)$$

This approximation is assumed valid[3] for $N > 1$.

Sound Level at a point in a sound field is the reading in decibels of a sound level meter constructed and operated in accordance with the latest edition of *American Standard Sound Level Meters for the Measurement of Noise and Other Sounds*.[4] The reading is taken with the proper weighting network switched into the circuit. The unit is dba, if the reading is taken on the A scale; dbb if taken on the B scale, and dbc if taken on the C or flat scale. The use of these scales is discussed later.

Attenuation is ten times the logarithm to the base 10 of the ratio of the sound intensities at any two points along any continuous acoustic path in the direction away from the source. The unit is the decibel. For a signal confined to a channel or duct, the intensity values are averaged over the cross-section.

Transmission Loss TL is ten times the logarithm to the base 10 of the sound energy incident on an obstruction in an acoustic path to the sound energy that is transmitted through the obstruction. The unit is the decibel.

Noise Reduction NR is the difference in decibels of the sound pressure levels at two points along an acoustic path in the direction away from the source; alternatively, it is the difference in decibels of the sound pressure levels existing at a single point before and after the addition of acoustic treatment to the path.

APPARATUS FOR MEASURING SOUND

The measurement of sound or noise is usually accomplished by means of (*a*) a sound level meter SLM consisting of a microphone, an amplifier, a variable attenuator, weighting networks, and an indicating meter which reads directly in decibels, and (*b*) an octave band analyzer OBA which is a set of filters for determining the sound pressure level of the sound being measured in each of eight octave-frequency bands. The approved sound level meter and octave band analyzer should comply with the specifications in the latest version of the *American Standard Sound Level Meters for Measurement of Noise and Other Sounds*, Z24.3–1944, and *American Standard Specifications for an Octave-Band Filter Set for the Analysis of Noise and Other Sounds*, Z24.10–1953, published by the American Standards Association.

The SLM is designed to indicate either the sound pressure level L_p or the sound level (if weighting networks are used) above the standard reference level of 0.0002 microbar. The SLM itself has three weighting networks, which are approximations to the equal loudness contours for pure tone sounds of three discrete loudness levels. The equal loudness contours give the L_p of a 1000 cps pure tone that sounds equally as loud to the average listener as the tone whose loudness level is desired.[3]

Unfortunately, standard sound level meters do not give an indication of the loudness of more complex noises. To serve as a basis for determining the loudness of more complex noises, measurements of complex sounds are taken on the flat scale (C scale) of the SLM using the OBA to determine the distribution of the sound pressure level as a function of frequency. Computations of loudness and loudness level are made from these data.

Allowable deviations in response and acceptable tolerances recognized in the standard for the sound level meter are: ±0.5 db at 80 cps to 630 cps; +2.0, −2.5 db at 25 cps; ±2.5 db at 2000 cps; ±6.0 db at 8000 cps. Calibration of the SLM and OBA should preferably be made before, during, and after each use by a calibrated loudspeaker.[3] In turn, the loudspeaker should be calibrated at the factory at frequent intervals. Instructions and precautions in the use of sound level meters are given in Reference 2.

APPROACHES TO THE GENERAL PROBLEM OF NOISE CONTROL

It is usually necessary to think of noise control problems as composed of three parts: (*1*) the source, (2) the path, (3) the receiver.

It is sometimes possible to reduce the noise at any or all of these parts. However, in construction design, the engineer is usually able to do something only with the path.

The source may be any piece of equipment or person generating audible noises. The transmission path may be a path directly through air or may be a path which includes solid structure such as walls, floors, pipes, duct walls, or air within ducts in various combinations. The receiver is usually a person who might be disturbed by the noise; however, the receiver might also be a delicate machine or manufacturing process that must be isolated from vibration.

The acoustic output of a source is ideally specified by its

total sound power level and the sound power level in each of a group of frequency bands, preferably octave frequency bands. Where the source is not confined to a duct or the like, it may also be necessary to specify the source directivity, i.e., the relative amount of sound radiating in each direction of interest. In general, the specification of the acoustic output of a source by a single number is not adequate for engineering design of noise control measures. The sound power outputs of fans and grilles as noise sources are discussed in later sections.

Acoustic losses along a path from source to receiver normally exist in any building structure. These losses are a function of frequency and can be defined adequately when expressed as losses in each of eight octave bands. Losses for common structures, and for ducts of various sizes and shapes, as well as for some packaged sound attenuation devices, are published. Some values particularly applicable to ventilating problems are given in a later section.

The response of a person as a receiver has been determined under certain conditions. Noise levels which are found acceptable to the average person under specified conditions are called *noise criteria*. Several frequently used noise criteria are summarized in a later section. The noise criteria to be used must be chosen with regard to the type of activity to be carried on in the space being considered. Where delicate machines or manufacturing processes are the receiver, special noise criteria must be determined to fit the need. Noise criteria should best be specified as sound pressure levels in octave frequency bands.

A good procedure for attacking a noise control problem in a ventilating system will be illustrated by reference to Fig. 1. The sound power level of the fan is expressed in dbe. Sound attenuation in the duct is composed of losses in the unlined and lined portions of the duct, losses at the bend, and end reflection losses. Added attenuation of the fan noise is achieved by adding additional lining to the duct or providing package attenuation units. Noise is also produced at the grille and is expressed in dbe. All losses (attenuation) are expressed in decibels. The procedure follows:

Step 1. Determine the sound power level of the grille noise either from published data, or from actual measurements, or from approximate data given in the section on Noise Generated by Grilles.

Step 2. Determine the sound pressure levels in octave bands at a specified listener's position due to grille noise alone which is radiated from the end of the duct, using the acoustical properties of the room and the position of the listener (see the following section on Determination of Room Levels).

Step 3. Determine the allowable sound pressure level in octave bands (the criterion) at the listener's position either from published standard data (see the following section on Criteria for Noise Control) or from discussions with the architect or the ultimate user of the room under design.

Step 4. Subtract the criterion levels from the sound pressure levels at the listener's position (in decibels) to determine that the levels at least meet the criterion in each octave band. If the grille noise is higher than the criterion in any octave band, a larger grille size must be used.

Note: The total noise in the room is due to both the grille noise and the fan noise. If the grille noise levels just meet the criterion, then the fan noise emitted in the room must be at least 5 db below the criterion. Alternatively, the grille noise levels and the fan noise levels in the room could each be 3 db below the criterion, because when two noises of the same intensity are combined, the total level is 3 db higher than either. As a third choice, the fan noise could just meet the criterion, and the grille noise be at least 5 db below the criterion.

Step 5. Obtain the sound power level in octave bands of the fan, either from published data, or from actual measurements, or from approximate formulas given in the following section on Noise Generated by Fans.

Step 6. Determine the existing attenuations in the path, for example, natural duct losses, losses at bends, and reflection losses at the outlet (see the following section on Sound Attenuation in Ducts).

Step 7. Determine the net source power levels by substracting values from Step 6 from Step 5.

Step 8. Determine the sound pressure levels in octave bands at a specified listener's position using as basic data the net source power level from the duct, the acoustical properties of the room, and the position of the listener as done in Step 2.

Step 9. Subtract the criterion levels from the sound pressure levels at the listener's position (in decibels) as done in Step 4 to obtain the required amount of noise reduction NR in each of the eight octave bands (refer again to note following Step 4).

Step 10. Choose an economical means of providing the required NR. The noise reduction required usually must be obtained by treating the ducts between the source and the receiver either by adding an absorbing lining or by inserting a package unit (see Fig. 1) of known attenuation as a function of

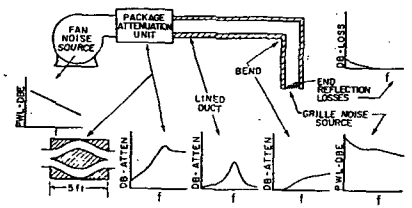

Fig. 1 . . . . Typical Ventilation System Problem

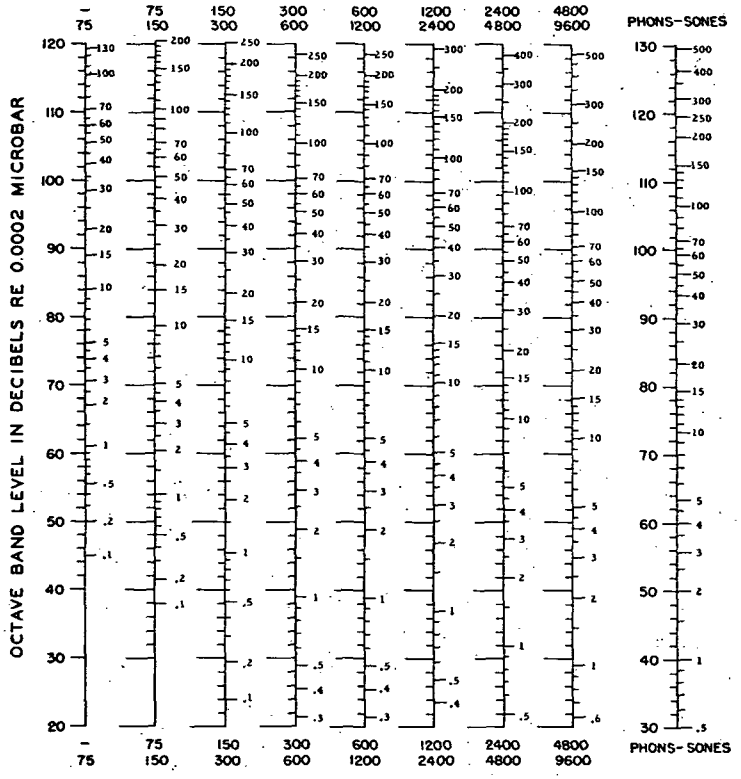


frequency. Because noise may be induced by vibration, a consideration of the fan mounting may be necessary. Also, if the fan room is adjacent to a quiet space, the construction of the fan room walls to provide adequate noise reduction should require attention. It is usually good policy to provide slightly more acoustical treatment than is necessary, thus obtaining a safety factor. A safety factor often used is 5 db greater noise reduction than would be indicated by the above procedure.

Frequently the controlling noise source in a building with a central station system is sound transmission through the walls of the apparatus room or from a duct plenum. Where such a room or plenum is near occupied rooms, the noise transmitted through the walls must be determined. The combined sound pressure levels resulting at a listener's position should be compared with the criteria as done in Step 4 for noise produced by grilles.

CRITERIA FOR NOISE CONTROL

Criteria for noise control in building spaces have evolved in the United States from several large scale studies and from the experiences of engineers who have recorded favorable and unfavorable reactions to known background noises in many types of rooms.[5]

The acoustical engineer should carefully question the user of the building to make certain of the kind of uses that he has in mind. For example, a coliseum used for sports only, need not be as quiet as a coliseum also used for concerts. As another example, a hall for band concerts need not be as quiet as one for chamber music. In fact, some rooms are better if they are not too quiet. It has been found that libraries, drafting rooms, and study rooms that are too quiet are not so desirable as they would be with moderate noise levels. In very quiet rooms of these types, sounds such as whispering, turning of pages, creaking of the floor, coughing, closing of doors, etc., act to distract the occupants and to make them complain of noise.

The calculated total loudness in sones can be converted to loudness level in phons by means of the nomogram at the right.
(From Reference 3. Used by permission.)

Fig. 2 .... Nomograms Relating L_s in Octave Bands to Loudness in Sones

Introduction of a continuous spectrum noise properly distributed as a function of frequency produces a *quieter* condition even though the background noise is actually higher. Rumbles, rattles, audible single frequency components, beats between components, and intermittency in a noise often make it objectionable even though the noise as measured seems to meet the criterion.

Noise Specification

There are at least four possible ways of specifying the noise. The first way is simply to give the octave band spectrum of the noise. This method provides the information that is essential to the design engineer and no substitute can suffice. The other three of these methods of specifying noise are single-number numerical quantities that indicate something about the influence of the noise on the average human being. These three methods are useful as summaries of the octave band spectrum, but, taken separately, they are of limited value to the design engineer. The definitions of each of four commonly used ways of specifying noise are as follows:

1. *Octave Band Spectrum*. The octave band spectrum is comprised of the readings of sound pressure level in the eight octave frequency bands (see the section on Acoustical Terminology). The readings are taken with the sound level meter weighting networks set on *flat* (C-scale) and the units are decibels (dbe). The specification of a complete octave band noise spectrum is necessary for satisfactory acoustic design in all cases.

2. *Speech Interference Level* SIL. The speech interference level is a single number found by taking the arithmetic average of the sound pressure levels in the three octave frequency bands 600–1200, 1200–2400, and 2400–4800 cps. The unit is the decibel (db). The speech interference level indicates the ease of speech communication in the presence of the noise so rated.

3. *Loudness Level* L_N. The loudness level is a single number computed from octave band levels according to the procedure following. The unit is the phon.

To obtain the loudness level in phons, obtain the sound pressure levels in the eight octave bands and read from Fig. 2 the loudness in sones for the respective bands. The sum of the loudnesses will be:

$$\Sigma N = N_1 + N_2 + N_3 + N_4 + N_5 + N_6 + N_7 + N_8 \qquad (10)$$

The loudness in *sones* of the total noise is given by

$$N = N_m + 0.3\,(\Sigma N_i - N_m) \qquad (11)$$

where

N_m = the loudness of the loudest band.

ΣN_i = the sum of the loudnesses of all eight bands.

To convert from loudness in sones to loudness level in phons, use Equation 9 or the nomogram at the right-hand side of Fig. 2.

The loudness level in phons indicates the subjective loudness but does not indicate the ease of speech communication.

4. *Sound Level*. The sound level is a single reading taken on the sound level meter with the meter operated as follows:[2, 6]

Sound-Level Range	Weighting	Unit
Below 55 db.....	A	dba
55–85 db.....	B	dbb
Above 85 db.....	C (Flat)	dbc

Sound level measured with the A-scale can be correlated most closely with speech interference level but the two are not numerically the same. The C-scale is *always* used with the octave band analyzer and is used where otherwise specified.

Criteria

Noise criteria have been developed from detailed studies and engineering experience in a number of architectural spaces.[4] The acceptability of background noise for various types of activities normally performed in rooms and enclosures can be related to two principal characteristics of the noise: (1) Speech interference level, SIL, and (2) Loudness level, L_N. Definitions of these two quantities are given in the preceding section on Noise Specification. The speech interference level is governed by the amount of high-frequency noise (between 600 and 4800 cps) and the loudness level is governed by both the high- and low-frequency noise.

For most types of spaces the loudness level in phons is 22 to 25 units higher than the speech interference level in dbc. However, for factories, sports coliseums, restaurants, and similar spaces where cost of acoustic treatment dictates a maximum amount of compromise, the loudness level may rise as much as 30 units above the speech interference level.

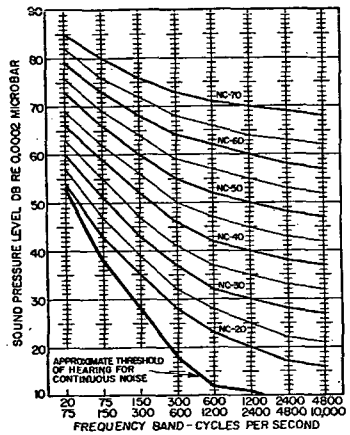
Acceptable background noise criteria have been established for these two conditions and are presented in Figs. 3 and 4. Each curve is designated by a number indicating the speech interference level obtained. The numbers in the first column of Table 1 and Table 2 identify the curve which defines recommended noise levels for the various types of spaces listed.

With regard to the choice between Figs. 3 and 4, Fig. 3 should be used whenever possible, particularly where there is a possibility that the sound may be fluctuating, such as often occurs with turbulence in a ventilating system. Fig. 4, or numbers in the range between Figs. 3 and 4, may be used when economic factors dictate a compromise and when there is a definite assurance that the noise will not be of a fluctuating type.

In engineering design, all eight octave band levels selected from the curves of Fig. 3 or 4 should be used. In construction specifications, reference may be made to THE GUIDE and the selected *NC* or *NCA* curve may be referred to by number, e.g., *NC*-35.

Where octave band analyses of the noise cannot be made and a rough approximation of accepted criteria must be obtained by use of a sound level meter only, the A-scale values which would be read for the noise spectra specified in Column 1 are given in Column 2 for comparison purposes. It should be understood, however, that an A-scale reading gives a measure of the overall noise using a weighted network; it does not specify the spectrum. For example, the noise spectrum shown as *NC*-25 in Fig. 3 would give an overall A-scale measurement of 35 dba, but a measured value of 35 dba does not mean that the actual noise measured has the same spectral shape or is as satisfactory as the specified *NC*-25 spectrum. The lack of octave band analysis can be partly offset by a subjective observation; if the noise sounds unnatural because of excessive amounts of high pitched or low pitched noise or has particularly noticeable amounts of pure tones, the spectrum will probably depart widely from the specified one. In such cases it is advisable to make an octave band analysis of the noise, if possible.

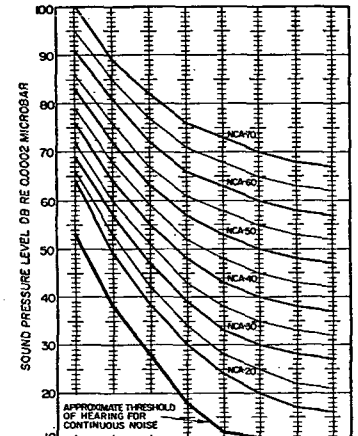
KINDS OF NOISE



The noise introduced into a room or building by ventilating or air-conditioning equipment may be divided into two general kinds, depending on how it reaches the room:

1. *Noise transmitted through the ducts.*
   - *a.* From equipment such as fans, motors, sprays, etc.
   - *b.* From outside, and transmitted through duct walls into air stream.
   - *c.* From duct wall vibrations, transmitted into air stream.
   - *d.* From air currents, including eddying noises.
   - *e.* Cross talk and cross noises between rooms connected by the same duct system.
   - *f.* From dampers and air valves located near branch duct take-offs and outlets.
   - *g.* Noise produced by grilles or diffusers.
2. *Noise transmitted through the building construction.*
   - *a.* From machine mountings as vibration.
   - *b.* From equipment through room wall surfaces.

The following text will present data and discussion of methods whereby solutions of the noise problem can be obtained when the allowable room noise level, and the path through which the noise reaches the room, are known.



NOISE GENERATED BY FANS

Aerodynamic noise from all types of fans may be broadly divided into a rotational component and a vortex component. The rotational component is associated with the impulse given to the air each time a blade passes a given point and is hence a series of discrete tones at the fundamental blade passing frequency and harmonics thereof. The vortex component of noise is largely due to the shedding of vortexes from the fan

Each NC curve has a loudness level in phons that is 22 units greater than the Speech Interference Level in decibels (expressed by the NC number of the curve). These curves should be used in design or specifications wherever a favorable relation between the low frequency and the high frequency portion of the spectrum is desired (see text).

Fig. 3 .... Criterion Curves for Use with Table 1 in Determining the Permissible (or Desirable) L_p Values in 8 Octave Frequency Bands

Same as Fig. 3 except that each NCA curve has a loudness level in phons that is 30 units greater than the Speech Interference Level in decibels (expressed by the NCA number of the curve). These curves may be used in design or specifications in place of those of Fig. 3 wherever economy dictates a maximum compromise and where, in addition, the fan and turbulence noise is steady and free of low frequency pure tone components (see text).

Fig. 4 .... Criterion Curves for Use with Table 1 in Determining the Permissible (or Desirable) L_p Values in 8 Octave Frequency Bands

blades. It is random in character and has a continuous spectrum over a wide range of frequencies determined by the fan geometry and operation. It may also have many nonharmonic single-frequency components determined by blade geometry and local air velocity. Since the laws of generation of these two types of noise are different, they will vary in importance for different types of fans and operating conditions.[6, 7]

In addition to aerodynamic noise, there are usually several non-aerodynamic sources of noise in equipment involving fans. Such sources include noise resulting from unbalance, bearing noise, brush noise, magnetic noise, and belt noise.

The number of blades of a centrifugal fan generally is governed by optimum air-flow design. The noise generation decreases but slightly for more than the optimum number of blades.

Powerful tones of definite pitch may be generated in fans when the wakes from the impeller blades impinge on an obstruction such as a badly located or shaped cut-off in a centrifugal fan, or struts or motor supports which are badly shaped and too close to the impeller of an axial flow or propeller fan. This interference noise has the same frequency characteristics as rotation noise.[8]

A shroud around a propeller fan may serve to reduce noise considerably if it is working properly. Such reduction is generally most effective at the higher harmonics. However, if the flow breaks down over part of the shroud, the noise may become considerably worse than for an unshrouded case.

As the operating pressure across axial fans is increased the maximum sound intensity is shifted from the fundamental to higher harmonics. This effect is not observed for centrifugal fans.

Effect of Fan Parameters on Noise vs. Performance

Fan Laws. The principal laws governing the mechanical performance of a fan, whether centrifugal or axial, are fairly well established and are given in Chapter 22.

Fixed Point of Rating. A fixed point of rating of a given size fan at a given speed is one for which the capacity (volume flow) is chosen as a given fraction of the free delivery capacity. Having chosen this capacity ratio, the ratio of pressure to the static no-delivery pressure is determined. This fixed point of rating will have a fixed efficiency within the limitation of certain manufacturing details. The fan laws serve to relate the performance of two members of a symmetrical series of fans operating at the same fixed point of rating whether at the same or different speeds.

Correlation of Fan Noise with Size, Static Pressure, Speed, and Capacity. The empirical relations between the noise generated by a fan and its size, static pressure, speed, and capacity are as follows:

Change in overall sound power level varies as:

$$70 \log_{10}(\text{size}_2/\text{size}_1) + 50 \log_{10}(\text{speed}_2/\text{speed}_1) \quad (12)$$

$$20 \log_{10}(\text{size}_2/\text{size}_1) + 25 \log_{10}(\text{pressure}_2/\text{pressure}_1) \quad (13)$$

$$10 \log_{10}(\text{capacity}_2/\text{capacity}_1) + 20 \log_{10}(\text{pressure}_2/\text{pressure}_1) \quad (14)$$

These relations also apply only for a fixed point of rating.

A double width fan is essentially two fans of the same size, speed, and sound pressure level and therefore its sound power level will be $10 \log_{10} 2$ or 3 db greater than for the single one.

Example 1: Consider a 36½-in. diameter fan operating at 700 rpm. If it produces a noise level of 70 dbc what will be the level if a 49-in. diameter fan operating at 1000 rpm is substituted for it?

