PREFACE TO THE 34th EDITION

The 34th Edition of the HEATING VENTILATING AIR CONDITIONING GUIDE, 1956, contains 1176 pages of technical text—16 pages more than the largest previous edition. In addition, new material equivalent to 14 pages has been added where condensation of previous text was possible.

Substantial improvements have been made in 16 chapters, some of which have been almost completely rewritten. In the outline of changes which follows, it will be noted that special attention has been given to subjects dealing with heat transmission of building materials, cooling load, chimneys, estimating fuel consumption, baseboard and finned-tube radiation, snow melting, central systems for air conditioning, air duct design, air heating and cooling coils, automatic control, pipe and tube characteristics and insulation, automobile air conditioning, heat transfer measurements, and codes and standards.

The following paragraphs describe the significant changes in the chapters having the most important revisions:

*Chapter 1—Terminology.* Revisions have been made in several definitions to obtain agreement with values adopted by the 9th and 10th General Conference on Weights and Measures.

*Chapter 4—Fluid Flow.* Most of the illustrations have been improved. A number of clarifications have been made in the text.

*Chapter 9—Heat Transmission Coefficients of Building Materials.* The chapter has been enlarged to permit addition of many materials to the list showing design values for conductivity and conductance. New information has been included for estimating the conductances of air spaces bounded by reflective surfaces. New tables facilitate the determination of the effect of adding insulation to wall, floor, and roof sections. A new chart makes it possible to correct quickly for the effect of framing members. The revision was prepared by the ASHAE Technical Advisory Committee on Insulation assisted by staff members of the ASHAE Research Laboratory.

*Chapter 13—Cooling Load.* Weather design data have been added for 21 Canadian cities, and a number of improvements have been made in the text.

*Chapter 17—Chimneys and Draft Calculations.* The discussion of the theory of draft calculations has been rewritten. The sections on residential chimneys and gas appliance chimney requirements have been revised and enlarged.

*Chapter 18—Estimating Fuel Consumption for Space Heating.* The table of degree days has been extended to include 287 U. S. and 40 Canadian cities using up-to-date information furnished by the U. S. Weather Bureau and the Canadian Meteorological Service.

*Chapter 22—Hot Water Heating Systems.* A number of improvements have been made in the section on high temperature systems.

*Chapter 23—Radiators, Convectors, Baseboard and Finned-Tube Units.* Sections were added to supply information on baseboard and finned-tube units of present design. The chapter was largely rewritten.

*Chapter 24—Panel Heating.* The section on snow melting was rewritten and enlarged to include recent developments in this field and to provide new viscosity and other data for the designer.

*Chapter 26—Unit Air Conditioners and Unit Air Coolers.* Much of the text was rewritten to describe present types of units as well as up-to-date practice in their application.

*Chapter 27—Pipe, Fittings, Welding.* New tables were added to indicate the suitability of various pipe, tube, and fitting materials for different applications. Characteristics of drainage, waste and vent pipe and tube were discussed in the text and added to the table on dimensions and properties of copper tube.

*Chapter 28—Pipe and Industrial Insulation.* Typical conductivities of insulating materials were affirmed or revised by the ASHAE Technical Advisory Committee on Insulation.

*Chapter 30—Central Systems for Air Conditioning.* The chapter was enlarged and largely rewritten with new text and diagrams describing year-round systems, unitary systems, high- and low-pressure induction convectors, and both dual duct and fan coil units.

**Chapter 32—Air Duct Design.** The chapter was rewritten by a subcommittee of the Technical Advisory Committee on Air Distribution to simplify explanation and use of formulas for duct design. New tables were added to extend the data on friction losses in elbows and fittings, and those due to area changes.

**Chapter 36—Heating and Cooling Coils.** Information on use of coils and their selection was revised to indicate practical considerations involved. An example was added to show method of calculating the cooling load on coils.

**Chapter 39—Automatic Control.** This enlarged chapter was completely rewritten employing current nomenclature in the field to describe up-to-date automatic controls, their application and coordination.

**Chapter 48—Transportation Air Conditioning.** The sections on automobile and railway passenger car air conditioning were revised and enlarged.

**Chapter 52—Instruments and Measurements.** The text describing the use of thermocouples and the measurement of thermal conductivity and conductance was enlarged and revised.

**Chapter 53—Codes and Standards.** Revisions were made where necessary to show latest editions and to include new standards in the field of heating and air conditioning which have become available.

In addition to changes mentioned for specific chapters, many improvements in other chapters were made as a result of a general review given the previous edition by the Guide Committee.

The 24-page detailed subject index has been continued to facilitate the finding of information under the various subject headings which readers might be expected to use.

The Catalog Data Section has been expanded to include reference material on products of 335 manufacturers of heating, ventilating, cooling and air conditioning equipment. A comprehensive subject index makes it easy to find names of manufacturers and their products available for use by the designer.

The complete list of Society committee members, other engineers, and authorities who have contributed material and assistance in the preparation of this edition cannot be given here because of lack of space. These sources of information are extremely important in keeping *THE GUIDE* up to date with current practice. The Guide Committee wishes to express its appreciation of the assistance received from all sources, and takes particular pleasure in mentioning the following individuals who have been especially helpful:

|                    |                 |                     |
|--------------------|-----------------|---------------------|
| H. W. ALTEA        | W. S. HARRIS    | F. J. REED          |
| D. W. BOYD         | A. I. HEIM      | H. E. ROBINSON      |
| C. B. BRADLEY      | W. O. HUEBNER   | K. O. SCHLENTNER    |
| A. D. BRANDT       | J. M. KANE      | J. P. STEWART       |
| W. P. CHAPMAN      | O. S. LIEBERG   | R. F. TAYLOR        |
| R. E. CHERNE       | R. D. MADISON   | H. C. S. THOM       |
| J. H. CLARKE       | P. J. MARSCHALL | R. K. THULMAN       |
| L. F. FLAGG        | D. C. MCCOY     | J. R. THYGESON, JR. |
| S. F. GILMAN       | G. E. McELROY   | J. D. VERSCHOOR     |
| NATHANIEL GLICKMAN | H. E. MCKENZIE  | D. J. VILD          |
| J. A. GOFF         | M. W. McRAE     | R. W. WATERFILL     |
| CHARLES GRAHAM     | E. B. MOORE     | G. L. WIGGS         |
| C. A. GUSTAFSON    | L. C. PLAETH    | C. F. WOOD          |

This 34th edition of *THE GUIDE* is presented by the Guide Committee with the anticipation and hope that it will be of great value as a means of keeping users abreast of current practice in the heating, ventilating, cooling, and air conditioning field.

selection, 688, 1129

# Z

**Zone control**, 587  
Zone of evaporative regulation,  
1115

**Zoning**, 552, 637, 908  
control, 637, 908  
hot water system, 552  