Solution: From Equation 12,

$$\text{Change in level} = 70 \log_{10} \frac{49}{36.5} + 50 \log_{10} \frac{1000}{700} = 16.8 \text{ db}$$

$$\text{Noise level of second fan} = 70 + 16.8 = 86.8 \text{ dbc}$$

Fan noise does not follow equations exactly. The radiated sound power of a centrifugal fan, for example, is not all concentrated on the blade frequency. While the overall sound power level seems to follow these equations fairly closely, the various components in the different frequency bands may show greater deviation. In the case of axial flow fans there is a wider range in characteristics of the vortex noise, so it would be expected that a slightly greater deviation from these equations exists than for centrifugal fans. This is particularly true as speed is increased. The fundamental or blade frequency exists over a wider range of pressure in the case of the centrifugal fan. In the axial fan, the harmonics are more easily excited and often the second and third harmonics exceed the level of the fundamental.[8]

Specific Plots

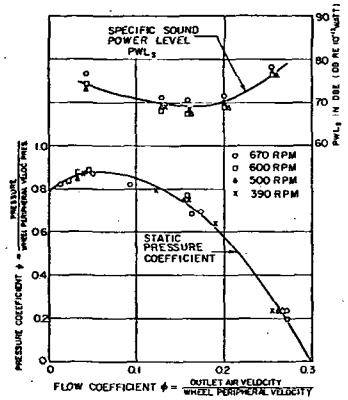
Curves which describe the characteristics of an entire series of similar fans can be plotted by using dimensionless coordinates.[7] To describe the pressure characteristics the pressure coefficient ψ can be plotted against the flow coefficient ϕ as shown in Fig. 5, where

$$\psi_t = \frac{p_t}{\left[\frac{(\pi)(D)(\text{rpm})}{4005}\right]} = \frac{\text{total pressure}}{\left(\begin{matrix}\text{wheel peripheral} \\ \text{velocity pressure}\end{matrix}\right)} \quad (15)$$

Table 1 .... Recommended Noise Criteria for Rooms[a]
Noise levels to be Measured in Unoccupied Rooms

Type of Space	Recommended Noise Criterion Curve	Computed Equivalent Sound Level Meter Readings[a] Weighting Scale-A dba
Broadcast studios	NC 15–20	25–30
Concert halls	NC 20	30
Legitimate theaters (500 seats, no amplification)	NC 20–25	30–35
Music rooms	NC 25	35
Schoolrooms (no amplification)	NC 25	35
Conference rooms for 50	NC 25	35
Apartments and hotels	NC 25–30	35–40
Assembly halls (amplification)	NC 25–30	35–40
Homes (sleeping areas)	NC 25–35	35–45[b]
Conference rooms for 20	NC 30	40
Motion picture theaters	NC 30	40
Hospitals	NC 30	40
Churches	NC 30	40
Courtrooms	NC 30	40
Libraries	NC 30	40
Small private offices	NC 30–35	40–45
Restaurants	NCA 45	55
Coliseums for sports only (amplification)	NCA 50	60
Stenographic offices (typing and business machines)	NC 50	60
Factories	NCA 40–65	50–75

Note: Each noise criteria curve is a code for specifying permissible sound pressure levels in eight octave bands. It is intended that in no one frequency band should the specified level be exceeded. The computed equivalent dba numbers in the right-hand column are presented for information only and are no longer recommended for use in specifications. Ventilating systems should be operating and outside noise sources, traffic conditions, etc., should be normal when measurements are made.



[a] If the noise is predominantly in the speech bands so that the spectrum does not have the shape of the recommended noise criterion curve, the recommended dba numbers should be lower by 5 dba.

[b] Room air conditioners made prior to 1957 commonly produce levels of 50 to 60 dba in sleeping areas.

Table 2 .... Recommended Noise Criteria for Offices[a]

NC Curve of Fig. 3	Communication Environment	Typical Applications
NC20 to NC30	Very quiet office—telephone use satisfactory—suitable for large conferences.	Executive offices and conference rooms for 50 people.
NC30 to NC35	Quiet office; satisfactory for conference at a 15-ft table; normal voice 10 to 30 ft; telephone use satisfactory.	Private or semiprivate offices, reception rooms, and small conference rooms for 20 people.
NC35 to NC40	Satisfactory for conferences at a 6–8 ft table; telephone use satisfactory; normal voice 6 to 12 ft.	Medium-sized offices and industrial business offices.
NC40 to NC50	Satisfactory for conferences at a 4–5 ft table; telephone use occasionally slightly difficult; normal voice 3 to 6 ft; raised voice 6 to 12 ft.	Large engineering and drafting rooms, etc.
NC50 to NC55	Unsatisfactory for conferences of more than two or three people; telephone use slightly difficult; normal voice 1 to 2 ft; raised voice 3 to 6 ft.	Secretarial areas (typing), accounting areas (business machines), blueprint rooms, etc.
Above NC55	Very noisy; office environment unsatisfactory; telephone use difficult.	Not recommended for any type of office.

[a] Noise measurements made for the purpose of rating the noise level in an office by comparison with these criteria should be performed with the office in normal operation, but with no one talking at the particular desk or conference table where speech communication is desired (i.e., where the measurement is being made). Background noise with the office unoccupied should be lower by approximately 5 to 10 units.

These data are for a particular fan. The quantities ψ_s, ϕ, and PWL$_s$ are discussed in the text. Such curves apply to all fans in a similar series.

Fig. 5 . . . . Specific Fan Characteristic Curves, Including Specific Sound Power Level

$$\psi_s = \frac{p_s}{\left[\frac{(\pi)(D)(\text{rpm})}{4005}\right]} = \frac{\text{static pressure}}{\left(\begin{matrix}\text{wheel peripheral}\\ \text{velocity pressure}\end{matrix}\right)} \quad (16)$$

$$\phi = \frac{(\text{cfm})/(\text{Outlet Area})}{(\pi)/(D)(\text{rpm})} = \frac{\text{outlet velocity}}{\text{wheel peripheral velocity}} \quad (17)$$

where

D = wheel diameter, feet.
p_s = static pressure.
p_t = total pressure.

Such curves apply to all fans in a similar series, i.e., a series of fans differing in size only while preserving complete similarity in shape by having all linear dimensions changed in the same proportions.

An overall specific sound power level PWL$_s$ in dbe as shown in Fig. 5 can also be defined that will be applicable to all fans in a family.[7] It is obtained by means of Equation 18 which follows:

$$\text{PWL}_s = \text{PWL} - 10\log_{10}[q \cdot p^2] \text{ dbe} \quad (18)$$

where

q = quantity of air discharged, cfm.
p = pressure, inches of water.
PWL = sound power level actually measured.

Since static pressure p_s is more frequently measured for fans than total pressure p_t, p_s may be used under most normal operating conditions (when the difference between p_s and p_t is less than 20 percent) and the error will then be less than 1 db. Near free discharge, p_s becomes zero and p_t must be used. In other words, PWL$_s$ is the sound power level that a similar (although hypothetical) fan would produce when operating at 1 cfm and a total pressure of 1 in. of water. As an example, the specific power level for one fan tested is shown on Fig. 5.

Although few data are available to confirm the conclusion, it is indicated that such a plot also holds throughout a series of fans for all eight of the frequency bands provided rotor or blade passage frequencies are not predominant.

Approximate Overall Sound Power Level

In practice, data of the type shown in Fig. 5 are usually not available. Hence, in design an estimate has to be made of the overall sound power level and of the shape of the noise spectrum. Tests on centrifugal fans ranging in size from 0.01 hp to 100 hp show that the sound power level in a duct *either* upstream or downstream from the fan can be found within ±4 db from the simple relation:[9, 10]

$$\text{PWL} = 100 + 10\log_{10}W_E + 10\log_{10}p \text{ dbe} \quad (19)$$

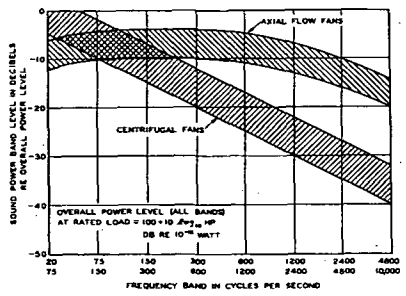
where

W_E = nameplate electrical horsepower of the motor driving fan (assuming that the motor is operating near rated hp).
p = pressure head, inches of water.
dbe = number of decibels re 10^{-13} watt.

(See discussion following Equation 18.)

The assumption is made that the fan is being operated near the *knee* on its operating characteristics, i.e., near maximum efficiency or near the minimum in the curve of specific sound power (upper curve on Fig. 5).

By assuming a fan mechanical efficiency of 50 percent, Equation 19 can be put in the form of Equation 18 with PWL$_s$ = 65 dbe, i.e.,



$$\text{PWL} = 65 + 10\log_{10}q + 20\log_{10}p \text{ dbe} \quad (20)$$

where

q = air quantity, cfm.
p = pressure head, inches of water.

(See discussion after Equation 18.)

It should be emphasized that Equations 19 and 20 are intended to be used only when actual noise data are not available. All fans of the same power input are not equally noisy. The example illustrated in Fig. 5 demonstrates this fact since the minimum value of PWL$_s$ for *this particular fan* is 69 db, 4 db higher than the value used in Equation 20. It is on the edge of the stated limit of approximation ±4 db.

The overall power level is first determined from Equation 19 or 20 and is added algebraically to the ordinate in Fig. 6. Acoustics by L. L. Beranek (McGraw-Hill, 1954 Second Printing). Used by permission.

Fig. 6 . . . . Chart for Determining the Sound Power Band Levels for Ventilating Fans of Two Types

Approximate Octave Band Spectrum

Within about ±4 db approximation, and assuming no turbulence in the duct or the coupling between it and the fan, the octave band spectrum for a centrifugal fan, relative to the overall sound power level, is given in Fig. 6.

Limited data on vane-axial fans,[11] where sound pressure level measurements were made in the discharge duct, indicate that the overall sound power level is about the same as that for centrifugal fans. However, the spectrum shape of the vane-axial fan noise has a shape something like that shown in Fig. 6.

More recent free field measurements on axial fans indicate that perhaps the drop in level at the high and low ends of the spectrum are more pronounced.[8] The solid line in Fig. 7 is typical of the sound power spectrum for the axial fans reported, as taken directly from the free field measurements. Application of a correction for the end reflection losses from the discharge opening (see Fig. 11) gives the dashed curve in Fig. 7, which corresponds to the relative sound power level in the duct. This spectrum shape for the axial fan appears to be based on more extensive data than those of Fig. 6.

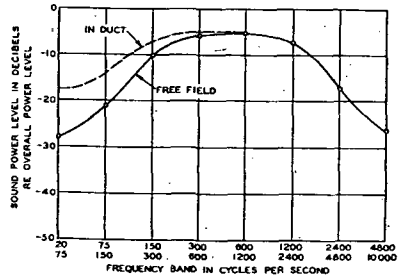
NOISE GENERATED BY GRILLES AND DIFFUSERS

Grille Noise

The subject of grille noise has not been covered thoroughly in the literature. The information given in this chapter has been taken *from the advertising literature of several grille* manufacturers and from recent experiments at the Massachusetts Institute of Technology.

In general, grille noise at the lower frequencies is dependent primarily on the size and shape of the grille opening, on the mass flow per minute, and on the temperature of the air. At the higher frequencies, the noise is determined primarily by the area of the grille, the velocity of air through the free (open) areas (not the core or nominal area), and the pressure drop across the grille.

For two simple types of grille, stamped and deflector vane, power levels are given in Fig. 8. These power levels are given in terms of the speech interference level, PWL$_{SIL}$. Conversion to the speech interference level in db in the room at a listener's position is described in the section on Determination of Room Levels. In the absence of more complete information, it may be assumed that the power levels of the noise produced by the grilles themselves at low frequencies are inconsequential.



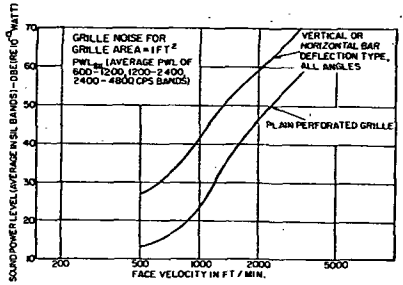


Fig. 7 . . . . Sound Power Spectrum for Single-stage Axial Fan[8]

The noise is expressed as the sound power level in dbe in each of the three speech interference bands (PWL$_{SIL}$).

Fig. 8 . . . . Grille Noise for a Grille Area of One Square Foot

Fig. 8 is for a grille core area of 1 sq ft. Correction to other areas of grille is made by the relation:

$$\text{Decibel addition} = 10\log_{10}A \text{ db}$$

where

A = core area, square feet.

Values of the decibel addition for various values of A are given in Table 3.

Table 3 . . . . Decibel Correction for Area

A sq ft	Decibel Addition	A sq ft	Decibel Addition	A sq ft	Decibel Addition
0.5	−3	8	9	70	18
1	0	16	12	100	20
2	3	20	13	200	23
4	6	40	16	400	26

Example 2: Assume a deflector vane type of grille with a core area of 2 sq ft. Determine the sound power level in the speech interference bands for an air velocity of 2000 fpm.

Solution: From Fig. 8, the PWL$_{SIL}$ for a 1 sq ft deflection grille is 59 dbe. From Table 2, an addition of 3 more dbe is required, so that PWL$_{SIL}$ = 62 dbe.

Diffuser Noise

Aside from the information furnished by diffuser manufacturers, to their users, on sound levels generated by air diffusers, few other data are available. Recently, however, some test results on several types of ceiling air diffusers have yielded a satisfactory correlation of the sound generating characteristics of these devices.[12] The data, covering ceiling diffusers ranging in size from 4- to 18-in. neck diameter, show that the

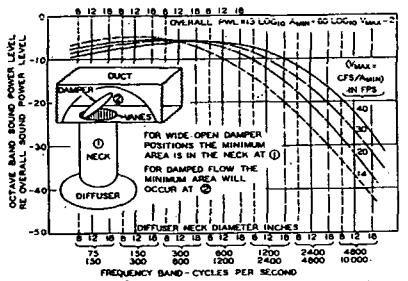

Fig. 9 .... Octave Band Spectrum of Ceiling Diffusers

overall sound power level (from 75 to 10,000 cps) can be found within ±2 db by the equation:

$$PWL_7 = 13 \log_{10} A_{min} + 60 \log_{10} V_{max} - 2 \text{ dbe} \qquad (21)$$

where

PWL_7 = overall sound power level in the seven octave bands from 75 to 10,000 cps, decibels *re* 10^{-13} watt.

A_{min} = minimum flow area for the air passing through the diffuser, square feet. For undamped flow the minimum area will normally occur in the diffuser neck, whereas for damped flow it will occur at the damper position (see Fig. 9).

V_{max} = *maximum air velocity* (q/A_{min}), *feet per second.*

q = quantity of air discharged, cubic feet per second.

For ceiling diffusers of cone-type construction used in conjunction with deflecting vanes and a damper, Fig. 9 presents the approximate octave band spectrum relative to the overall sound power level as given by Equation 21. The curves of Fig. 9 agree within approximately 3 db of the octave band data collected on 8-, 12-, and 18-in. neck diameter ceiling diffusers.

NOISE GENERATED BY OTHER SOURCES

Objectionable noise may be produced by fan motors, pumps, compressors, etc. The designer must give attention to these sources of noise. It is not possible to predict the noise, because units from different manufacturers differ greatly in the noise produced.

Objectionable noise is also generated in the duct system by excessive air velocity or poor duct fittings. No systematically taken data have been published from which conclusions can be drawn. The reader is referred to Chapter 21 Air Duct Design for good design practice.

Table 4 .... Approximate Attenuation in Straight Sheet-Metal Duct Runs in Decibels Per Foot

Duct	Size, Inches	All Frequencies
Small	6 x 6	0.1
Medium	24 x 24	0.05
Large	72 x 72	0.01

SOUND ATTENUATION IN DUCTS

Unlined Straight Sheet-Metal Ducts

The attenuation of sound in straight sheet-metal ducts is a function of the length, shape, and size of the duct. If a thermal insulating material is applied to the outside of the duct this will also affect the attenuation characteristics.[13] Attenuation values in common use are given in Table 4.[14]

A recent investigation conducted at the Massachusetts Institute of Technology indicates that the attenuation values given in Table 4 are probably satisfactory above a frequency of 500 cps, but are in most cases significantly lower than the observed values of attenuation below this frequency.[13] Only two sizes of ducts were tested, a 12 x 12 in. and a 12 x 24 in. However, these ducts were investigated not only bare, but also with two types of glass fiber thermal insulation applied to the outside of the duct. The first type used was a 1-in. thick glass fiber insulation with a density of 0.75 lb per cu ft. The second type was a glass fiber semirigid 1-in. board with a density of 6 lb per cu ft. Attenuation values were determined by plotting SPL readings made at 3-ft intervals over a total duct length of 40 ft. The results are presented in Table 5.

It should be noted from Table 5 that the addition of thermal insulation to the outer duct walls had little or no effect on the attenuation in the four octave bands above 600 cps for the ducts tested, and that the values are substantially in agreement with Table 4. In the lower octave bands, however, the effect of added thermal insulation on attenuation is indeed striking. More data on larger size ductwork is needed to confirm these results.

Branches

At a junction where a duct divides or has side branches or outlets, the sound power traveling down the duct divides.

The decibel reduction in sound power from the main duct

Table 5 .... Octave Band Attenuation of Bare and Thermally Insulated Straight Sheet-Metal Ducts

Duct Size Inches	Type of Insulation	Density	Attenuation—db per ft							
			Frequency Band—Cycles per Second

0.4	4	0.1	10
0.32	5		

to any branch may be calculated as 10 log₁₀ of the ratio of the branch area to the total area of all branches leaving the junction. Generally the total area of the branches leaving a junction is greater than that of the duct entering a junction; therefore, the area of the branch should not be divided by the area of the supply duct. In a complicated branched system, errors incurred by such a practice may accumulate to several db. Table 6 gives the db reduction for various ratios of branch duct area to the total branch duct area.

Square Corner Bends

Square corner bends can be quite effective in noise reduction provided they are widely separated in the system. The noise reduction for a single square corner bend with no turning vanes, unlined, is shown in Fig. 10 Part A. Turning vanes are usually employed in square corner ducts. When the width of the turning vanes is small, say less than one-fourth wavelength of the sound, they do not affect the noise reduction. At higher frequencies, they decrease the noise reduction substantially below that shown in Fig. 10 Part A.

When a square corner bend is lined with sound absorbing material, the lining should be extended several duct widths beyond the corner in the direction of sound transmission. For square bends lined in this manner the attenuation may be estimated from Fig. 10 Part B.

The attenuation is given for eight octave frequency bands with D in inches as the parameter.

Fig. 10 .... Attenuation in Decibels Provided by (A) Unlined Bend, and (B) Lined Bend in a Duct with the Lateral Dimension D

End Reflection Losses

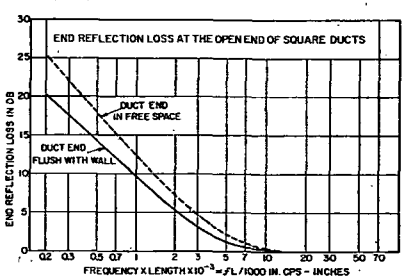
All of the noise power that is produced in a duct by a fan (or by turbulence) does not radiate from the end of a duct into the room. Instead, part of the power is reflected back from the end toward the fan. The amount of noise power reflected is related to the product of the frequency of the sound and the length of a duct side L, assuming that the duct is square. If the duct is not square, the value of L is taken to be approximately equal to $\sqrt{L_x L_y}$. The end reflection loss is shown in Fig. 11 for two cases: (1) a duct ending in free space and (2) a duct ending flush with the wall.

Duct Lining Procedure

In the past, the most common method of obtaining sound absorption in ventilating systems has been to line the duct with absorbing material. It is usually more convenient to line all four sides of the duct, but a lining on one side over a longer length of the duct will, in general, give the same effect for the same area of applied acoustical material. Subject to certain restrictions, the attenuation of a fully lined duct to single-frequency sounds may be expressed by the approximate Equation 22.[15]

$$R = 12.6l \frac{P}{A} \alpha^{1.4} \text{ db} \qquad (22)$$

where



R = attenuation, decibels.

l = length of lined duct, feet.

P = perimeter of duct, inches.

A = cross-sectional area of duct, square inches.

α = absorption coefficient of lining (a function of frequency).[16]

The abscissa equals fL/1000 where f is the geometric mean frequency of an octave band in cps and L is the duct dimension in inches. Two cases are shown, with the duct end flush in the wall and with the duct end projecting into the room.

Fig. 11 .... End Reflection Losses in Decibels at the Open End of a Square Duct of Area L^2

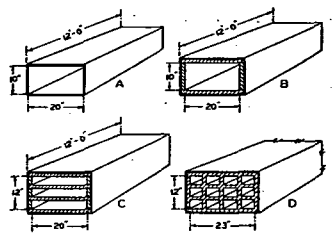


Table 7 .... Attenuation Data for Typical 1-in. and ½-in. Thick Duct Lining Board

256	0.38	0.26	$3.2\, l \frac{P}{A}$	0.25	0.15	$1.9\, l \frac{P}{A}$
512	0.70	0.60	$7.6\, l \frac{P}{A}$	0.40	0.28	$3.5\, l \frac{P}{A}$
1024	0.80	0.73	$9.2\, l \frac{P}{A}$	0.72	0.63	$7.9\, l \frac{P}{A}$
2048	0.79	0.72	$9.1\, l \frac{P}{A}$	0.78	0.71	$8.9\, l \frac{P}{A}$

This formula was empirically developed for a set of duct sizes ranging from 9 x 9 in. to 18 x 18 in.; for cross-sectional dimension ratios of 1:1 to 2:1; for frequencies between 256 and 2048 cycles; and for absorption coefficients between 0.20 and 0.80. The duct lining material used was 1-in. rock wool sheet. The absorption coefficients of a material of this type in one-half and one-inch thickness are listed in Table 7.

It is also possible to calculate the absorption by a very complicated mathematical theory.[17, 18] Such calculations are in substantial agreement with Equation 22. This equation may be in error when applied to other types of duct lining and to duct sizes and shapes greater than those specified.

With every application, the use of sound absorptive material should be considered in the dual function of insulation and sound absorption. It has been shown theoretically that the reduction (in decibels per linear foot) of sound transmitted along a duct lined with sound absorbing material is related in a rather complicated manner to the size and shape of the duct, to the frequency of the sound, and to the sound absorbing characteristics of the lining. Experimental evidence likewise indicates that there is no simple formula involving the variables which will apply accurately to all cases. However, it may be stated generally that the attenuation in decibels at a given frequency is directly proportional to the length of lined duct. It decreases as the cross-sectional area increases, and increases as the aspect ratio is increased.

A. Unlined metal duct
B. Lined duct
C. Splitter plate type absorber
D. Cell-type absorber

The open area is the same for each case shown if 1 in. thick absorption material is assumed.

Fig. 12 .... Acoustic Treatment of Ducts

Rectangular Cells (Plate or Cell Absorbers)

If the available length of duct between the main duct (or the fan) to the grille is shorter than the length of lining indicated as necessary by Equation 22, the duct may be subdivided into smaller ducts as shown in Fig. 12, or it can also be even more subdivided by an egg-crate construction. In such a construction in which all the subdivided ducts are the same size, sound will be equally absorbed down each channel. It is, therefore, only necessary to calculate the sound attenuation of an individual channel. For this, Equation 22 is adequate, assuming that the thickness of the material is halved if it forms a common splitter between two cells.

When the number of splitter plates or cell partitions is large, the percentage free area of the gross duct size may be materially reduced. This leads to a further sound attenuation. Values of the attenuation possible, due to this cause, are given in Table 8.

Table 8 .... End Reflection of Plate or Cell Absorbers

Percentage Free Area of Absorber	50	40	30	25	20
Attenuation db	1	2	4	5	6

Plenum Absorption

In systems where individual ducts are directed to a number of rooms, and sound treatment is required in every duct, a sound absorption plenum on the fan discharge as shown in Fig. 13 will often prove the most economical arrangement.

Based on both experiment and ray acoustics theory, the following approximate expression has been derived for acoustic plenum attenuation.[19]

$$\text{db (attenuation)} = 10 \log_{10} \frac{1}{\frac{S_e \cos\theta}{2\pi d^2} + \frac{1-\alpha}{\alpha S_w}} \qquad (23)$$

where

α = absorption coefficient of the lining (dimensionless).
S_e = plenum exit area, square feet.
S_w = plenum wall area, square feet.
d = distance between entrance and exit, feet.
θ = the angle of incidence at the exit, i.e., the angle which the direction d makes with the normal to the exit opening.

For frequencies sufficiently high so that the dimensions of the plenum exceed about one wavelength, Equation 23 will predict the sound attenuation within a few decibels. At low frequencies, somewhat more attenuation is realized than will be computed by Equation 23, due to the existence of a resonant muffler action in the duct-plenum system.

Outlet Sound Absorbers

Outlet sound absorbers are rectangular or plate cells installed directly behind an outlet or they may be the lining of a pan or plaque outlet. They are particularly effective in the elimination of high frequency whistles which are generated by air flow in the ducts. They are also employed in large systems with long runs where only a few outlets near the fan require treatment. Frequently outlet cells are the only means of correcting existing noisy installations, as the duct sections directly behind the outlets may be the only sections accessible for treatment. (See Fig. 14.)

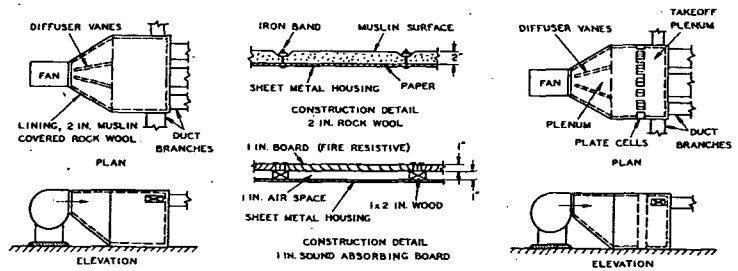

Fig. 13 .... Absorption Plenums With and Without Sound Cells

Package Units

Package units for attenuating sound in ducts are coming more and more into common use. These units have the advantage of providing, in a short length, a known amount of noise reduction with a minimum opportunity for errors in installation and for erosion of materials. The cost of inspection of the completed job is eliminated and the outside dimensions of the duct can be reduced as compared to a lined duct.

These units are available in sizes to fit 6 x 12 in. ducts up to 80 x 84 in. ducts. Charts are supplied by the manufacturers giving the attenuations and pressure drops for different types of units.

In Figs. 15 and 16, the noise reductions and static pressure drops for several types of package units are shown. Manufacturers' literature should be consulted for exact values.

Selection of the Absorptive Material

When a sound wave impinges on the surface of a porous material, a vibrating motion is set up within the small pores of the material by the alternating sound waves. As the ratio of the cross-sectional area of the pores to their interior surface is small, the resistance to the movement of air in the pores is large. This viscous resistance within the pores of the material converts a portion of the sound energy into heat. The decimal fraction representing the absorbed portion of the incident sound wave is called the absorption coefficient. Considerable absorption may also result, particularly in the low-frequency range, from the flexural vibrations of the duct. In the selection and application of the absorptive material, the following points should be considered:

1. For the absorption of the low-frequencies below 500 cps the material should be 2- to 12-in. thick. Thin materials, particularly when mounted on hard solid surfaces, will absorb only the high frequencies.

2. In order to provide as much low-frequency noise absorption as possible by means of flexural vibration, it is desirable to fasten the absorptive panels discontinuously. This result may be attained to some extent by spot cementing, but better results are obtained when it is possible to fasten the absorptive panels to furring strips, leaving an air space behind. However, the exact resonance characteristics of the panels, and thus their absorption, are so unpredictable that flexural vibration cannot be relied upon for a specific value of attenuation.

Requirements for a good sound absorption material are: (1) high absorption at low frequencies;[16] (2) adequate strength to avoid breakage; (3) fire resistance and compliance with national and local code requirements; (4) low moisture absorption; (5) freedom from attack by bacteria and algae; (6) low surface coefficient of friction; (7) particles should not fray off at the higher design velocities; and (8) freedom from odor when either dry or wet.

DETERMINATION OF ROOM LEVELS

In the previous sections on fan and grille noise, sound power levels were given in dbe referred to 10^{-13} watt. These quantities as they appear at the duct termination (grille) must be

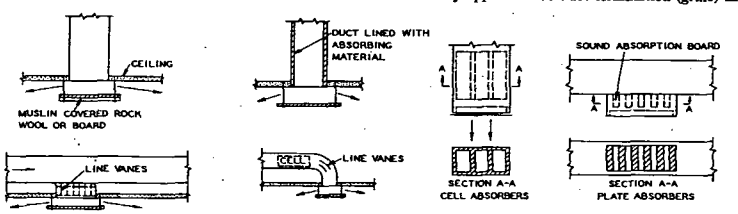

Fig. 14 .... Outlet Cells for Pan Outlets or Grilles

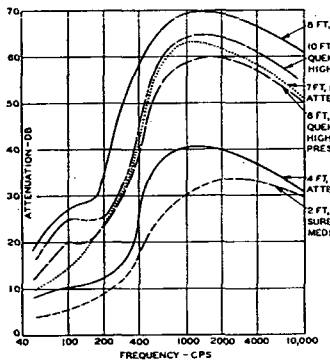

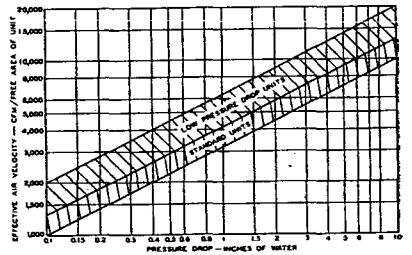

Fig. 15 .... Typical Values of Sound Attenuation Through Several Types of Package Units

Note: Early models of these units sometimes gave higher pressure drops than those shown above. Data of certified test laboratories on current unit should be consulted where possible.

Fig. 16 .... Approximate Pressure Drop Across Typical Package Units

converted to sound pressure levels in the room, because it is sound pressure to which the ear and the sound level meter respond. The sound pressure level at a distance r from the grille opening and at an angel θ with respect to an axis perpendicular to its surface is given by the equation[20]

$$L_p = \text{PWL} + 10 \log_{10}\left(\frac{Q}{4\pi r^2} + \frac{4}{R}\right) + 0.5 \text{ dbc} \qquad (24)$$

where

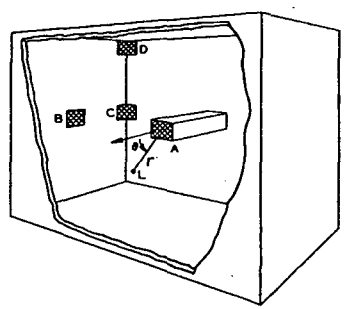
PWL = sound power level emitted at the duct termination and is the power summation of the attenuated fan noise and the grille noise in dbe (see *Example 3*).
Q = directivity factor and is a dimensionless function of θ.
r = distance from the duct opening, feet.
R = the room constant, square feet. (R increases with the amount of acoustical absorption in the room and generally depends somewhat upon frequency.)

In Fig. 17 four methods are shown for terminating a ventilating duct in a room. In each of these cases, the noise power radiates into the room. Low-frequency sounds radiate equally in all directions. High-frequency sounds tend to *beam* in the direction the duct opening is facing. The *magnitude of this* beaming effect is described mathematically by the directivity factor Q. After the sound at any frequency has reflected from a wall, it generally travels around the room many times to produce reverberant sound. This fact appears in Equation 24, wherein the first term in the parenthesis described the *direct sound (prior to reflection)* and the second term described the *reverberant* sound (the result of many reflections).

The directivity factor Q is of importance only when the listener is near the duct termination, i.e., when r is small. At large distances, i.e., when the first term becomes negligible compared to the second, the listener hears only the reverberant sound.

For the four duct positions of Fig. 17, approximate values of Q are given in Fig. 18 for $\theta = 0$ deg and for $\theta = 45$ deg. The abscissa is the product of frequency times L assuming that the duct is approximately square with an area of L^2 sq in. If the duct is rectangular, the value of Q should be computed for L equal to the smaller dimension.

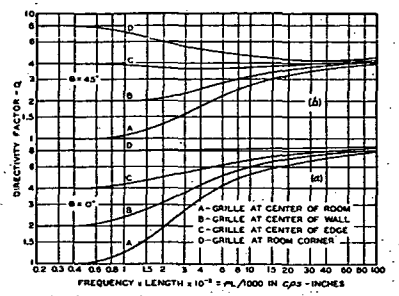
The room constant R is defined by the equation



$$R = \bar{a}S/(1 - \bar{a}) \qquad (25)$$

where

$\bar{a}$ = average sound absorption coefficient (dimensionless) for the room at the mid-frequency of the band of noise being considered.
S = total area of the boundary surfaces of the room, sq ft.



Where a room contains several surfaces, each with different absorption coefficients, the average absorption coefficient may be determined by the equation

$$\bar{a} = \frac{S_1 a_1 + S_2 a_2 + \cdots}{S_1 + S_2 + \cdots} \qquad (26)$$

A. Duct projecting in the room
B. Duct in the center of and flush with the wall
C. Duct in the center of one edge
D. Duct in the corner
The listener L is at distance r and angle θ from the duct opening.

Fig. 17 .... Four Typical Means for Terminating a Ventilating Duct in a Room

A. The value of Q is given for θ = 0, i.e., directly in front of the duct opening.
B. Same as for (A) except the value of Q is given for θ = 45 deg.
The frequency of f is in cps and the duct is assumed to be square with an area L^2 in square inches.

Fig. 18 .... Directivity Factor Q for the Four Duct Configurations of Fig. 17

where

S_1, S_2 = the areas of each type of absorbing material. a_1, a_2 etc., = the absorption coefficients of each type of material at the mid-frequency of the band of noise being considered. (Values of a for many materials are published by the Acoustical Materials Association.[14])

For estimating purposes, approximate values of the room constant R may be obtained from Fig. 19 as a function of room size for five classes of rooms.

The value of the second and third terms of Equation 24 (including 0.5 db) is plotted in Fig. 20 with distance r from the source as the abscissa, with the sound pressure level in decibels as the ordinate and the room constant R in sq ft as the parameter.

The directivity factor Q is given at the bottom left-hand side of the graph. The procedure for using the graph is as follows:

Determine the room constant R and the directivity factor Q for the particular direction θ of interest. Enter Fig. 20 at the bottom at the distance r. Then move diagonally to the left until the value of Q is reached. Then move vertically until the value R is reached. Then read the relative sound pressure level from the ordinate. An example is shown by the dotted line in Fig. 20 for $r = 7$ ft, $Q = 2$, and $R = 2000$ sq ft. The relative sound pressure level is added algebraically to the sound power level to yield the sound pressure level at the distance r and the angle θ in the room (see Equation 24).

It is seen from Fig. 20 that the noise from a ventilating duct is less at distances far from it than nearby. Moreover, at large distances, the levels produced in the room depend only on the power level of the source and the room constant and not on the directivity factor and the distance r.

Example 3: To illustrate the application of the noise criteria and control procedures outlined in this chapter, calculation will be made for the required treatment for the ventilation system supplying the library reading room of Fig. 21. This room has a total volume of 80,000 cu ft and may be considered as an *average room* for acoustic properties (see Fig. 19). The total air supply to the reading room is 6000 cfm which is equally divided between four 12 x 18 in. supply grilles located along one wall. The supply of outdoor air is from a central fan system which handles a total of 25,000 cfm at 2-in. water static pressure and requires a 15 hp motor.

Solution: It is necessary to determine the noise level in the reading room as a result of the ventilating system, both for the position of the nearest listener to a grille, and for a position remote from the supply grilles since it is impossible to tell beforehand which will be greater. The required attenuation for acceptable octave band noise levels will then be determined.

Analysis of Fan and Duct System

The acoustic power level of the fan should be computed from Equation 18 when the specific power level is available. In this example it is assumed that the specific sound power level is not known. Therefore, employ the approximate Equations 19 or 20. From Equation 19:

$$\text{PWL}_{(\text{duct AB})} = 100 + 10 \log 15 + 10 \log 2 = 114.7 \text{ dbe}$$

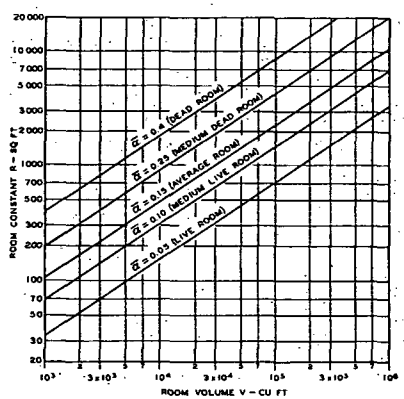
or from Equation 20:

$$\text{PWL}_{(\text{duct AB})} = 65 + 10 \log 25{,}000 + 20 \log 2 = 115 \text{ dbe}$$

which agreement is better than the accuracy expected from these equations.

Of this total acoustic power generated by the fan the main interest is in the part that reaches the reading room. At each duct branch the power will divide approximately as the ratio of the branch duct area to the total duct area after the branch. Thus at Station B (Fig. 21) the acoustic power delivered to the 18 x 48 in. duct, neglecting any attenuation in the system, will be

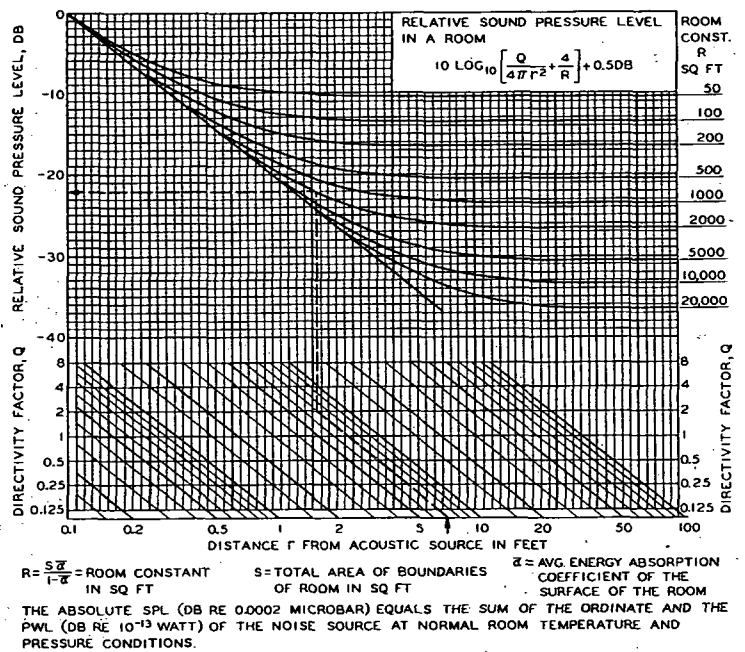
$$\text{PWL}_{(\text{duct BC})} = \text{PWL}_{(\text{duct AB})} + 10 \log (A_{\text{branch}}/A_{\text{total}})$$



$$= 115 + 10 \log \left[\frac{18 \times 48}{(24 \times 48) + (18 \times 48)}\right] = 111 \text{ dbe}$$

At Station C the power division gives

$$\text{PWL}_{(\text{duct CD})} = 111 + 10 \log \left[\frac{12 \times 48}{(18 \times 24) + (12 \times 48)}\right]$$



$$= 108 \text{ dbe}$$

Thus neglecting, at first, the attenuation in the connecting duct

These proportions give $S = 6.25V^{2/3}$. The parameter is the average sound-absorption coefficient for the room. The subjective ratings dead, live, etc., are the author's[20] and are not necessarily in standard use.

Fig. 19 .... Value of the Room Constant R as a Function of Room Volume for Rooms with Proportions of About 1:1.5:2

The listener's position is at a distance r and an angle θ with respect to the duct opening. Q is determined from θ and from the duct dimensions (see Fig. 18). To use the graph proceed as for the example shown by the dotted line for r = 7 ft, Q = 2, and R = 2000 sq ft. The sound pressure level in the room equals the sum of the ordinate and the sound power level. Normal room temperature and pressure conditions are assumed.

Fig. 20 .... Curves for Determining the Sound Pressure Level in the Room Relative to the Sound Power Level

system, the total acoustic power delivered to the room by the fan will be 108 dbe. Assuming that the branch fittings at *D*, *E*, and *F* are similar to that at *C* in Fig. 21, the unattenuated fan acoustic power delivered to each of the four 12 x 18 in. grilles will be approximately

$$PWL_{(\text{duct DB})} = 108 - 10 \log 4 = 102 \text{ dbe}$$

The octave band spectrum of the centrifugal fan noise is given by Fig. 6. This chart indicates that the power level in the first band (20–75 cps) will be about 102-1 or 101 dbe, and the power level in each succeedingly higher octave band will be 5 dbe less. These levels are entered in line 1 of the calculation Table 9.

The next step is to determine the natural duct attenuation between the fan discharge and the room supply grilles. From Table 4 the attenuation for straight sheet-metal ducts of *medium size* is 0.05 db per ft at all frequencies. Let us assume that all of the ducts of this system fall within this medium category. The total length of the duct run from Station *A* to Station *H*, Fig. 21, is 90 ft. The straight duct attenuation is, therefore, 0.05 (90) = 5 db, which is entered in line 2 of Table 9. It should be noted here that the ducts *CD* and *DH* of 12 x 48 and 12 x 15 in. dimensions, respectively, are of about the same size as those reported in Table 5. Hence if we assume the attenuation for these two *bare* ventilation ducts can be taken from Table 5, it will be found that the straight duct attenuation between *C* and *H* (35 ft) will be approximately 10 db in the lowest two octave bands, 6 db in the third band, and 3 db for all octave bands above 300 cps. That is, using Table 5 for ducts *CD* and *DH*, and Table 4 for ducts *AB* and *BC*, the first three columns in line 2, Table 9, would read 12, 12, and 9 db in that order, and the other columns would be unchanged at 5 db. It would appear, therefore, that the 5 db attenuation values for the lower three octave bands are probably overly conservative. The divided-flow fitting at *B* may be considered equivalent in attenuation to an 18-in. square bend. Values are read from Fig. 10, Part A and entered as line 3 in the calculation table. The rounded corners of the branch flow fittings at *C*, *D*, *E*, *F*, and *G* are assumed to have no attenuation. The 12 x 15 in. risers serving each of the wall grilles have a square bend (see Fig. 22), and attenuation values are read from Fig. 10, Part A and entered as line 4 of Table 9. The attenuation due to the end reflection loss at the grille face is given by Fig. 11. For the 12 x 18 in. grilles used here $L = \sqrt{12 \times 18} = 14.7$ in. Thus, for the first octave band (20–75 cps), which has a geometric mean frequency of 40 cps, $fL/1000 = (40 \times 14.7)/1000 = 0.58$ and the end loss is 13 db.

The attenuation in the other octave bands is similarly determined and entered in line 5 of Table 9. The total natural duct attenuation is now found by summing lines 2, 3, 4, and 5 of Table 9, and the result appears in line 6. This total attenuation *may now* be subtracted from the unattenuated power level in line 1 to give the estimated acoustic power level radiated into the room from the outlet grille at Station *H*. Line 7 of Table 9 gives the result.

Determining Room Sound Pressure Levels

The next step, then, is to calculate the sound pressure level at the position in the room occupied by the listener nearest to *any one grille, and for the overall reverberant sound pressure* level in the room due to the sound power radiated from all of the grilles. Fig. 22 shows that the position of the nearest listener is 7 ft from the grille. To determine L_p at this position, determine the directivity factor *Q* at 45 deg to the grille face; this is found from Fig. 18. The parameter $fL/1000$ is determined by taking the characteristic length *L* as the shortest side of the grille face or 12 in. Thus, for the first octave band, $fL/1000 = 40\ (12)/1000 = 0.48$. This value together with all the corresponding values for the other seven octave bands are entered in line 8 of Table 9. Line 9 of the table gives the corresponding directivity factors as read from Fig. 18, using curve *B* since the grille is flush with the wall but not at an edge or corner.

It was initially assumed that the library reading room had average acoustical properties, and consequently, the room constant *R* in sq ft may be read from the line marked *average room*

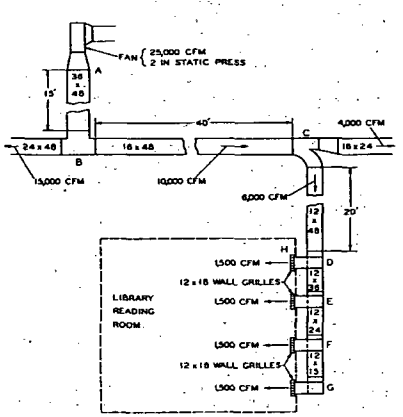

Fig. 21 .... Assumed Ventilating System for *Example 3*

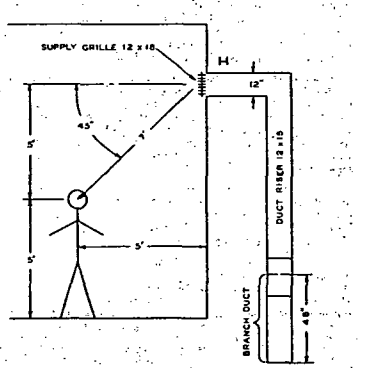

Fig. 22 .... Location of Nearest Listener to a Supply Grille

of Fig. 19. For a total room volume of 80,000 cu ft the result is R = 2000 sq ft. The relative sound pressure levels for an observer 7 ft from the grille may now be read from Fig. 20 making use of the directivity factors and the room constant as found. The dotted line in Fig. 20 shows that the relative L_p for the 20–75 cps band is −22 db. This relative L_p is entered in line 10 of Table 9. The sound pressure level at the 7-ft position from the grille is given by the addition of line 7 and line 10 in the calculation table. This result appears as line 11.

If there were only one grille in the room the calculation for room sound pressure level would be the only one required. However, since there are four grilles it is necessary to determine the general reverberant sound pressure level in the room due to the acoustic power radiated from these four sources to see if it is greater than the previous calculation. Neglecting the small additional duct attenuation which occurs in the somewhat longer duct runs to the other three room grilles, the total acoustic power radiated from the four grilles will be four times that from one grille. Hence the total acoustic power level from all grilles will be 10 log 4 or 6 db higher than from a single grille. In line 12 of Table 9, therefore, enter the PWL of all grilles by adding 6 db to the single grille value of line 7. The relative L_p for an observer in the reverberant sound field is read from the horizontal part of the R = 2000 sq ft curve of Fig. 20 as −26 db, and entered in line 13 of Table 9. The sum of line 12 and line 13 values from Table 9 gives, in line 14, the general reverberant sound pressure level in the room. Comparison of line 11 and line 14 shows that the latter is 2 db higher at the lower frequencies and, therefore, should be used in determining any noise treatment for the ventilating system or room.

Room Criteria

For this example the speech interference level criteria will be used. Examination of Table 1 shows that an acceptable noise level for libraries will be given by the *NC*-30 curve of Fig. 3. The values read from this curve are entered as line 15 of Table 9. The difference between these criterion sound pressure levels and the computed L_p in line 14 of the table gives the required attenuation for the ventilating system. This final result appears as line 16 in Table 9.

Treatment

The type of treatment of the ventilating system to obtain the attenuation given in line 16 of the calculation table will depend on many factors as discussed in the section on Sound Attenuation. One satisfactory treatment might employ a 4-foot package unit whose attenuation characteristics, as given in Fig. 15, are entered in the final line 17 of Table 9. The additional 2 db of attenuation required in the second and third octave bands could be obtained by lining approximately 10 ft of the 12 x 48 inch duct with 1-inch liner. However, as was pointed out above, the straight duct attenuation in line 2 is probably too conservative in these lower octave bands, hence the package unit would most likely provide a satisfactory treatment.

A calculation is now made of the acoustic power level generated by the grille itself. The face velocity of the grille is 1500 cfm/1.5 sq ft = 1000 fpm. From Fig. 8, assuming a vertical or horizontal bar deflection type grille, the average power level in the speech interference bands (600–1200, 1200–2400, 2400–4800 cps) for a face velocity of 1000 fpm is 41 dbe per square foot of grille area or 41 + 10 log 1.5 = 43 dbe for the grille in this example.

From line 10 of the calculation table the relative L_p in the speech interference bands (600–4800 cps) is −20 db. Consequently the L_p of the grille noise at 7 ft is 43 − 20 = 23 db. This is well below the 30 db criterion selected for this room and therefore, is satisfactory.

In reverberant fields all four grilles contribute so the total acoustic power level of the four grilles is 43 + 10 log 4 = 49 dbe. From line 13 of Table 9 the relative L_p is −26 db and therefore the reverberant L_p will be 49 − 26 or 23 db, which by coincidence is the same as that calculated at the 7-ft distance from one grille and, therefore, is also satisfactory.

The calculation of grille noise in this example was left to the end in order to keep a simple continuity to the principal problem of calculating the fan noise in the room. Experience shows that it is advantageous to calculate the grille noise early in the problem as indicated in the outline given in the text so that if the grille size must be changed its correct value may be used in calculating fan noise attenuation.

CROSS TRANSMISSION BETWEEN ROOMS AND THROUGH DUCT WALLS

Ducts serving more than one room permit cross talk between the rooms and should be lined with acoustical material. Where the rooms are close together and the ducts short, the ducts should be subdivided to provide ample acoustical treatment. Lagging material similar in character to acoustical board, when placed on the outside of ducts, serves to prevent noise, originating outside the ducts, being carried inside the ducts and into the air stream.

A case where outside lagging is desirable occurs when ducts originate at the fan in the equipment room and pass through this room on the way to the room being conditioned or ventilated. Unless the ducts are lagged, some of the mechanical noise from air in the equipment room may be transmitted through the wall of the duct into the air stream, and thereby carried into the room. In such cases, that portion of the duct which is exposed to the sounds in the equipment room should be lagged with material, such as cork, pipe covering, or other sound damping material, to prevent the sound from entering the duct at this point. Numerical data are not available to permit a simple and practical calculating procedure to determine thickness of covering which should be used for this purpose.

Laboratory measurements have shown that the loss through a sheet of No. 22 gage metal is 24 db. When a sheet of rock wool insulation 1 in. thick and weighing 1.4 lb per square foot is added to this, the insulation value is increased to 29 db. In general, however, adding a layer of insulation or pipe covering does not materially increase the sound insulation value unless the material is dense, or unless it is surfaced with another sound impervious layer such as metal or board. Standard reference books should be consulted for sound insulating properties of various materials. Inside lining material, used in the case previously mentioned, would serve as an absorber of the sound transmitted through the duct walls, and thus act as a means of preventing the transfer of noise into the air stream. Inside lining may also be used in ducts to absorb noise which reaches the air stream from equipment such as fans, sprays, and coils; noise due to eddying currents set up by elbows, dampers, and similar obstructions; and noise transmitted from room to room in a common duct system.

CONTROLLING VIBRATION FROM MACHINE MOUNTINGS

It is impossible to select equipment which will operate without producing some mechanical noise and, since the equipment must be mounted in a building, it is probable that a part of this noise will be transmitted to the building to such a degree as to make noisy conditions in the rooms which are to be air conditioned.

Much of this noise may be transmitted by the duct if it is rigidly connected to the fan outlet. It is common practice to make the connection between the fan and the duct with a canvas sleeve which effectively restricts noise at this point. Noise may also enter the building through the mounting of the motor and the fan. Flexible mountings should be provided in all installations, but these mountings must be carefully designed so that they will actually reduce the energy transmitted between the machinery and the supporting floor. If a flexible material is used, it is desirable to investigate the installation

so that it is not short-circuited by through bolts which are improperly insulated, and by electrical conduit which is not properly broken and is attached both to the equipment and to the building. The flexible mounting, if improperly engineered, may actually increase the energy transmitted between the equipment and the supporting floor.

In the proper isolation of vibration, which is usually in the lower range of frequencies and does not include the *airborne* vibrations known as sound, there is one basic formula which is important in the solution of the problem. It is the formula of transmissibility as governed by the equation:

$$T = \frac{1}{\left(\frac{f}{f_n}\right)^2 - 1} \qquad (27)$$

where

T = transmissibility of the support.
f = frequency of the vibratory force.
f_n = natural frequency of the machine unit on its support (damping = 0).

Equation 27 shows that the transmissibility approaches unity for disturbing frequencies considerably lower than the natural frequency of the mounting. As the disturbing frequency is increased, the transmissibility is also increased until at the resonant frequency, where $f = f_n$ the transmissibility becomes infinite. This is not true in practice because all materials have some internal damping effect. However, operating at or very close to the resonant frequency is always serious as forces and stresses may be multiplied 10 to 100 times. As the disturbing frequency becomes greater than the natural frequency, the transmissibility becomes a smaller quantity, and at the value of $f/f_n = \sqrt{2}$ it again has the value of unity. Beyond this point true isolation begins. At a ratio of 3 to 1 for f to f_n the isolation is effective enough for practical application, and experience and economical design have shown that a ratio of 5 to 1 is good. For high speeds, higher ratios for f to f_n are easily attained and give better results for effective vibration control. For the lower speeds as experienced with compressor work the higher ratios become uneconomical. At these lower speeds the unbalanced force goes down as the square of the speed ratio, so that it is quite practical to compromise and use a lower ratio of f to f_n, say 2 or 3 to 1.

For a given installation, the speed of the compressor is fixed by the specifications; therefore the value of f is fixed. That leaves only f_n to be determined, and that is accomplished by the choice of mounting material and design for the support of the machine. It is well to keep in mind that when trying to isolate vibration, no attempt should be made to isolate the driving and driven piece of equipment separately. The two should be mounted on a rigid frame, and then the entire assembly isolated according to the rules presented in this chapter.

The value of f_n can be controlled by the flexibility of the machine support, and when the deflection of the machine support is proportional to the load applied (such as with springs or nearly so with rubber-in-shear) the value of f_n can be determined by Equation 28:

$$f_n = \frac{1}{2\pi}\sqrt{\frac{g}{d}} \qquad (28)$$

where

g = gravitational constant = 32.2 feet per (second) (second).

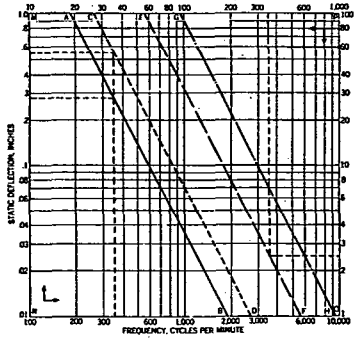

Fig. 23 .... Static Deflection for Various Frequencies

d = static deflection of supporting material, feet.
f_n = natural frequency of the machine unit on its support (damping = 0), cycles per second.

By the use of Equation 28 a set of curves may be plotted as shown in Fig. 23. The first line AB, plotted as the critical frequencies for the various static deflections, is a curve showing the worst possible conditions or resonant conditions.

Plotting another curve CD, which is $\sqrt{2}$ times curve AB, shows the area $MCDN$ in which the resilient material or mounting does more harm than good. Plotting curves EF (3 times curve AB) and GH (5 times curve AB) shows area $EGHP$ which represents efficient and economical isolation. Area $GPOH$ is excellent isolation, but for all except the highest speeds, becomes rather uneconomical because of the large deflections required.

Example 4: An electric motor driven compressor unit is to be isolated. The compressor is partially balanced and operates at a speed of 360 rpm. The speed of the motor is 1160 rpm, and it is belt-connected to the compressor. Total weight of the compressor and motor is 4500 lb.

Solution: The minimum disturbing frequency to be isolated is 360 cycles per minute. Assume that the desired ratio of forced to natural frequency is 3 as a minimum, and that 5 is desired. The desired natural frequency of the mounting is 360 ÷ 5 = 72 cycles per minute.

From Fig. 23 a deflection of 7 in. is required to attain a natural frequency of 72 cycles per minute. This value may be obtained from critical curve AB for 72 cycles, or from curve GH (5 times critical) for 360 cycles. For a ratio of 3 the deflection would be 2.5 in.

The next step is to determine the total weight to be supported by the springs. For low speed partially balanced compressors, it has been found necessary to add a foundation weighing 2 to 3 times the weight of the motor and compressor, in order to maintain the machine movement below 0.03 in.

Compressor and motor	4500 lb
Concrete foundation	9000 lb
Total	13,500 lb

Practical application dictates the number of springs to be used, which is based on the design of the machine foundation and the supporting floor structure. However, it is desirable to design for at least 8 springs and one or two spares for cases of unknown weights. As many as 50 springs have been used on one installation. The distribution of the springs must be balanced against the masses to be supported. Otherwise the

foundation design and supporting structure determine the location of the springs.

The choice of the material used in the design of the resilient mounting is also important. For the slow-speed type compressor, a common speed found in practice is 360 rpm. For speeds below this, isolation should not be attempted except under careful supervision. Referring to Fig. 23, it is found that for 360 rpm the static deflection required for a ratio of f/f_s of 3 to 1 (line *EF*) is 2.5 in., and for a ratio of 5 to 1 (line *GH*) it is 7 in. For these values of deflection the only choice of material is the coil spring. This is also true for speeds up to about 700 rpm. In consideration of the transverse spring constant (so as to maintain good ratios among the various degrees of freedom) experience has shown that the spring should be designed with a *working height* equal to 1.0 to 1.5 times the outside diameter. A long spring of small outside diameter has very low transverse rigidity, and therefore requires some additional means of preventing side drift of the unit, and on very sensitive applications this may tend to destroy the isolation efficiency. For speeds of 700 to 1200 rpm the required deflections range from 0.22 in. to 0.80 in. For speeds of 700 to 1200 deflections range from 0.22 in. to 0.8 inch. For these conditions springs or rubber-in-shear can be used. Special rubber is required if the isolators are likely to be contaminated by oil. For speeds higher than 1200 rpm rubber-in-shear, as well as cork specially made for vibration isolation, can be applied with good results. These limitations are by no means absolute, because certain liberties may be taken without impairing the result if all possible degrees of freedom have been taken into account in the design of the installation.

When a machine unit is properly isolated it will have a definite amount of movement which is determined by the ratio of the unbalanced forces to the total mass of the machine. If this resultant machine movement is too great for the necessary connections or the satisfaction of the customer, it can be reduced in two ways only without destroying the quality of the isolation; first, adding mass or dead weight to the machine (such as concrete) common in the application of low speed, partially balanced machinery; second, accurately balancing (both statically and dynamically) all moving parts so as to eliminate the vibration at the source. This latter method is the best engineering practice and is the modern trend. However, even with well balanced machinery, installed in the vicinity of quiet offices, it is usually necessary to properly isolate the equipment to prevent the transmission of vibration likely to cause complaints.

Where limitation of machine movement is desired during the starting and stopping periods, the application of friction or hydraulic damping will serve without seriously interfering with the efficiency of the isolation.

CHAPTER 26

STEAM HEATING SYSTEMS

Classification of Steam Heating Systems by Types; One-pipe, Two-pipe, Subatmospheric and Orifice Systems; Sizing Piping for Steam Heating Systems; Pressure-Reducing Valves; Boiler Connections; Condensate Return Pumps; Vacuum Heating Pumps; Traps; Drips; Connections to Heating Units; Control Valves

STEAM heating systems may be classified according to any one of, or combination of, the following features: (1) piping arrangement, (2) pressure or vacuum conditions obtained in operation, (3) method of returning condensate to the boiler.

Classification by Piping Arrangement

A steam heating system is known as a *one-pipe system* when a single main serves the dual purpose of supplying steam to the heating unit and conveying condensate from it. Ordinarily, to each heating unit there is but one connection which must serve as both the supply and the return, although separate supply and return connections may be used.

A steam heating system is known as a *two-pipe system* when each heating unit is provided with two piping connections, and when steam and condensate flow in separate mains and branches.

Heating systems may also be described as *up-flow* or *down-flow*, depending on the direction of steam flow in the risers; and as a *dry-return* or a *wet-return*, depending on whether the condensate mains are above or below the water line of the boiler or condensate receiver.

Classification by Pressure or Vacuum Conditions

Steam heating systems may also be classified as *high-pressure*, *low-pressure*, *vapor*, and *vacuum* systems, depending on the pressure conditions under which the system is designed to operate.

A system is known as a *high-pressure system* when the operating pressures employed are above 15 psig; as a *low-pressure system* when pressures vary from 0 to 15 psig; as a *vapor system* when the system operates under both vacuum and low-pressure conditions without the use of a vacuum pump; and as a *vacuum system* when the system operates under vacuum and low-pressure conditions with the use of vacuum pump.

When automatic controls are employed to vary the pressure conditions in the system in accordance with outside weather conditions, the system may be known as a *subatmospheric*, *differential*, or *synchronized* system. These latter classifications are proprietary designations.

When orifices are employed on the inlets to the heating units the system may be known as an *orifice system*.

Classification by Method of Returning Condensate

When condensate is returned to the boiler by gravity, the system is known as a *gravity return system*. In this system all heating units must be elevated sufficiently above the water line of the boiler, so that the condensate can flow freely to the boiler. Elevation of the heating units above the water line must therefore be sufficient to overcome pressure drops due to flow, as well as pressure differences due to operation.

Referring to Fig. 1 it will be noted that the boiler and wet-return form a U-shaped container, with the boiler steam pressure on the top of the water at one end, and the steam main pressure on the top of the water at the other end. The difference between these two pressures is the *pressure drop* in the system, i.e., the friction and resistance to the flow of steam in passing from the boiler to the far end of the main, and the pressure reduction in consequence of the condensation occurring in the system. The water in the far end will rise sufficiently to overcome this difference in order to balance the pressures, and it will rise far enough to produce a flow through the return pipe and overcome the resistance of check valves, if installed.

If a one-pipe steam system is designed, for example, for a total pressure drop of ⅛ psi, and utilizes a Hartford return connection instead of a check valve on the return, the rise in the water level at the far end of the return, due to the difference in steam pressure, would be ⅛ of 28 in. (28-in. head being equal to one pound per square inch), or 3½ in. Adding 3 in. to overcome the resistance of the return main, and 6 in. as a factor of safety for heating up, gives 12½ in. as the distance the bottom of the lowest part of the steam main and all heating units must be above the boiler water line. The same system, however, installed and sized for a total pressure drop of ½ psi, and with a check valve in the return, would require ½ of 28 in., or 14 in. for the difference in steam pressure, 3 in. for the flow through the return, 4 in. to operate the check valve, and 6 in. for a factor of safety, making a total of 27 in. as the required distance. Higher pressure drops would increase the distance accordingly.

When conditions are such that condensate cannot be returned to the boiler by the action of gravity, and either traps or pumps must be employed, the system is known as a *mechanical return system*. There are three general types of

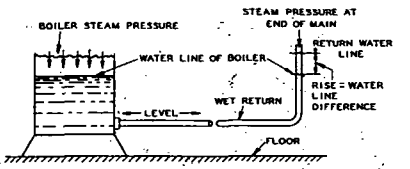

Fig. 1.... Difference in Steam Pressure on Water in Boiler and at End of Steam Main

mechanical condensate return devices in common use: (*a*) the alternating return trap, (*b*) the condensate return pump, and (*c*) the vacuum return pump.

In systems where pressure conditions in the system vary between that of a gravity return and a forced return system, a boiler return trap or alternating receiver is employed and the system may be known as an *alternating return system.*

When condensate is pumped to the boiler under pressures of the atmosphere or above, the system is known as a *condensate pump return system.*

When condensate is pumped to the boiler under vacuum conditions, the system is known as a *vacuum return system.*

In either the *condensate* or *vacuum pump systems* it is highly desirable to arrange for gravity flow to a receiver and to the pump. The pump then forces condensate into the boiler against its pressure.

ONE-PIPE SYSTEMS

One-pipe systems, as previously defined, are systems in which steam and condensate flow in the same pipe. Radiators and other heating units, in general, have only one piping connection from main to unit, although it is possible to employ two connections to the same main as indicated in Fig. 2. Unit heaters in one-pipe systems may also have separate connections to the wet-return.

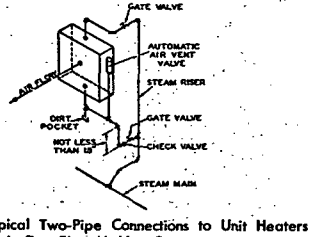

Fig. 2 .... Typical Two-Pipe Connections to Unit Heaters in One-Pipe Air-Vent Systems

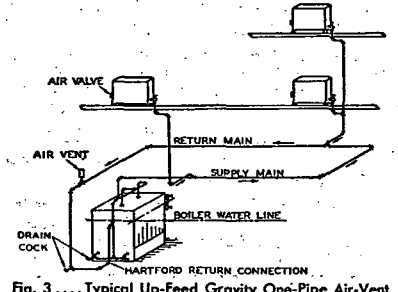

Fig. 3 .... Typical Up-Feed Gravity One-Pipe Air-Vent System

There are several variations in the piping arrangement of a one-pipe system as follows:

1. *Up-feed one-pipe systems where the radiators and other heating units are located above the supply mains.* The mains in this instance convey both steam and condensate. Therefore, it is preferable to limit this design to systems with a connected load under 2500 sq ft EDR. Such a system is illustrated in Fig. 3. Typical connections to radiator or risers are illustrated in Figs. 4 and 5 and method of changing sizes of mains in Fig. 6.

Branches from steam mains in one-pipe gravity steam systems should use the *preferred* connection shown in Fig. 7, but where radiator condensate does not flow back into the main, the *acceptable* method shown in the same figure may be used. This acceptable method has the advantage of giving a perfect swing joint when connected to the vertical riser or radiator connection, whereas the preferred connection does not give this swing without distorting the angle of the pipe. Runouts are usually made about 5 ft long to provide flexibility for movement in the main.

2. *Up-feed one-pipe system with a connected load in excess of 2500 sq ft EDR, where radiators and other heating units are located above the mains, as illustrated in Fig. 8.* It will be noted that the mains are dripped at each riser connection to a wet-return, as indicated in Fig. 5, so that the mains carry a minimum of the condensation. This feature is always desirable in the design of any one-pipe steam system. Radiators immediately above the mains may be connected as shown in Fig. 4. Up-feed systems are not recommended for systems higher than four or five stories.

3. *Down-feed one-pipe systems, where the radiators and other heating units are located below the supply main.* In this

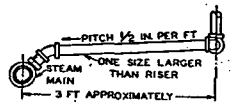

Fig. 4 .... Typical Steam Runout where Risers Are Not Dripped

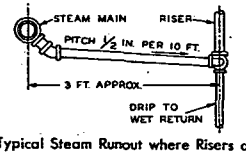

Fig. 5 .... Typical Steam Runout where Risers are Dripped

Fig. 7 .... Methods of Taking Branch from Main

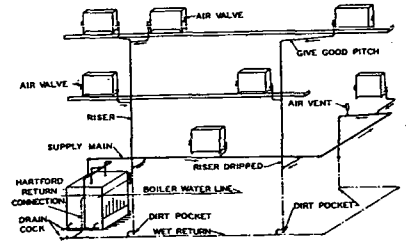

Fig. 8 .... Preferred Up-Feed Gravity One-Pipe Air-Vent System

arrangement only risers and connections to heating units convey both steam and condensate, and both are flowing in the same direction. The steam main is kept relatively free of condensate by dripping through the drop risers. Drain valves should be installed on all wet-return mains and on the return header at the boiler.

Each radiator or heating unit in a one-pipe system must be supplied with a thermostatic air valve which functions to relieve air from the heating unit under pressure, and to close when steam itself heats the thermostatic element of the valve.

To improve steam circulation in one-pipe systems quick-vent air valves should be provided at the ends and at intermediate points where the steam main is brought to a higher elevation, or where dropped below the water line. It is desirable to install the air-vent valves about a foot ahead of the drips, as indicated in Fig. 8, to prevent possible damage to their mechanisms by water.

Air valves are of two general types, the pressure and the vacuum types. The pressure type permits the inflow of atmospheric air to the system when the steam pressure in the system falls below atmospheric pressure. The vacuum type, which contains a small check valve, prevents the air from flowing back to the system and thereby maintains vacuum conditions in the system, and a consequent evaporation or generation of steam or vapor at subatmospheric pressures, and at consequent lower temperatures. Systems which use vacuum valves are known as *vapor* or *vacuum*

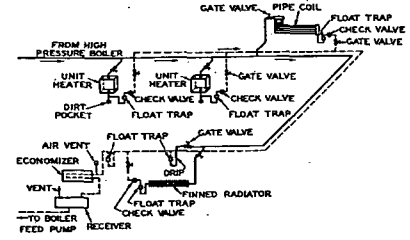

Fig. 9 .... Typical High-Pressure Heating System

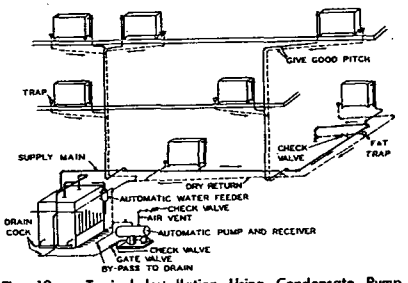

Fig. 10 .... Typical Installation Using Condensate Pump

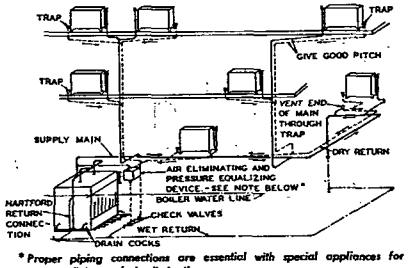
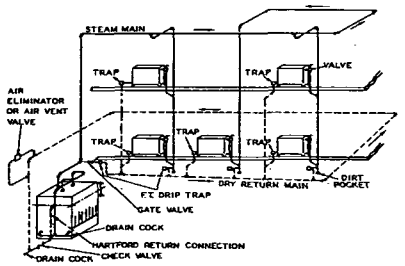
one-pipe systems. The vapor or vacuum systems will maintain a more uniform temperature condition than the pressure *systems.*



Each heating unit in a one-pipe system may also be provided with a valve on the connection to the unit, although this is not essential except to shut the unit off when it is not desired for heating. Valves on one-pipe systems must be either fully opened or fully closed. No throttling or modulating position can be maintained since, if a valve is partially closed, condensate will not drain from the unit. This condition is dangerous because it may create a low water condition in the boiler with consequent burning or cracking of the boiler, or create a hazard due to the freezing of the waterlogged heating unit itself.

TWO-PIPE SYSTEMS

Two-pipe systems, as previously defined, are systems in which steam and condensate flow in separate pipes. Two-pipe systems may operate under high-pressure, low-pressure, vapor, or vacuum conditions. Either the up-flow or the down-flow arrangement of mains may be employed.



Two-Pipe High-Pressure Systems

Two-pipe high-pressure systems operate at pressures above 15 psig, usually from 30 to 150 psig. They are usually used in large industrial buildings, which are equipped

* *Proper piping connections are essential with special appliances for pressure equalizing and air elimination.*

Fig. 11 .... Typical Up-Feed Two-Pipe System with Automatic Return Trap*

Note: When an air eliminator or vent valve is used on a vapor system, the boiler pressure must not exceed the static head necessary for the return by gravity of the condensate.

Fig. 12 .... Typical Down-Feed Two-Pipe System

with unit heaters or large built-up fan units, or in which high-pressure steam is required for process work.

Fig. 9 illustrates a typical high-pressure system. Because of the high pressures and the great differential between steam and return mains, it is possible to locate returns above the heating units and lift the condensate to these returns.

The condensate can be flashed into steam in low-pressure mains if any are available, or passed through an economizer heater before being discharged to a vented receiver. It is, of course, necessary to provide for the elimination of air from high-pressure systems, just as in low-pressure systems.

Return traps used on high-pressure systems are usually of the bucket, inverted-bucket, float, or impulse type. They are described in a later section Steam Traps.

Two-Pipe Low-Pressure Systems

Low-pressure systems operate at pressures of 0 to 15 psig. The piping arrangement of both up-feed and down-feed low-pressure systems is identical with those of two-pipe vapor systems described in the following section. The only difference between the two systems is in the type of air valve used. The air valves used in low-pressure systems usually do not contain the check discs and hence, the system cannot operate under a vacuum. The low-pressure systems are not as popular as the vapor systems, because they

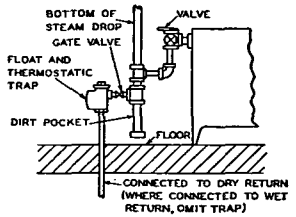


Fig. 13 .... Detail of Drip Connections at Bottom of Down-Feed Steam Drop

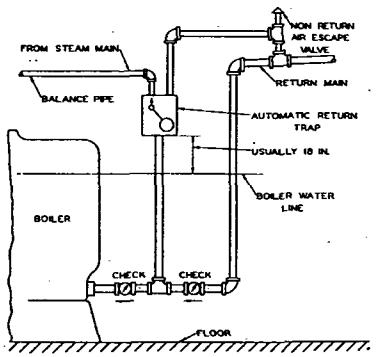

Fig. 14 .... Typical Connections for Automatic Return Trap

have the disadvantage of not holding heat when the rate of steam generation is diminishing. They also have the disadvantage of corroding to a greater extent than vapor systems, due to the continued presence of new air in the system.

Low-pressure systems have the advantage, however, of returning condensate to the boiler readily and not retaining it in the piping, as may be possible in vapor systems when the system pressure exceeds the static head provided for the gravity return at the boiler. Fig. 10 illustrates the conversion of a conventional gravity return system to a typical low-pressure system with a condensation pump. A check valve and a gate valve must always be installed between the pump discharge and the boiler. A check valve on the receiver vent will prevent the backflow of air when the system is cooling down.

Two-Pipe Vapor Systems

Two-pipe vapor systems operate at pressures varying from 20-in. vacuum or more (depending upon the tightness with which the system is assembled) to 15 psig without the use of a vacuum pump. A typical two-pipe up-feed vapor system is shown in Fig. 11, and a typical two-pipe down-feed system is illustrated in Fig. 12. The method of dripping drop

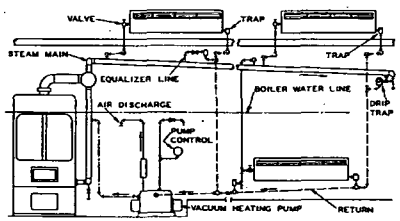

Fig. 15 .... Typical Two-Pipe Vacuum Pump System

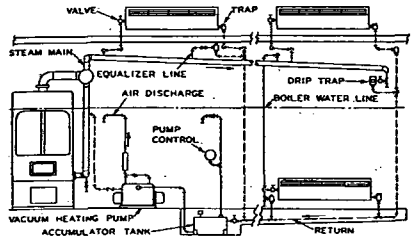

Fig. 16 .... Accumulator Tank Installation in Typical Two-Pipe Vacuum Pump System

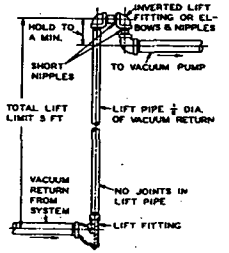
risers in a down-feed system is illustrated in Fig. 13. Radiators discharge their condensate and air through thermostatic traps to the dry-return main. Air is eliminated, when the system is under pressure, at the ends of the supply and return mains just before they drop to the wet return. The vent valves are of the float rather than float and thermostatic type since there should be no steam in the return main as long as the thermostatic traps on the radiators or convectors are operating properly. The float element of the valve closes the valve when, due to pressure differences, water rises to the point of overflow in the main. The vent valves are also provided with a small check disc which closes to prevent the inflow of air to the system when the pressure drops below atmospheric pressure. This enables the system to operate under vacuum conditions at lower steam temperatures for a period of four to eight hours, depending on the tightness of the system.

Vapor systems may also be provided with an automatic return trap or alternating receiver which automatically returns condensate to the boiler when the boiler is steaming under pressure conditions which would prevent the return of condensate by gravity. The typical connections for an automatic return trap are illustrated in Fig. 14. The two check valves are necessary for its successful operation.

Each heating unit in a vapor system, as in all two-pipe systems, is provided with a graduated or modulating valve which permits the control of heat in the radiator by varying the opening of the valve.



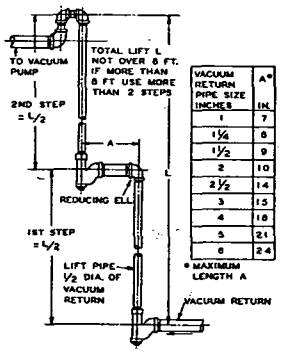


Fig. 17 .... Method of Constructing a Lift in a Return Line

Two-Pipe Vacuum Systems

Vacuum systems operate under conditions of both low pressure and vacuum, but employ the vacuum pump to insure maintenance of subatmospheric pressures in the return piping for all operating conditions. The pump thus assists the supply steam in overcoming the resistance of the system piping and insures rapid circulation and even heating. The system may operate transiently with subatmospheric pressure in the supply piping during the time the rate of steam generation is equivalent to or less than the total connected load.

A typical two-pipe vacuum system is illustrated in Fig. 15.

Fig. 18 .... Construction of a Step Lift

The return risers are connected in the basement into a common return main which slopes downward toward the vacuum pump. The vacuum pump withdraws the air and water from the system, separates the air from the water and expels it to atmosphere, and pumps the water back to the boiler or other receiver, which may be a feed-water heater or hot well. It is essential that no connection be made from the supply side to the return side at any point except through a trap. The return system should provide unrestricted gravity flow of the condensate and air to the pump receiver so that the vacuum differential may be more uniformly applied throughout the return system. In some instances, load conditions make it necessary to drop the return below the level of the vacuum pump inlet before this pump can be reached. This can be taken care of when using a vacuum pump by installing a float controlled auxiliary accumulator tank, pitted if necessary, just ahead of the vacuum pump inlet as shown by Fig. 16. The auxiliary tank as shown still permits an uninterrupted gravity flow from all return lines, but it does reduce the vacuum on the returns by 1-in. Hg for every foot of lift. The lift should be limited to 5 ft.

Lifts should be avoided, but on individual mains near the end of the system a lift fitting may be employed. Fig. 17 shows a single-step lift, which may be used up to 5 ft of lift. When the lift is greater but does not exceed 8 ft, it should be divided into two lifts shown in Fig. 18. It is preferable

to use commercial stock sizes of lift fittings, but if these are not available in the sizes required a satisfactory lift connection can be made from standard pipe fittings as shown by Fig. 19. When a lift assembly requires a union, it should be installed in a horizontal run. The use of a lift in any part of the system results in slower heat-up as well as interrupted return of the condensate from the section ahead of the lift. Lift fittings should not be used in place of an auxiliary tank in the return main at the inlet to the vacuum pump receiver.

A condensate pump may be used as a mechanical lift where severe outlying lift conditions cannot be avoided. This may be piped into the system as shown by Fig. 20 in such a manner as not to interfere with the normal functioning of the vacuum pump and without loss of vacuum on the returns preceding the condensate pump.

TWO-PIPE SUBATMOSPHERIC SYSTEMS

Subatmospheric systems are similar to vacuum systems but, in contrast, provide control of building temperature by variation of the heat output from the radiators. The radiator heat emission is controlled by varying the pressure, temperature, and specific volume of steam in circulation. These systems differ from the ordinary vacuum system in that they maintain a controllable partial vacuum on both the supply and return sides of the system, instead of only on

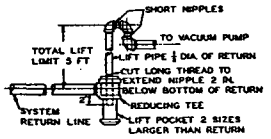

Fig. 19 .... How to Build a Lift Fitting

the return side. In the vacuum system, steam pressure above that of the atmosphere exists in the supply mains and radiators practically at all times. In the subatmospheric system, atmospheric pressure or higher exists in the steam supply piping and radiators only during severe weather. Under average winter temperature the steam is under partial vacuum which in mild weather may reach as high as 25-in. Hg, after which further reduction in heat output is obtained by restricting the quantity of steam.

The rate of steam supply is controlled by a valve in the steam main or by thermostatically controlling the rate of steam production in the boiler. The control valve may be of the automatic *modulating* or *floating* type governed thermostatically from selected control points in the building, or it may be a special pressure reducing valve which will maintain the desired subatmospheric pressures by continuous flow into the heating main. In some systems radiator supply valves include adjustable orifices, or are equipped with regulating orifice plates. The sizes of orifices used are larger than for other types of orifice systems because, for equal radiator sizes, the volume flowing is larger. Orifices are omitted on some systems. Radiator traps and drips are designed to operate at any pressure from 15 psig to 26-in. Hg.

Steam for heating domestic hot water should be taken from the boiler header back of the control valve so that pressures sufficiently high for heating the water may be maintained on the heater. The subatmospheric method of

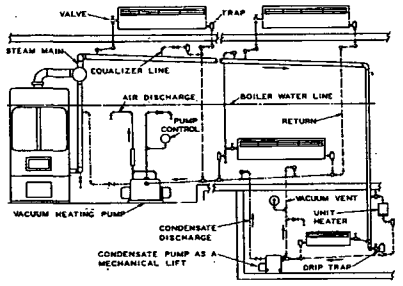

Fig. 20 .... Use of Condensate Pump as a Mechanical Lift

heating can be used for the heating coils of ventilating and air-conditioning systems. The flexible control of heat output secured by this method materially reduces the required size of bypass around the heaters. Some applications of subatmospheric systems are proprietary.

TWO-PIPE ORIFICE SYSTEMS

Orifice steam heating systems may have piping arrangements identical with vacuum systems. Some of these omit the radiator thermostatic traps, but use thermostatic or combination float and thermostatic traps on all drip points. A return condensate pump with receiver vented to atmosphere, a return-line vacuum pump, or a return trap, is generally used to return the condensate to the boiler or place of similar disposition, such as a feed-water heater or hot well. The heat emission from the radiators is controlled by varying the pressure differential maintained.

The principle on which these systems operate is that the steam flow through an orifice will vary with square root of pressure drop when the ratio of the absolute pressures on the two sides of the orifice exceeds 58 percent. If the absolute pressure on the outlet side is less than 58 percent of the absolute pressure on the inlet side, no further increase in flow will be obtained as a result of the increased pressure difference. If an orifice is so designed in size as to exactly fill a radiator with 2 psig steam on one side and ¼ psig on the other, the absolute pressure relation is

$$\frac{14.7 + 0.25}{14.7 + 2.0} = 0.90 \text{ or } 90 \text{ percent.}$$

If the steam pressure were dropped to ¼ psig on the supply pipe, the pressure on each side of the orifice would be balanced and no steam flow would take place. From this it will be apparent that if an orifice of a given diameter will fill a given radiator with steam when there is a given pressure on the main, reducing this steam main pressure will permit filling various desired portions of the radiator down to the point where the main pressure equals the back pressure in the radiator, provided the supply pipe pressures are closely controlled. If orifices are designed on a similar basis for a given system and proportioned to the heating capacity of the radiators they serve, all radiators will heat proportionately to the steam pressure. The range of pressure variation is limited by the permissible noise level of the steam flowing under the pressure difference required for

maximum heat output. The control of the steam supply is obtained by a valve placed in the steam main to maintain a determined pressure, and by varying the vacuum in the return lines. The valves are frequently set manually from a remote location, guided by temperature indicating stations in the building; or thermostatically controlled from a thermostat on the roof, which automatically measures the differential of outdoor and indoor temperatures. Since the range through which the pressures may be varied is usually from 0 to 4 psig, the control should be capable of maintaining close regulation of the desired space temperatures, particularly in mild weather.

A recommended orifice schedule is shown in Table 1. Some systems use orifices not only in radiator inlets, but also at different points in the steam supply piping for the purpose of balancing the system to a greater extent. In this manner the difference between the initial and terminal pressure in the steam main may be compensated to a great extent. For example, if the initial pressure is 3 psig and the pressure at the end of the main is 2 psig, an orifice could be used in each branch for the purpose of obtaining a more uniform pressure throughout the system. Such a provision may be particularly useful in this system for branches close to the boiler where the drop in the main has not yet been produced. Some orifice systems are proprietary.

SIZING PIPING FOR STEAM HEATING SYSTEMS

The functions of the piping system are the distribution of the steam, the return of the condensate, and, in systems where no local air vents are provided, the removal of the air. The distribution of the steam should be rapid, uniform, and without noise, and the release of air should be facilitated as much as possible, because an air bound system will not heat readily nor properly. In designing the piping arrangement, it is desirable to maintain equivalent resistances in the supply and return piping to and from a radiator. Arrangement of the piping so that the total distance from the boiler to the radiator is the same as the return piping distance from the heating unit back to the boiler, tends to obtain such a result. The condensate which collects in steam piping as well as in radiators must be drained to prevent interference with the ready flow of the steam and air. The effect of back pressure in the returns and excessive revaporization, such as occurs where condensate is released from pressures considerably higher than the vacuum or pressure in the return, must be avoided.

It is important that steam piping systems distribute steam not only at full *design* load, but during excess and partial loads. Usually the average winter steam demand is *less than half* of the demand at the *design* outdoor temperature. Moreover, in rapidly warming up a system even in moderate weather, the load on the steam main and returns may exceed the maximum operating load for severe weather, due to the necessity of raising the temperature of the metal in the system to the steam temperature, and the building to the *design* indoor temperature. Investigations of the return of condensate have revealed that as high as 143 percent of the design condensation rate may exist under conditions of actual operation. Expressed in gallons per minute per 1000 sq ft equivalent direct radiation the theoretical condensing rate of the system at the design indoor temperature is 0.5. During the warming-up period this value will approach 0.72 gpm.

The piping design of a heating system is greatly influenced by its operating characteristics. Heating systems do

Note.—The radiator orifice plates recommended in this table are made of brass stampings 0.023 in. thick cup-shaped to be inserted in radiator valve unions.

[a] S. S. Sanford and C. B. Sprenger: Flow of steam through orifices into radiators (ASHVE Transactions, Vol. 37, 1931, p. 371).

not operate under constant conditions, because conditions change continually, due to variation in load. As the system is being filled with steam, the pressures existing in various locations may be different from those which exist for appreciable periods at other locations, although at equilibrium conditions the pressures are approximately the same. In designing piping it is of particular importance to arrange the system to preclude trouble caused by such pressure differences. The systems which readily release the air, permit uniform pressures to be attained in much shorter time intervals than those which are sluggish. Results are given in Fig. 21, from investigations[1] to determine the rate of condensate and air return from a two-pipe gravity heating system. Variations in the steam pressure during the warming-up period, when the rate of air elimination and condensation is high, are clearly indicated in these curves.

It is evident that the condensate flow during the initial warming-up period reaches a peak, which is greater than the constant condensing rate eventually reached when the pressure becomes uniform. Moreover, the peak condensing

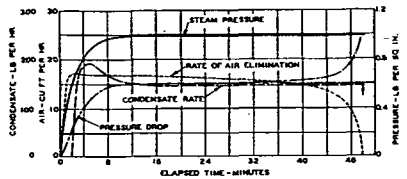

Fig. 21 .... Relation Between Elapsed Time, Steam Pressure, Condensate and Air Elimination Rates

rate is obtained when the system steam pressure is lower than that existing during a period of constant condensing rate. It will also be noted that the peak rate of air elimination does not coincide with the higher condensing rate.

Steam Flow

The rate of flow of dry steam, or steam with a small amount of water flowing in the same direction, is in accordance with the general laws of gas flow, and is a function of the length and diameter of the pipe, the density of the steam, and the pressure drop through the pipe. This relationship, developed by Unwin and later by Babcock, has been used for years as a means of determining steam flow through pipes. The new charts for weight-flow rate, pressure drop, and velocity presented in this chapter take into account the Reynolds number and its effect on friction loss, two items which were not considered when using the Unwin or Babcock formulas.

The data presented in Figs. 22, 23, 24, 25, 26 and Table 5, in later sections of this chapter, are based on the Moody Friction Factor where the absolute roughness of the internal pipe surface is that of new commercial steel or wrought iron. The Reynolds number, as expressed by Equation 9, Chapter 4, is

$$N_{Re} = \frac{dV\rho}{\mu} \qquad (1)$$

where

V = velocity of the steam, feet per second.
d = internal diameter of the pipe, feet.
ρ = density of saturated steam at a specified saturation pressure, pounds per cubic foot.
μ = absolute viscosity, pounds per foot-second.

Table 2 .... Pressure Drops in Common Use for Sizing Steam Pipe[a]

(For Corresponding Initial Steam Pressures)

Initial Steam Pressure, Psig	Pressure Drop Per 100 Ft, Psi	Total Pressure Drop in Steam Supply Piping, Psi
Subatmos. or vacuum return	2-4 oz	1-2 psi
0	½ oz	1 oz
1	2 oz	1-4 oz
2	2 oz	8 oz
5	4 oz	1½ psi
10	8 oz	3 psi
15	1 psi	4 psi
30	2 psi	5-10 psi
50	2-5 psi	10-15 psi
100	2-5 psi	15-25 psi
150	2-10 psi	25-30 psi

[a] Equipment, control valves, etc., must be selected on the basis of delivered pressures.

The velocity is determined by the equation

$$V = \frac{W}{3600\rho A} \qquad (2)$$

where

W = given weight-flow rate, pounds per hour.
A = internal pipe area, square feet.

The values used for the absolute viscosity of saturated steam are those of Lieb, published in *Combustion*, December, 1940. The relative roughness of the internal pipe surface is obtained by dividing the absolute surface roughness by the internal pipe diameter. The values for absolute roughness are those presented by L. F. Moody in *Mechanical Engineering*, Vol. 69, 1947, p. 1005, and appear in Table 1, Chapter 4. From the Reynolds number and relative roughness, the friction factor f is obtained from the Moody Friction Factor Chart, Fig. 4 of Chapter 4.

The head loss in feet is given by the equation

$$h = \frac{fLV^2}{2gd} \qquad (3)$$

where

f = friction factor.
L = length of pipe (100 ft).
g = acceleration due to gravity, 32.174 feet per (second) (second).

[a] From The American Society of Heating and Air-Conditioning Engineers Research Laboratory.

The pressure drop in psi per 100 ft of pipe is

$$\Delta P = \frac{\rho \Delta h}{144} \qquad (4)$$

Pipe Sizes

The determination of pipe sizes for a given load in steam heating depends on the following principal factors:

1. The initial pressure and the total pressure drop which may be allowed between the source of supply and at the end of the return system.
2. The maximum velocity of steam allowable for quiet and dependable operation of the system, taking into consideration the direction of condensate flow.
3. The equivalent length of the run from the boiler or source of steam supply to the farthest heating unit.
4. The direction of flow of the condensate, whether against or with the steam.

Initial Pressure and Pressure Drop

Theoretically, there are several factors to be considered such as initial pressure and pressure required at the end of the line, but it is most important that: (1) the total pressure drop does not exceed the initial gage pressure of the system, and in actual practice it should never exceed one-half of the initial gage pressure; (2) the pressure drop is not so great as to cause excessive velocities; (3) there is a constant initial pressure, except on systems specially designed for varying initial pressures, such as the subatmospheric, which normally operate under controlled partial vacuums, and orifice and vapor systems, which at times operate under such partial vacuums as may be obtained due to the condition of the fire; and (4) the rise in water due to pressure drop does not exceed the difference in level, for gravity return systems, between the lowest point on the steam main, the heating units, or the dry-return, and the boiler water line.

Table 2 lists pressure drops in common use with corresponding initial steam pressures for sizing steam piping. It is common practice to limit the total drop in the supply piping to approximately ⅓ of the initial pressure. The allowable pressure per 100 ft is thereby determined by the equivalent length. Designers may utilize total pressure drops up to ½ the initial pressure when steam velocities and operating pressure requirements of the selected equipment will permit. For initial pressures of 30 psig and higher many designers prefer to size steam piping on the velocity method.

The total pressure drop should never exceed one-half of the initial gage pressure when condensate is flowing in the same direction as the steam. Where the condensate must flow counter to the steam, the governing factor is the velocity permissible without interfering with the condensate flow. ASHAE Research Laboratory experiments limit this to the capacities given in Table 3 for horizontal pipes at various grades.

Maximum Velocity

The capacity of a steam pipe in any part of a steam system depends upon the quantity of condensate present, the direction in which the condensate is flowing, and the pressure drop in the pipe. Where the quantity of condensate is limited and is flowing in the same direction as the steam, only the pressure drop need be considered. When the condensate must flow against the steam, even in limited quantity, the velocity of the steam must not exceed limits above which the disturbance between the steam and the counter-flowing water may produce objectionable sounds, such as water hammer, or may result in the retention of water in certain parts of the system until the steam flow is reduced sufficiently to permit the water to pass. The velocity at which such disturbances take place is a function of (1) the pipe size, whether the pipe runs horizontally or vertically; (2) the pitch of the pipe if it runs horizontally; (3) the quantity of condensate flowing against the steam; and (4) freedom of the piping from water pockets which under certain conditions act as a restriction in pipe size.

Table 4 .... Length in Feet of Pipe to be Added to Actual Length of Run—Owing to Fittings—To Obtain Equivalent Length

Size of Pipe Inches	Length in Feet to be Added to Run

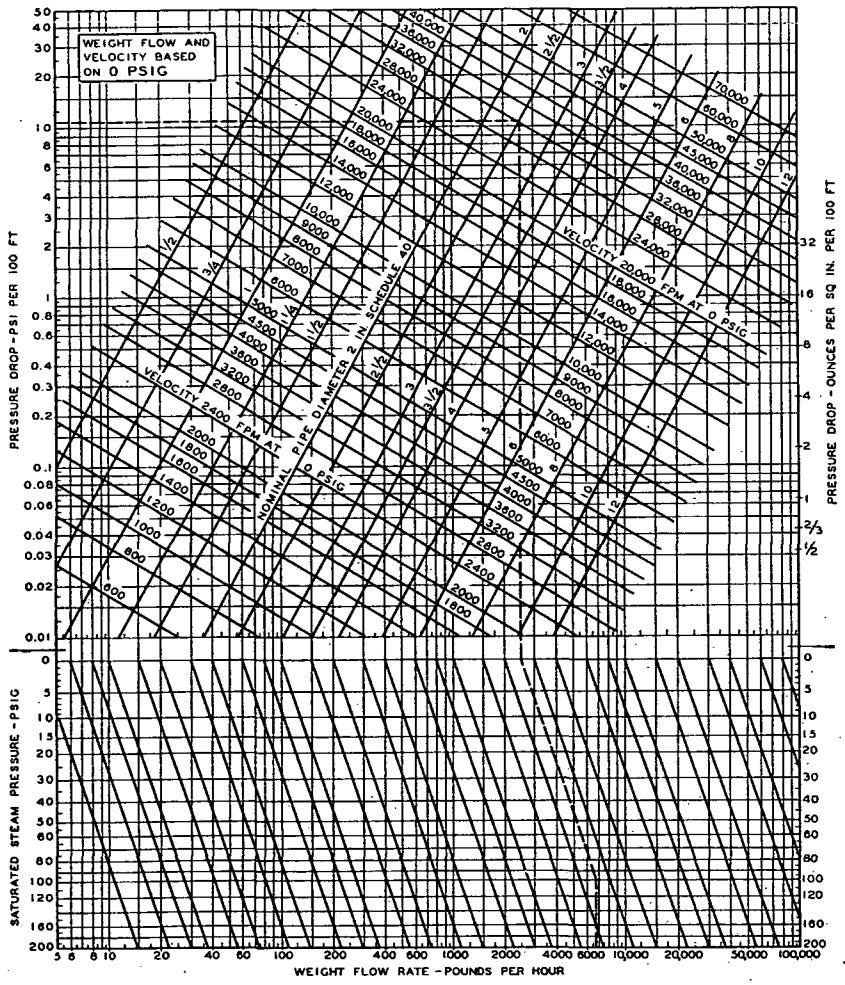
[a] Valve in full open position.
[b] Values given apply only to a tee used to divert the flow in the main to the last riser.

Example of length in feet of pipe to be added to actual length of run.



Measured Length = 132.0 ft
4 in. Gate Valve = 1.9 ft
4-4 in. Elbows = 36.0 ft
2-4 in. Tees = 36.0 ft
Equivalent = 205.9 ft

Reaming Important

It is extremely important that the ends of all pipe be reamed or filed. This insures full pipe area and minimizes disturbance of the steam or condensate stream.

Equivalent Length of Run

All tables for the flow of steam in pipes, based on pressure drop, must allow for the friction offered by the pipe, as well as for the additional resistance of the fittings and valves. These resistances generally are stated in terms of straight pipe; in other words, a certain fitting will produce a drop in pressure equivalent to the stated number of feet of straight run of the same size of pipe. Table 4 gives the number of feet of straight pipe usually allowed for the more common types of fittings and valves. In all pipe sizing tables in this chapter the *length of run* refers to the *equivalent length of run* as distinguished from the *actual length* of pipe

Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.

Fig. 22 .... Basic Chart for Weight-Flow Rate and Velocity of Steam in Schedule 40 Pipe Based on Saturation Pressure of 0 Psig

(With Multiplier Charts for Obtaining Weight-Flow Rates and Velocities at All Saturation Pressures Between 0 and 200 Psig)

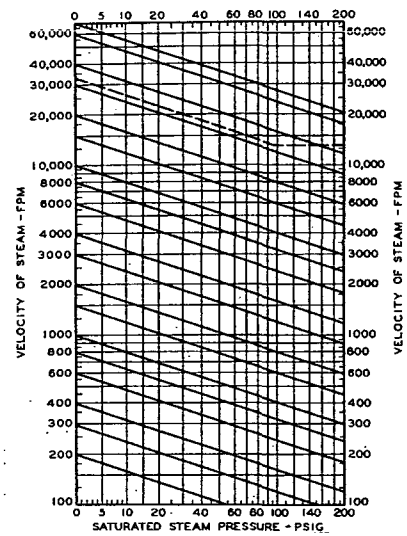


Fig. 22 (*Continued*).... Velocity Multiplier Chart

Example of Use of Basic and Velocity Multiplier Charts.

Given:

a. Weight-Flow Rate = 6700 lb per hr.

b. Initial Steam Pressure = 100 psig.

c. Pressure Drop = 11 psi per 100 ft.

Find:

a. Size of Schedule 40 pipe required.

b. Velocity of steam in pipe.

Solution: The following steps are illustrated by the broken line on Fig. 22:

Step 1. Enter Fig. 22 at a weight-flow rate of 6700 lb per hr and move vertically to the horizontal line at 100 psig.

Step 2. Follow along inclined multiplier line (upward and to the left) to horizontal 0 psig line. The equivalent weight flow at 0 psig is about 2500 lb per hr.

Step 3. Follow the 2500 lb per hr line vertically until it intersects the horizontal line at 11 psi per 100 ft pressure drop. The nominal pipe size is 2½ in. The equivalent steam velocity at 0 psig is about 32,700 fpm.

Step 4. To find the steam velocity at 100 psig, locate the value of 32,700 fpm on the ordinate of the velocity multiplier chart at 0 psig.

Step 5. Move along the inclined multiplier line (downward and to the right) until it intersects the vertical 100 psig pressure line. The velocity as read from the right (or left) scale is about 13,000 fpm.

Note: The preceding Steps 1 to 5 would be rearranged or reversed if different data were given.

[a] Based on Moody Friction Factor, where flow of condensate does not inhibit the flow of steam.

[b] The weight-flow rates at 3.5 psig can be used to cover sat. press. from 1 to 5 psig, and the rates at 12 psig can be used to cover sat. press. from 8 to 16 psig with an error not exceeding 8 percent.

[c] The steam velocities corresponding to the weight-flow rates given in this table can be found from the basic chart and velocity multiplier chart, Fig. 22.

in feet. The length of run is not usually known at the outset; hence, it may be necessary to assume some pipe size at the start. Such an assumption frequently is considerably in error, and a more common and practical method is to assume the length of run and to check this assumption after the pipes are sized. For this purpose the length of run usually is taken as double the actual length of pipe.

BASIC CHART FOR STEAM PIPE SIZING

Fig. 22 is the basic chart for determining the weight-flow rate and velocity of steam in Schedule 40 pipe for various values of pressure drop per 100 ft, based on zero psig saturated steam. By use of the multiplier charts it may be used at all saturation pressures between 0 and 200 psig.

TABLES FOR PIPE SIZING FOR LOW-PRESSURE

The basic chart, Fig. 22, can be used for sizing pipe on low-pressure systems. The values in Table 5 which are taken from the basic chart provide a more rapid means of selecting pipe sizes for the various pressure drops listed and for systems operated at 3.5 and 12 psig. The weight-flow rates shown for 3.5 psig can be used for saturated pressures from 1 to 6 psig, and those shown for 12 psig can be used for saturated pressures from 8 to 16 psig with an error not exceeding 8 percent.

Both Fig. 22 and Table 5 are for use where the flow of condensate does not inhibit the flow of steam. Columns *B* and *C* of Table 6 are for cases where steam and condensate flow in opposite directions as in risers or runouts that are not dripped. Columns *D*, *E*, and *F* are for one-pipe systems and include risers, radiator valves and vertical connections, and radiator and riser runout sizes, all of which are based on the critical velocities of the steam to permit the counterflow of condensate without noise.

Return piping may be sized with the aid of Table 7, where pipe capacities for wet, dry, and vacuum return lines are shown for several values of pressure drop per 100 ft of equivalent length. *It is customary to use the same pressure drop on both the steam and return sides of a system.*

Example 2: What pressure drop should be used for the steam piping of a system if the measured length of the longest run is 500 ft, and the initial pressure is not to be over 2 psig?

Solution: It will be assumed, if the measured length of the longest run is 500 ft, that when the allowance for fittings is added, the equivalent length of run will not exceed 1000 ft. Then, with the pressure drop not over one-half of the initial pressure, the drop could be 1 psi or less. With a pressure drop of 1 psi and a length of run of 1000 ft, the drop per 100 ft would be 0.1 psi, while if the total drop were 0.5 psi, the drop per 100 ft would be 0.05 psi. In both cases the pipe could be sized for a desired capacity according to the 0.1 and 0.05 pressure drop lines in Fig. 22. On completion of the sizing, the drop could be checked by taking the longest line and actually calculating the equivalent length of run from the pipe sizes determined. If the calculated drop is less than that assumed, the pipe size is all right; if it is more, it is probable that there are an unusual number of fittings involved, and either the lines must be straightened or the column for the next lower drop must be used, and the lines resized. Ordinarily, resizing will be unnecessary.

Table 6 .... Steam Pipe Capacities for Low-Pressure Systems

(For Use on One-Pipe Systems or Two-Pipe Systems in which Condensate Flows Against the Steam Flow)

This table is based on data developed through research investigations of the American Society of Heating and Air-Conditioning Engineers

Nominal Pipe Size, Inches	Capacity in Pounds per Hour				
	Two-Pipe Systems		One-Pipe Systems

16	22,000	19,000	—	—	—

Note: Steam at an average pressure of 1 psig is used as a basis of calculating capacities.

[a] Do not use Column B for pressure drops of less than 1/16 psi per 100 ft of equivalent run. Use Fig. 22 or Table 5 instead.

[b] Do not use Column D for pressure drops of less than 1/64 psi per 100 ft of equivalent run except on sizes 3 in. and over. Use Fig. 22 or Table 5 instead.

[c] Pitch of horizontal runouts to risers and radiators should be not less than ½ in. per ft. Where this pitch cannot be obtained, runouts over 8 ft in length should be one pipe size larger than called for in this table.

CHARTS FOR SIZING PIPE FOR HIGH-PRESSURE

Many installations of heating systems for large industrial-type buildings have been designed for the use of high-pressure steam, that is, without the use of pressure-reducing valves. Such systems usually involve the use of unit heaters or large built-up fan units with blast heating coils. Pressures on these systems vary from 30 to 150 psi. Temperatures are controlled by a modulating- or throttling-type thermostatic valve controlled by the air temperature in the room, fan inlet, or fan outlet.

Figs. 23, 24, 25, and 26 provide charts for sizing steam piping for systems of 30, 50, 100, and 150 psig at various pressure drops. These charts are based on the Moody Friction Factor, which takes into account the Reynolds number and the roughness of the internal pipe surfaces, and contain the same information as the basic chart of Fig. 22 but in a more convenient form.

Return pipe capacities given in Tables 8 and 9 are based on the following assumed pressures in the return piping:

Pressure Drop Lb/100 Ft	Pressure in Return Line (Psig)	
	30 psi System	150 psi System
⅛	½	1½
¼	1	2½
½	2	5
¾	3	7½
1	4	10
2	....	20

The pressure loss and line loss as given were substituted in the Babcock steam flow formula, and the resulting capacity was multiplied by 12 for 30-psig systems and by 16 for 150-psig systems to obtain the values given in Tables 8 and 9. The return-line pressures used were found by observation of operating systems. The Babcock formula was used in this case since information on condensate flow in return lines based on the Moody Friction Factor is not readily available.

Table 7 .... Return Main and Riser Capacities for Low-Pressure Systems—Pounds per Hour

(Reference to this table will be made by column letter G through Y)

This table is based on pipe size data developed through the research investigations of The American Society of Heating and Air-Conditioning Engineers

6	42,000	62,500	96,000	125,000	150,000	238,000

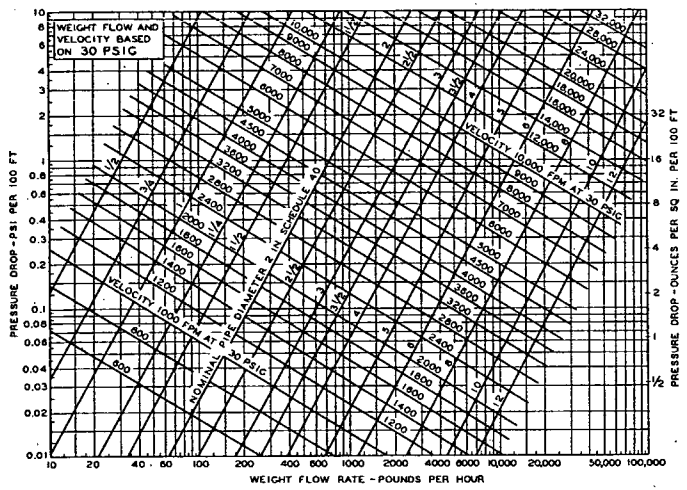
[a] *Note:* The above table is based on steam at pressures of 1 to 20 psig.

SIZING PIPING FOR ONE-PIPE GRAVITY SYSTEMS

Gravity one-pipe air-vent systems, in which the equivalent length of run does not exceed 200 ft, should be sized by means of Tables 5, 6, and 7 and Fig. 22 as follows:

1. *For the steam main and dripped runouts to risers* where the steam and condensate flow in the same direction, use 1/16 psi drop (Table 5 or Fig. 22).

2. *Where the riser runouts are not dripped* and the steam and condensate flow in opposite directions, and *also for the radiator runouts* where the same condition occurs, use Table 6, Column *F*.

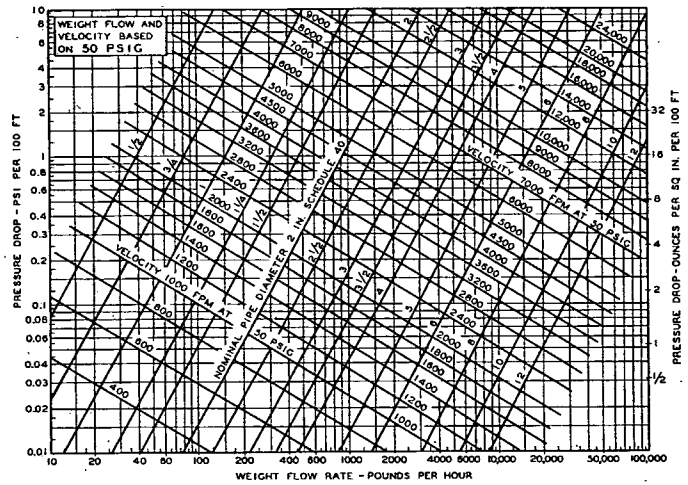


3. *For up-feed steam risers* carrying condensate back from the radiators, use Table 6, Column *D*.

4. *For down-feed systems, the main risers* of which do not carry any radiator condensate, use Table 6, Column *B*.

5. *For the radiator valve size and the stub connection*, use Table 6, Column *E*.

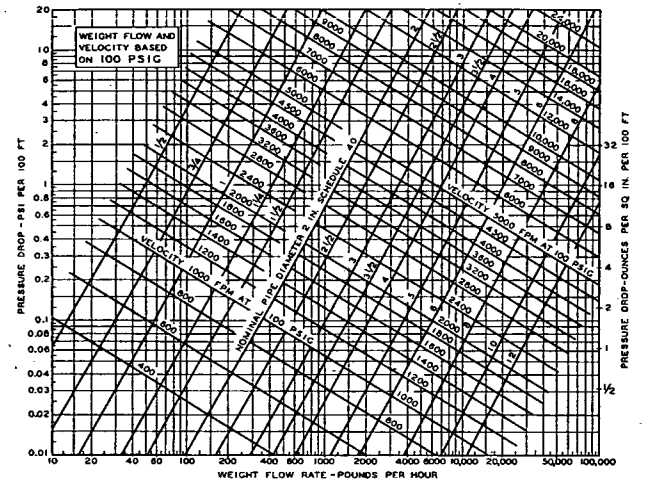
6. *For the dry-return main*, use Table 7, Column *O*.



7. *For the wet-return main*, use Table 7, Column *N*.

Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.

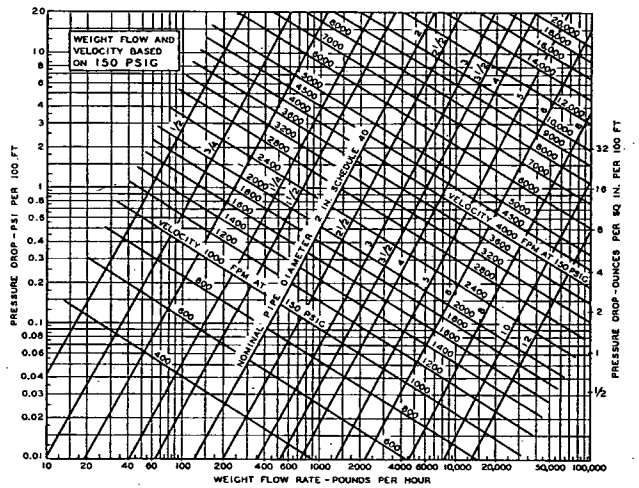
Fig. 23 .... Chart for Weight-Flow Rate and Velocity of Steam in Schedule 40 Pipe Based on Saturation Pressure of 30 Psig



(May be Used for Steam Pressures from 23 to 37 Psig with an Error Not Exceeding 8 Percent)

Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.

Fig. 24 .... Chart for Weight-Flow Rate and Velocity of Steam in Schedule 40 Pipe Based on Saturation Pressure of 50 Psig



(May Be Used for Steam Pressures from 40 to 60 Psig With an Error Not Exceeding 8 Percent)

Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.

Fig. 25 .... Chart for Weight-Flow Rate and Velocity of Steam in Schedule 40 Pipe Based on Saturation Pressure of 100 Psig

(May Be Used for Steam Pressures from 85 to 125 Psig With an Error Not Exceeding 8 Percent)

Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam.

Fig. 26 .... Chart for Weight-Flow Rate and Velocity of Steam in Schedule 40 Pipe Based on Saturation Pressure of 150 Psig

(May Be Used for Steam Pressures from 127 to 180 Psig With an Error Not Exceeding 8 Percent)

On systems exceeding an equivalent length of 200 ft, it is suggested that the total drop be not over ¼ psi. The return piping sizes should correspond with the drop used on the steam side of the system. Thus, where $\frac{1}{64}$ psi drop is being used, the steam main and dripped runouts would be sized from Fig. 22; radiator runouts and undripped riser runouts from Table 6, Column *F*; up-feed risers from Column *D*; the main riser on a down-feed system from Fig. 22 (it will be noted that if Column *E* is used the drop would exceed the limit of $\frac{1}{64}$ psi); the dry-return from Table 7, Column *L*; and the wet-return from Column *K*.

With a $\frac{1}{32}$ psi drop the sizing would be the same for as $\frac{1}{64}$ psi, except that the steam main and dripped runouts would be sized from Fig. 22, the main riser on a down-feed system from Fig. 22, the dry-return from Column *I*, and the wet-return from Column *H*.

Notes on Gravity One-Pipe Air-Vent Systems

1. Pitch of mains should not be less than ⅛ in. in 10 ft.
2. Pitch of horizontal runouts to risers and radiators should not be less than ½ in. per foot. Where this pitch cannot be obtained, runouts over 8 ft in length should be one size larger than called for in the table.
3. In general, it is not desirable to have a main less than 2 in. The diameter of the far end of the supply main should not be less than half its diameter at its largest part.
4. Supply mains, runouts to risers, or risers, should be dripped where necessary.
5. Where supply mains are decreased in size they should be dripped, or be provided with eccentric couplings, flush on bottom.

Example 3: Size the one-pipe gravity steam system shown in Fig. 27 assuming that this is all there is to the system, or that the riser and main shown involve the longest run on the system.

Solution: The total length of run actually shown is 215 ft. If the equivalent length of run is taken at double this, it will amount to 430 ft, and with a total drop of ¼ psi the drop per 100 ft will be slightly less than $\frac{1}{16}$ psi. It would be well in this case to use $\frac{1}{64}$ psi, and this would result in the theoretical sizes

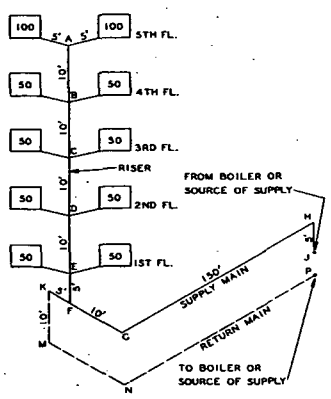


Fig. 27 .... Riser, Supply Main and Return Main of One-Pipe System

Table 10 .... Pipe Sizes for One-Pipe Up-Feed System Shown in Fig. 27

Part of System	Section of Pipe	Radiation Supplied EDR Sq Ft	Theoretical Pipe Size (Inches)	Practical Pipe size (Inches)
Branches to radiators	.....	100	2	2
Branches to radiators	.....	50	1¼	1¼
Riser	*A* to *B*	200	2	2
Riser	*B* to *C*	300	2½	2½
Riser	*C* to *D*	400	2½	2½
Riser	*D* to *E*	500	3	3
Riser	*E* to *F*	600	3	3
Runout to riser	*F* to *G*	600	3½	3½
Supply main	*G* to *H*	600	3	3
Branch to supply main	*H* to *J*	600	2½	3
Dry return main	*F* to *K*	600	1¼	2
Wet return main	*K* to *M*	600	1	2
Wet return main	*M* to *N*	600	1	2
Wet return main	*N* to *P*	600	1	2

indicated in Table 10. These theoretical sizes, however, should be modified by using a wet-return not less than 2 in., while the main supply, *G-H*, if from the uptake of a boiler, should be made the full size of the main, or 3 in. Also the portion of the main *K-M* should be made 2 in. if the wet-return is made 2 in.

SIZING PIPING FOR ONE-PIPE VAPOR SYSTEMS

Piping for one-pipe vapor systems is sized so as to permit only a few ounces pressure drop in the system. Otherwise, the method follows that outlined for sizing one-pipe gravity systems.

SIZING PIPING FOR TWO-PIPE HIGH-PRESSURE SYSTEMS

Steam supply piping for two-pipe high pressure can be sized for greater pressure drops than that of the return piping. For a system using steam at 30 psig, the total pressure drop can be 5 to 10 psi, and for 150 psig systems, 25 to 30 psi.

It has been observed that the maximum total pressure in the returns of a 30 psig system is about 5 psig, and that of a 150 psig system is about 20 psig. The pressure in the return mains is caused by the discharge of traps and flashing of condensate into steam because the return-line pressure is below that corresponding to the saturation temperature of the condensate. The usual practice in the sizing of high-pressure returns has been to size on the basis of ½ psi per 100 ft of pipe for 30 psig systems, and 1 psi per 100 ft for 150 psig systems. This is an average figure which corresponds generally to several of the previously published tables for the design of high-pressure return piping.

Notes on Two-Pipe High-Pressure Systems

Pitch of mains should not be less than ¼ in. in 10 ft.

Pitch of horizontal runouts to risers and heating units should not be less than ½ in. per ft.

SIZING PIPING FOR TWO-PIPE LOW-PRESSURE SYSTEMS

Piping for two-pipe low-pressure systems is sized in the same manner as for two-pipe vapor systems, except that the pressure drop throughout the system can be based on ½ psi to 1 psi drop.

SIZING PIPING FOR TWO-PIPE VAPOR SYSTEMS

While many manufacturers of patented vapor heating accessories have their own schedules for pipe sizing, an inspection of these sizing tables indicates that in general as small a drop as possible is recommended. The reasons for this are: (1) to have the condensate return to the boiler by gravity; (2) to obtain a more uniform distribution of steam throughout the system, especially when it is desirable to carry a moderate or low fire; and (3) to prevent large variations in pressure which would nullify the value of graduated valves on radiators.

For small vapor systems when the equivalent length of run does not exceed 200 ft, it is recommended that the main, and any runouts to risers that may be dripped, should be sized for about $\frac{1}{16}$ psi drop per 100 ft, using Fig. 22 or Table 5, while riser runouts not dripped and radiator runouts should be obtained from Column *C*, Table 6. The up-feed steam risers should be taken from Column *B*. For returns use Table 7, Column *O*, the upper portion for mains and the lower portion for risers. It should again be noted that the pressure drop in the steam side of the system is kept the same as on the return side, except where the flow in the riser is concerned.

On a down-feed system, the main vertical riser should be sized from Table 6, Column *B*, but the down-feed risers can be taken from Fig. 22 or Table 5 using a $\frac{1}{16}$ psi drop.

For vapor systems over 200 ft of equivalent length the drop should not exceed ⅛ to ¼ psi if possible. Thus, for a 400-ft equivalent run the drop should be not over $\frac{1}{32}$ psi per 100 ft. In this case the steam mains would be sized from Fig. 22, the radiator and undripped riser runouts from Table 6, Column *C*; and the risers from Fig. 22 because Column *B* gives a drop in excess of $\frac{1}{32}$ psi. On a down-feed system, Fig. 22 would have to be used for both the main riser and the smaller riser feeding the radiators in order not to increase the drop one $\frac{1}{32}$ psi. The return risers would be sized from the upper portion of the same column, while any wet-returns used would be sized from Column *I*. The same pressure drop is applied on both the steam and return sides of the system.

Notes on Vapor Systems

1. Pitch of mains should not be less than ⅛ in. in 10 ft.
2. Pitch of horizontal runouts to risers and radiators should not be less than ½ in. per ft. Where this pitch cannot be obtained, runouts over 8 ft in length should be one size larger than called for in the table.
3. It is not desirable to have a supply main smaller than 2 in.
4. When necessary, supply main, supply risers, or runouts to supply risers should be dripped separately into a wet-return, or may be connected into the dry-return through a thermostatic drip trap.

SIZING PIPING FOR TWO-PIPE VACUUM SYSTEMS

Vacuum, atmospheric, subatmospheric, and orifice systems are usually employed in large installations and have total drops varying from ¼ to 2 psi. Systems in which the maximum equivalent length does not exceed 200 ft preferably employ the smaller pressure drop, while systems over 200-ft equivalent length of run, more frequently are designed for the higher drop, owing to the relatively greater saving in pipe sizes. For example, a system with 2400-ft longest equivalent length of run could be designed for a pressure drop per 100 ft of 1 psi divided by 12, or $\frac{1}{64}$ psi. In this case the steam main would be sized from Fig. 22, and the risers also from Fig. 22 (Column *B*, Table 6, could be used as far as critical velocity is concerned, but the drop would exceed the limit of $\frac{1}{64}$ psi). Riser runouts, if dripped, would also be obtained from Fig. 22 but if undripped, from Column *C*, Table 6. Pipe sizes for other parts would be obtained as follows: radiator runouts from Column *C*; return risers from lower part of Column *S*, Table 7; and return runouts to radiators—one pipe size larger than the radiator trap connections.

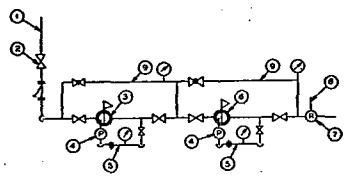
Notes on Vacuum Systems

1. Pitch of mains should not be less than ¼ in. in 10 ft.
2. Pitch of horizontal runouts to risers and radiators should not be less than ½ in. per ft. Where this pitch cannot be obtained, runouts over 8 ft in length should be one size larger than called for in the table.
3. In general, it is not considered desirable to have a supply main smaller than 2 in.
4. When necessary, the supply main, supply riser, or runout to a supply riser should be dripped separately through a trap into the vacuum return. A connection should not be made between the steam and return sides of a vacuum system without interposing a trap to prevent the steam from entering the return line.
5. Lifts should be avoided if possible, but when they cannot be eliminated they should be made in the manner described in this chapter.
6. No lifts can be used in orifice and atmospheric systems.

SIZING PIPING FOR INDIRECT HEATING UNITS

Pipe connections and mains for indirect heating units are sized according to the quantity of steam condensed by each unit. The condensate per unit depends upon the entering temperature and the air velocity, and may be obtained from manufacturers' rating tables. Where two or more units are placed in series, the entering air temperature for any unit will be the leaving temperature for the preceding unit.

When the amount of condensate has been obtained for each unit, the pipe sizes should be based on the length of run and the pressure drop desired, as in the case of radiators. It is generally desirable to place the indirect heating units on a separate piping system rather than to connect them to the piping which supplies direct radiation. For type of connections see section on Connections to Heating Units.



PRESSURE-REDUCING VALVES

While the illustrations of steam systems in this chapter indicate that they are supplied by separate boiler plants, it is also possible to have steam supplied by a remote boiler plant or by a district heating system at pressures higher than desired for the equipment served. District heating is discussed in Chapter 27.

There are certain fundamental principles that should be followed in the design of a building heating system which is to be supplied from district steam mains. Some of these are peculiar to district heating and some, although they may apply to any building, have been demonstrated to be particularly important when district steam is used. District heating companies have certain regulations regarding the consumer's installation to safeguard the mutual interest of supplier and consumer and to insure satisfactory and economical service. When an installation is designed, local regulations and code requirements should be observed.

Where steam is supplied from a boiler delivering steam at pressures higher than required for the heating system, one or more pressure-reducing valves (pressure regulators) are required. These are used in two classes of service, one

where the steam must be shut off tight to prevent build-up of pressure on the low-pressure side at time of no load, and the other where the low-pressure lines will condense enough steam to prevent build-up of pressure due to normal leakage through the valve. In the first case single-seated valves, either direct-operated or pilot-controlled, should be used and in the latter case double-seated valves, either direct-operated or pilot-controlled, may be used. Valves available are direct-operated, spring, weight, air-loaded, or pilot-controlled, using either the flowing steam or auxiliary air or water as the operating medium. The direct-operated, double-seated valve is less affected by varying inlet steam pressure than the direct-operated, single-seated valve. Pilot-controlled valves, either single- or double-seated, tend to eliminate the effect of variable inlet pressures.

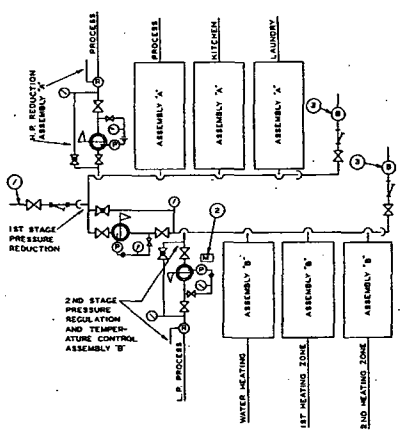
1. Service pipe from district steam main
2. Service valve
3. Pressure-reducing valve
4. Pilot
5. Balance line
6. Pressure-regulating valve
7. Safety relief valve
8. Relief valve discharge to outside
9. Bypass, one size smaller than pressure-reducing valve

Note: All fittings should be American Standard Class 250 cast iron and/or 300 lb steel.

(Used Where High-Pressure Steam is Supplied for Low-Pressure Requirements)

Fig. 28 .... Two-Stage Pressure-Reducing and Pressure-Regulating Equipment

Valves that shut off all steam are called *dead end* type. They are single-seated, and some of them have pilot operation or constant air loaders that provide close control of the reduced pressure. If a thermostatically controlled valve is installed after, and near, a reducing valve in such a manner as to cut off the passage of steam, the dead end type of reducing valve should be used and a suitable trap should be installed to provide for drainage of condensate formed between the reducing valve and the control valve. If a one-stage reduction is desired, it is necessary to use either a pilot-controlled or an air-loaded direct-operated pressure-reducing valve where low pressures are to be maintained closely.



Installation

The installation of pressure-reducing valves in pipe lines requires detailed planning. They should be installed to give ease of access for inspection and repair. There should be a bypass around each reducing valve of area equal to the area of the reducing-valve seat ring. The globe valve in a bypass line should be of a good type of construction, and must shut off absolutely tight. A steam pressure gage, graduated up to the initial pressure, should be installed on the low-pressure side. This should be ahead of the shut-off valve because the reducing valve can be more accurately and conveniently adjusted with the shut-off valve closed. A similar gage should be installed downstream from the shut-off valve for use during manual operation.

Strainers should be installed on the inlet of the primary pressure-reducing valve and are also desirable before the second-stage reduction if there is considerable piping between the two stages. If a two-stage reduction is made, it is well to install a pressure gage immediately before the reducing valve of the second-stage reduction for use in setting and checking the operation of the first valve. In all cases it is advisable to install a drip trap between the two reducing valves.

Safety valves located on the low-pressure side should be set at least 5 psi higher than the reduced pressure where the reduced pressure is under 35 psig and at least 10 psi higher than the reduced pressure if the reduced pressure is above 35 psig or is the first-stage reduction of a double reduction. A safety valve or valves, installed on the low-pressure side of a reducing valve or valves, should be of sufficient capacity and should be set to relieve the entire output of the reducing valves in the event pressure on the equipment exceeds the low-pressure setting by the values indicated above. The outlet from relief valves should be piped to a location where the discharge to atmosphere cannot jeopardize persons or property.[8] (See Figs. 28 and 29.)

Typical service connections are shown in Fig. 30 for low-

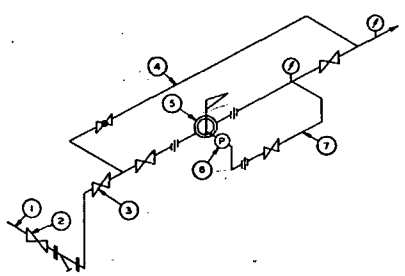
3. Bucket trap on header drip line



Note: Where process equipment is individually controlled, temperature control on header may be omitted. All fittings should be American Standard Class 250 cast iron or 300 lb steel in both reduction and regulation assemblies.

Fig. 29 .... Steam Supply Installation with Header for Process and Zone Connections

pressure service and Fig. 31 for high-pressure service. The district heating industry refers to valves according to their functional use. The pressure-reducing valve reduces pressure to a safe point, and the pressure-regulating valve regulates pressure to that required by equipment served. Fig. 31 illustrates the use of a pressure-regulating valve with a bypass. This bypass permits the operation of the system in case of failure in the pressure-regulating valve. In the smaller sizes, the bypass is sometimes omitted. When servicing is required, the pressure-regulating valve can be removed, a filler installed, and the inlet stop valves used for manual regulation of the pressure until repairs are made. Fig. 29 shows a typical service installation with a separate line to the various heating zones and process equipment. If the initial pressure is below 50 psig the first stage pressure-reducing valve may be omitted. In Assembly *A*, Fig. 29, the single-stage pressure-reducing valve is also the pressure-regulating valve.

If the radiation served is of cast iron and the inlet pressure exceeds 50 psig, the ASME Code[9] requires the installation of pressure-relief valves where the inlet pressure exceeds the safe working pressure of the steam-using equipment, except where two reducing valves are installed in series and *both* are set at or below the safe working pressure of the equipment serviced. This, however, is not two-stage reduction. See Fig. 31.

Two reducing valves, installed in series and both set at or below the safe working of the equipment serviced, introduce a source of safety while taking advantage of the more stable and satisfactory control provided by a single-step reduction. As can be seen from Fig. 31, the second valve which is set for a slightly higher reduced pressure is normally wide open and only comes into play to throttle the flow of high-pressure steam resulting from any failure of the primary valve. The increase of the system pressure to the higher pressure of the second valve is a signal that the primary valve requires maintenance. With bypasses as illustrated,

Fig. 30 .... Pressure-Regulating Valve with Bypass for Low Pressure Service

the primary valve can be serviced without shutting down the system. Since the valves are not both operating at the same time the distance between the valves is not critical.

When making a two-stage reduction, e.g., 150 to 50 psig and then 50 to 2 psig, allowance for expansion of steam on the low-pressure side of each reducing valve should be made by increasing the pipe area to approximately double the area of a pipe of the size of the reducing valve. This also allows steam flow to be at a more nearly uniform velocity. Separating the valves by a distance of at least 20 ft is recommended to reduce excessive hunting action of the first valve.

Fig. 28 shows a typical double-reduction installation where the pressure in the district steam main is higher than can safely be applied to building heating systems. The first or

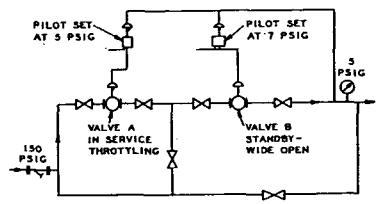

Fig. 31 .... Single-Stage Pressure Reduction—Series Installation

pressure-reducing valve effects the initial pressure reduction. The pressure-regulating valve regulates the steam to the desired final pressure.

Pilot-controlled or air-loaded direct-operated reducing valves may be used without limitation for all reduced pressure settings for all heating, process, laundry, hot water, etc. services. Spring-loaded direct-operated valves may be used for reduced pressures up to 50 psig providing they can pass the required steam flow without excessive deviation in reduced pressure.

Weight-loaded valves are used for reduced pressures below 15 psig and for moderate steam flows.

Pressure-equalizing or impulse lines must be properly connected to serve the type of valve selected. For direct-operated diaphragm valves with rubber-like diaphragms, the impulse line should be connected into the bottom of the reduced-pressure steam line to allow maximum condensate to exist on the diaphragm and in the impulse or equalizing line or, if connected to the top of the steam line, a condensate accumulator should be used to reduce variations in the head of condensate on the diaphragm. Equalizing or impulse lines for pilot-controlled and direct-operated reducing valves employing metal diaphragms should be connected into the expanded outlet piping approximately 2 to 4 ft from the reducing valve and pitched away from the reducing valve to prevent accumulation of condensate. Pressure impulse lines for externally pilot-controlled reducing valves employing compressed air or fresh water should be installed in accordance with manufacturer's recommendations.

Selection of Valve Size

Pressure-regulating valves should be sized to supply adequately the maximum steam requirements of the heating

Table 11.... Suggested Capacity of Pressure-Regulating Valves and Traps

Type of Control	Pressure-Regulating Valve Capacity Lb/(Hr)(Sq Ft EDR[a])
Continuous or modulating operation, intermittent with *on* periods over 3 hr in duration	⅓
Intermittent operation with *on* periods of ½ to 3 hr in duration	½
Intermittent operation with *on* periods of ½ hr or less	½[b]

[a] One square foot EDR = 240 Btu per hr.

[b] Except for 1-pipe systems or 2-pipe systems not orificed which should be 1 lb per sq ft EDR.

system or equipment. Consideration should be given to rangeability, speed of load changes, and accuracy of regulation required to properly handle system needs. This is especially important with temperature control systems using intermittent flow of steam to heat the building.

Certain types of pilot-operated pressure-regulating valves can be used as a temperature control valve in some temperature control applications, by actuating the pilot by means of a damper operator or small automatic control valve.[4]

Pressure-regulating valve capacities recommended for use with various types of temperature control are shown in Table 11.

Care should be exercised in selecting the size of a reducing valve. The safest method is to consult the manufacturer. It is essential that sizes of piping to and from the reducing valve be such that they will pass the desired amount of steam with the maximum velocity desired. A common error is to make the size of the reducing valve the same size as that of the service, or outlet pipe size. Generally, this will make the reducing valve oversized and cause wiredrawing of valve and seat due to the resultant small lift of the valve.

On installations where the steam requirements are relatively large and variable, wiredrawing and cycling control may occur in mild weather or during reduced-demand periods. To overcome this condition, two reducing valves are installed in parallel, with the sizes selected on a 70 and 30 percent proportion of maximum flow. For example, if 10,000 lb of steam per hour are required, the size of one valve is on the basis of 7000 lb, and the other on the basis of 3000 lb. During mild weather (spring and fall) the larger valve is set for slightly lower reduced pressure than the smaller one and hence remains closed as long as the smaller can supply the demand. During the remainder of the heating season the valve settings are reversed to keep the smaller one closed except when the larger is unable to supply the demand.

BOILER CONNECTIONS

Steam

Cast-iron, sectional heating boilers usually have several outlets in the top. Two or more outlets should be used whenever possible to reduce the velocity of the steam in the vertical uptakes from the boiler, and thus to prevent carrying of water into the steam main. Piping connections to the steam header are shown in Fig. 32.

Return

Cast-iron boilers are generally provided with return tappings on both sides, while steel boilers are generally equipped with only one return tapping. Where two tappings are provided, both should be used to effect proper circulation through the boiler. Recommended piping connections including the Hartford return for a battery of steam boilers having the *condensate returned by a pump*, are shown in Fig. 32. Connections for a single boiler are shown in Fig. 33. The 90-deg elbow, short horizontal nipple, and tee at the top of the Hartford connection may be replaced by an inverted Y fitting if the condensate flows to the boiler by *gravity*. The point at which the condensate enters the equalizer pipe should be 4 in. below the normal water line when a pump is used and usually 2 to 4 in. for gravity return.

The inverted Y fitting should *not be used* if condensate is *returned by a pump* because the fitting may direct the condensate upward into the equalizer pipe where it will cause noise due to rapid condensation of some steam. Proper selection of a pump capacity and discharge pressure is required in any case because a pump may deliver water at such a high rate that steam and cold condensate are brought into contact and cause noise.

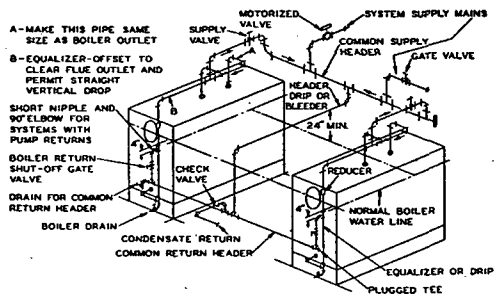

Fig. 32.... Piping Including Hartford Return Connection for Boilers in Battery

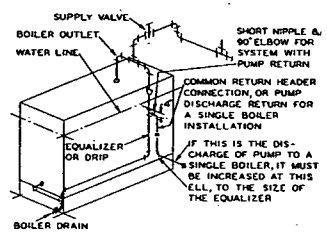

Fig. 33.... Boiler Piping Including Hartford Return Connections

Sizing Boiler Connections

Little information is available on the sizing of boiler runouts and steam headers. Although some engineers prefer an enlarged steam header to serve as additional steam storage space, there ordinarily is no sudden demand for steam in a steam heating system, except during the heating-up period, at which time a large steam header is a disadvantage rather than an advantage. The boiler header may be sized by first computing the maximum load that must be carried by any portion of the header under any conceivable method of operation, and then applying the same schedule of pipe sizing to the header as is used on the steam mains for the building. The horizontal runouts from the boiler, or boilers, may be sized by calculating the heaviest load that will be placed on the boiler at any time, and sizing the runouts on the same basis as the building mains. The difference in size between the vertical uptakes from the boiler, which should be of same size as the boiler outlet tapping, and the horizontal main or runout, is compensated for by the use of reducing ells.

Return connections to boilers in gravity systems are made the same size as the return main itself. Where the return is split and connected to two tappings on the same boiler, both connections are made the full size of the return line. Where two or more boilers are in use, the return to each may be sized to carry the full amount of return for the maximum load which that boiler will be required to carry. Where two boilers are used, one of them being a spare, the full size of the return main would be carried to each boiler, but if three boilers are installed, with one spare, the return line to each boiler would require only half of the capacity of the entire system, or, if the boiler capacity were more than one-half the entire system load, the return would be sized on the basis of the maximum boiler capacity. As the return piping around the boiler is usually small and short, it should not be sized to the minimum.

With returns pumped from a vacuum or receiver return pump, the size of the line may be calculated from the water rate on the pump discharge when it is operated, and the line sized for a very small pressure drop. The relative boiler loads should be considered, as in the case of gravity return connections. Boiler header and piping sizes should be based on the total load.

CONDENSATE RETURN PUMPS

Condensate return pumps are used for gravity systems when the local conditions do not permit the condensate to return to the boiler under the existing static head. The return of the condensate permits the water to pass repeatedly through the cycle of vaporization, with subsequent condensation and return to the boiler. During such repeated cycles any incrustants or other substances in solution are precipitated and the water de-activated to a considerable extent, so that corrosion of a serious nature is seldom ever encountered where the condensate is repeatedly used. Serious corrosion is more frequently found in systems in which the condensate is wasted, and fresh make-up water is continually being introduced.

A generally accepted condensate pump unit for low-pressure heating systems consists of a motor-driven centrifugal pump with receiver and automatic float control. Other types in use include rotary, screw, turbine and reciprocating pumps with steam turbine or motor drive, and direct-acting steam reciprocating pumps.

The receiver capacities of these automatic units should be sized so as not to cause too great a fluctuation of the boiler water line if fed directly to the boiler, and at the same time not so small as to cause too frequent operation of the unit. The usual unit provides storage capacity between stops in the receiver of approximately 1.5 times the amount of condensate returned per minute, and the pump generally has a delivery rate of 2 to 3 times the normal flow. This relation of receiver and pump size to heating system condensing capacity takes account of the peak condensation rate.

A typical installation of a motor-driven automatic condensate unit is illustrated in Fig. 10.

VACUUM HEATING PUMPS

On vacuum systems, where the returns are under a vacuum, and subatmospheric systems, where the supply piping, radiation, and the returns are under a vacuum, it is necessary to use a vacuum pump to discharge the air and noncondensable gases to the atmosphere and to dispose of the condensate. Direct-acting steam-driven reciprocating vacuum pumps are sometimes used where high-pressure steam is available, or where the exhaust steam from the pump can be utilized. In general, however, these have been replaced by the automatic motor-driven return-line heating pump especially developed for this service. Steam-turbine drive is also frequently used where steam at suitable pressures is available, the steam being used afterward for building heating. The usual vacuum pump unit consists of a compact assembly of exhausting unit for withdrawing the air-vapor mixture and discharging the air to atmosphere, and a water removal unit which discharges the condensate to the boiler. They are furnished complete with receiver, separating tank, and automatic controls mounted as an integrated unit on one base. There are also special steam-turbine driven units which are operated by passing the steam to be used in heating the building through the turbine with only a 2 to 3 psi drop across the turbine required for its operation. Under special conditions such as installations where it is necessary to return the condensate to a high-pressure boiler, auxiliary water pumps may be supplied. In some instances separate air and water pumps may be used.

For rating purposes[4] vacuum pumps are classified as *low*

vacuum and *high vacuum*. Low-vacuum pumps are those rated for maintaining 5½ in. Hg vacuum on the system, and high-vacuum pumps are those rated to maintain vacuums above 5½ in. Hg.

The required air and condensate removal capacity of vacuum pumps depends upon the size and type of heating system to which they are applied.

The required condensate capacity is closely related to the amount of radiation installed together with the range of the heating requirement. For average design conditions, the theoretical condensing rate of a heating system is approximately 0.5 gpm per 1000 sq ft equivalent direct radiation (EDR) served. Vacuum-pump water-delivery rates generally should be the same as for condensate pumps, which range from 2 to 3 times the design condensing rate. This provides sufficient capacity for peak loads, and for intermittent automatic operation.

The wide varying operating range and characteristics of individual heating systems have a greater effect on the quantity of air to be removed than on the condensate to be handled. The air-handling requirement cannot be found by applying a common factor to the equivalent direct radiation design load although this would be possible in determining the condensate. For low-vacuum systems, where the returns are controlled at an average vacuum of 5.5-in. Hg vacuum and the temperature averages 160 F, the various manufacturers of vacuum pumps provide pump capacities from 0.3 to 1.0 cfm of air per 1000 sq ft equivalent direct radiation served. For high-vacuum systems, the vacuum-pump air capacity requirements are generally greater. A capacity of 2.0 cfm of air, at 20-in. Hg vacuum per 1000 sq ft equivalent direct radiation served, is a typical capacity *furnished on high-vacuum systems*. These higher air capacities on subatmospheric controlled systems are required basically because of the increase in vacuum which expands the volume of air and vapor that is to be removed to maintain circulation at the higher operating vacuum.

It is particularly important on high-vacuum installations to see that the entire system is tight in order to reduce the amount of inward air leakage and, furthermore, to assure that relatively higher temperature steam is prevented from entering the vacuum return lines through leaky traps, high-pressure drips, etc. The hotter the returns, the lower will be the possible vacuum for a given air leakage into the system. It is for this reason that the condensate from equipment using steam at high pressure should not be connected directly to a vacuum return line, but should drain to a flash tank or flash leg through a high-pressure trap. The receiver should have an equalizing connection to a low-pressure steam main and drain through a low-pressure trap to the vacuum return main, as indicated later in this chapter in section on Drips.

Vacuum-Pump Controls

*In the ordinary vacuum system, the vacuum pump is con*trolled by a vacuum regulator which cuts in when the vacuum drops to the lowest point desired, and cuts out when it has been increased to the highest point, these points being varied to suit the particular system or operating conditions. In addition to this vacuum control, a float control is included which will start the pump whenever sufficient condensate accumulates in the receiver, regardless of the vacuum on the system. A selector switch is usually provided to allow operation at night as a condensate pump only, also to give manual or continuous operation when desired.

There are several variations in the control of the vacuum maintained on the system by the pump. In some subatmospheric systems where orifices are used, the vacuum-pump control maintains a pressure difference between the supply and the return piping, which is held within relatively close limits. There are other subatmospheric systems which utilize special temperature-pressure actuated controls for maintaining the desired conditions in the return lines. Where various zones are connected to the same return main, the return vacuum must be controlled to meet the requirements of the zone operating at the lowest steam supply pressure.

Piston-Displacement Vacuum Pumps

Piston-displacement return vacuum heating pumps may be either electric or steam driven. Their piston speed in feet per minute should not exceed 20 times the square root of the number of inches in their stroke. They are usually supplied with an air separating tank, open to the atmosphere, placed on the discharge side of the pump, and at an elevation sufficiently high to allow gravity flow of the condensate to the boiler. If the boiler pressure is too high for such gravity feed, then an additional steam pump for feeding the boiler is desirable. The extra pump is sometimes avoided by using a closed separating tank with a float-controlled vent. In both arrangements, the air taken from the system must be discharged against the full discharge pressure of the vacuum pump. In the case of high- or medium-pressure boilers, it is better to use the atmospheric separator and the second pump.

In figuring the required displacement for such pumps, a value of from 6 to 10 times the volumetric flow of condensate is used for average vacuums and systems.

STEAM TRAPS

Steam traps, as the name implies, are automatic devices used to trap or hold steam in an apparatus or piping system until it has given up its latent heat, and to allow condensate and air to pass as soon as it accumulates. In general, traps consist of a vessel in which to accumulate the condensate, an orifice through which the condensate is discharged, a valve to close the orifice port, mechanisms to operate the valve, and inlet and outlet openings for the entrance and discharge of the condensate from the trap vessel.

Steam traps are classified according to the type of operating device by which they function. The traps which are available on the market today may be classified as (1) float, (2) thermostatic, (3) float and thermostatic, (4) upright bucket, (5) inverted bucket, (6) flash, (7) impulse, (8) lifting, and (9) boiler return trap or alternating receiver.

Float Traps. Float traps operate by the rise and fall of a float due to a change of condensate level in the trap. When the trap is empty, the float is in its lowest position and the discharge valve is closed. As condensate accumulates in the trap chamber, the float rises and gradually opens the valve, and the pressure of the steam pushes the condensate out of the valve. The discharge from a float trap is generally continuous, since the opening of the valve is proportioned to the flow of condensate through the trap. A gage glass may be used to indicate the height of condensate in the trap chamber.

Unless float traps are well made and proportioned, there is danger of considerable steam leakage through the discharge valve due to unequal expansion of the valve and seat, and the sticking of moving parts. Float traps are made in sizes from ½ to 3 in., and for pressures varying from vacuum conditions to 200 psig. Float traps are used for draining condensate from steam separators, steam headers, blast coils, heating systems, steam-water heaters, laundry equipment, sterilizers, and other equipment. When used for draining low-pressure systems, float traps should be equipped with a thermostatic air vent (see Float and Thermostatic Traps). Fig. 34 illustrates a single-port float trap.

Thermostatic Traps. Thermostatic traps function by means of elements which expand and contract under the influence of heat and cold. In early types of thermostatic traps, carbon posts and bimetallic elements were used for expansion. In general, the modern type of thermostatic trap consists of thin corrugated metal bellows or discs enclosing a hollow chamber. The chamber is either filled with a liquid, or a small amount of a volatile liquid, such as alcohol, is introduced. The liquid expands or becomes a gas when steam comes into contact with the expansive element. The pressure created in either case expands the element and closes the valve of the trap against the escape of steam. When condensate or air comes in contact with the element, it cools and contracts, opening the valve and allowing them to escape.

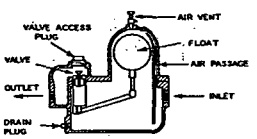

Fig. 34 .... Single Port Float Trap

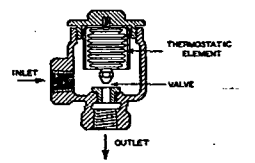

Fig. 35 .... Thermostatic Trap Bellows Type

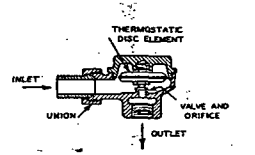

Fig. 36 .... Thermostic Trap Disc Typeat

The discharge from this type of trap is intermittent. Thermostatic traps find their use generally for the draining of condensate from radiators, convectors, pipe coils, drips, unit heaters, water heaters, cooking kettles, and other equipment. Except for radiators and convectors, it is recommended that a strainer be installed on the inlet connection to the trap to prevent dirt, pipe scale, and other foreign substance from entering the trap. A cooling leg of a length of pipe should also be provided ahead of the trap on unit heaters and similar apparatus to cool the condensate in order to help in the trap action. Thermostatic traps are made in sizes from ½ to 2 in., and for pressures ranging from vacuum conditions to 200 psig. Figs. 35 and 36 illustrate types of thermostatic traps which are available at the present time.

Float and Thermostatic Traps. This type of trap is a combination of the float trap and the thermostatic trap, and finds its use in the draining of condensate from unit heaters, blast heaters, and coil heaters for water, oil, or other liquids where there is apt to be a large volume of condensate which would not permit successful operation of thermostatic traps alone. The function of the float element of this trap is to handle the condensate, and of the thermostatic element to permit the flow of air and to prevent the flow of steam around the float valve. Float and thermostatic traps are made in sizes from ½ to 2 in. and usually operate under pressures varying from vacuum conditions to 40 psig, although some are made to operate at a maximum pressure of 200 psig. Fig. 37 illustrates a typical float and thermostatic trap.

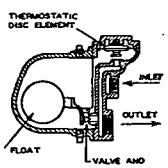

Fig. 37 .... Typical Float and Thermostatic Trap

Upright Bucket Traps. In this type of trap, the condensate enters the trap chamber and fills the space between the bucket and the walls of the trap. This causes the bucket to float, and *forces the valve against its seat, the valve and its stem usually* being fastened to the bucket. When the condensate in the chamber rises above the edges of the bucket, it overflows into it and causes the bucket to sink, thereby withdrawing the valve from its seat. This permits the steam pressure acting on the surface of condensate in the bucket to force the water to the discharge opening. When the bucket is emptied, it rises and closes the valve and another cycle begins. The discharge from this type of trap is intermittent, and it requires a definite differential pressure (usually 1 psi at least) between the inlet and outlet of the trap in order to lift the condensate out of the bucket to the return opening.

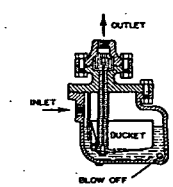

Fig. 38 .... Upright Bucket Trap

Upright bucket traps are used for draining condensate and air from blast coils, unit heaters, steam mains, laundry equipment, sterilizers, water and oil heaters and other equipment. This type of trap is particularly suited for use where there are pulsating pressures, such as occur in draining steam lines and separators at reciprocating pumps or engines. It is not influenced by pulsations or wide fluctuations of pressure. Upright bucket traps are obtainable in sizes varying from ½ to 2½ in., and for pressures varying from vacuum to 1200 psig. Fig. 38 illustrates an upright bucket trap.

Inverted Bucket Traps. In this type of trap, steam, condensate, and air enter the trap under the bell or inverted bucket. Steam floats the inverted bucket and closes the valve. Condensate entering the trap enables the inverted bucket to fall, opening the valve. The condensate then discharges through the open valve until steam again enters and displaces the water contained in the bucket, thus restoring its buoyancy. The steam pressure entering through the open valve discharges the trap. Air is eliminated automatically by passing through the small vent hole located in the top of the inverted bucket.

Inverted bucket traps for use on low-pressure systems, particularly with blast coils or unit heaters, are usually furnished with a large capacity opening equipped with a bimetallic thermostatic element which closes when heated by steam, and opens when cooled by air and condensate, allowing air to escape from the inverted bucket to the trap outlet. Inverted

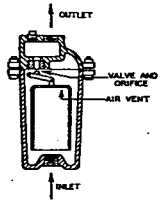

Fig. 39 .... Inverted Bucket Trap

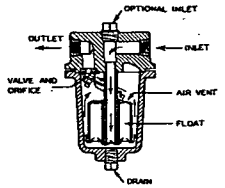

Fig. 40 .... Inverted Bucket Trap with Central Guide

bucket traps are used for draining condensate and air from blast coils, unit heaters, steam drips, laundry equipment, sterilizers, steam water heaters, and other equipment. They are particularly suited for draining condensate from steam lines or equipment where abnormal amounts of air must be discharged, and where there is also foreign matter such as dirt, sludge, and oil draining to the trap.

The discharge from inverted bucket traps, like that of the upright bucket traps, is intermittent and requires a definite differential pressure between the inlet and the outlet of the trap in order to lift the condensate from the bottom of the trap to the outlet of same. Inverted bucket traps are made in sizes from ½ to 3 in., and for pressures varying from vacuum to 2400 psig. Figs. 39 and 40 illustrate some of the types of inverted bucket traps which are available on the market at the present time.

Flash Traps. These traps depend on the property of condensate at a high pressure and temperature to flash into steam at a lower pressure. Condensate flows freely through the orifice of the trap due to the pressure difference from inlet to outlet of trap until steam enters the inlet chamber and mixes with the remaining condensate, heating the condensate and causing it to flash, thereby choking the flow through the orifice and allowing more condensate to accumulate in the trap. The discharge from flash-type traps is intermittent. There are no moving parts in this type of trap. The orifice, however, is adjustable for the pressure differential required. A gage glass or float indicates whether the trap is operating.

These traps can be used for draining condensate from steam, water, and oil heaters; blast heaters; unit heaters; dryers; vulcanizers; kitchen equipment; laundry equipment; evaporators; steam lines; and other equipment, where the pressure differential between steam supply and condensate return does not drop below 5 psi. Flash-type traps are made in sizes from ½ to 3 in., and for pressures varying from vacuum to 450 psig. Fig. 41 illustrates a trap of the flash type.

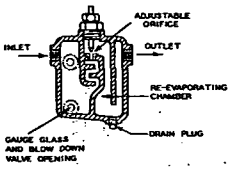

Fig. 41 .... Flash Trap

Impulse Traps. These traps are a modification of the flash trap, and depend on the same principle of flash for their operation. In the impulse trap the flashing action is utilized to govern the movement of a valve by causing changes in pressure in a control chamber above the valve. A small portion of condensate, called control flow, bypasses continuously through the control chamber. At low and medium temperatures, the discharge through the center orifice reduces control chamber pressure, and the valve opens for free discharge of air and condensate.

When condensate reaches near-steam temperature, part of the control flow flashes into vapor, due to reduced pressure in control chamber. The increased volume of the condensate-vapor mixture restricts the discharge through the center orifice, and therefore the reduced pressure in control chamber builds

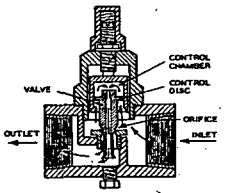

Fig. 42 .... Impulse Trap

up, closes the valve, and shuts off all discharge of hot condensate, except the small amount flowing through center orifice.

Under normal condensate loads, the valve opens and closes at short intervals. Under heavy loads, the valve opens wide and the discharge is heavy and continuous. Impulse traps can be used for draining condensate from steam mains, unit heaters, laundry equipment, kitchen equipment, oil and water heaters, sterilizers, and other equipment where the pressure at the trap outlet is not greater than 25 percent of the inlet pressure. Impulse traps are made in sizes from ½ to 2 in., and for pressures ranging from 1 to 600 psig. Fig. 42 illustrates a trap of the impulse type.

Lifting Traps. This type of trap is an adaptation of the up-

right bucket trap. It has the added feature of an auxiliary pressure inlet through which steam is introduced at a pressure higher than that of the trap inlet pressure. This high-pressure steam forces the condensate to a point above the trap, and against a back pressure higher than that which is possible with normal steam pressure. Lifting traps are made in sizes from 1 to 3 in., and for pressures ranging from vacuum to 150 psig. Fig. 43 illustrates a trap of the lifting type.

Boiler Return Trap or Alternating Receiver. This device is not actually a steam trap in that it is not used to trap or hold steam, but is an adaptation of the lifting trap. It is used for returning condensate to a low-pressure boiler, when due to excess pressure, the condensate cannot flow to the boiler by gravity without flooding the return mains, and endangering the boiler by permitting it to go dry. The boiler return trap is a vessel (vented to the atmosphere) in which condensate collects until a float-operated mechanism equalizes the boiler and

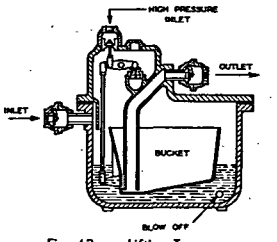

Fig. 43 .... Lifting Trap

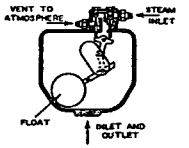

Fig. 44 .... Boiler Return Trap or Alternating Receiver

trap pressure to enable the water in the trap to flow with the boiler by gravity.

These traps are available in sizes from 1½ to 2½ in., and for pressures varying from 0 to 100 psig. A typical boiler return trap is shown in Fig. 44, and a typical connection to a low-pressure heating system in Fig. 14.

Steam Trap Installations

The following general rules should govern the installation of traps of all types:

1. A vertical drip, as long as possible, and a strainer should be installed between the trap and the apparatus it drains. Exceptions to this rule are the installation of thermostatic traps in radiators, convectors, and pipe coils. These, in general, are attached directly to the units without strainers.

2. Whenever it is necessary to maintain, in continuous service, apparatus which is to be drained, it is advisable to install a gate valve on each side of the trap, and a valved bypass around the trap, so that the trap may be removed and repaired and condensate drained through the throttled bypass valve.

3. Whenever it is necessary to install traps for lift service, as when the condensate must be discharged to a main located above the trap, or where the trap must discharge against a definite back pressure, a check valve and a gate valve should be installed on the discharge side of the trap, the check valve to prevent continuous pressure on the discharge side of the valve, and the gate valve to shut off pressure in case the trap is removed for service or repair.

DRIPS

A steam main in any type of steam heating system may be dropped to a lower level without dripping if the pitch is downward with the direction of steam flow. The steam main in any heating system can be elevated if dripped. Fig. 45 shows a connection where the steam main is raised and is drained to a wet-return. If the elevation of the low point

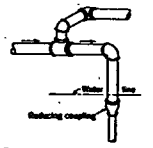

Fig. 45 .... Dripping Main Where It Rises to Higher Level

is above a dry-return, it may be drained through a trap to the dry-return in two-pipe vapor, vacuum and subatmospheric systems. Horizontal steam pipes may also be run over obstructions without a change in level, if a small pipe is carried below the obstruction to care for the condensate (Fig. 46). Horizontal return pipes may be carried past doorways and other obstructions by using the scheme illustrated in Fig. 47. It will be noted that the large pipe, in this case, runs below the obstruction, and the smaller one over it.

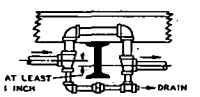

Fig. 46 .... Looping Main Around Beam

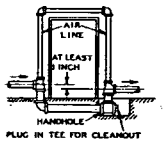

Fig. 47 .... Looping Dry Return Main Around Opening

Offsets in steam and return piping should preferably be made with 90-deg ells, but occasionally fittings of other angles are used, and in such cases the length of the diagonal offset will be found as shown in Fig. 48.

Dirt pockets, desirable on all systems employing thermostatic traps, should be so located as to protect the traps from scale and sludge which will interfere with their operation. Dirt pockets are usually made 8 in. to 12 in. deep, and serve as receivers for foreign matter which otherwise would be carried into the trap.

On vapor systems where the end of the steam main is

dripped into the wet-return, the air venting at the end of the main is accomplished by an air vent passing through a thermostatic trap into the dry-return line as shown in Fig. 49. On low-pressure or vacuum systems, the ends of the

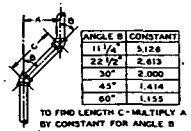

Fig. 48 .... Constants for Determining Length of Offset Pipe

steam mains are dripped and vented into the return through drip traps opening into the return line. A float and thermostatic type trap is recommended for dripping steam mains and risers as indicated in Figs. 50 and 51.

The dripping of high-pressure mains, or of equipment using high-pressure steam into low-pressure or vacuum re-

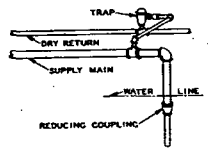

Fig. 49 .... Dripping End of Main into Wet Return

turns, is generally accomplished by the use of a flash tank or flash leg into which the high-pressure trap is arranged to discharge. This tank provides the required space for the flashing from high-temperature condensate to low-pressure steam to take place. The low-pressure steam therein generated is passed directly to the low-pressure steam mains, and the condensate is discharged through a second trap to the low-pressure or vacuum return. A typical arrangement of a flash leg, with sizes required for varying capacities, is given in Fig. 52.

CONNECTIONS TO HEATING UNITS

Riser, radiator, and convector connections must not only be properly pitched at the time they are installed, but must

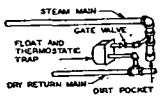

Fig. 50 .... Dripping End of Steam Main into Dry Return

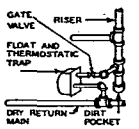

Fig. 51 .... Dripping Heel of Riser into Dry Return

be arranged so that the pitch will be maintained under the strains of expansion and contraction. These connections may be made by swing joints which permit the expansion or contraction to occur under heating and cooling without bending of pipes. To take care of expansion in long risers, either expansion joints of commercial construction or pipe swing joints are used. Anchoring of pipes between expansion joints is desirable.

Two satisfactory methods of making runouts for one-pipe systems for either the up-feed or the down-feed type are

shown in Fig. 53. Where the vertical distance is limited and the runouts must run above the floor, the radiator may be set on pedestals or raised by means of high legs. A method of connecting a unit heater to a one-pipe steam heating system is illustrated in Fig. 2.
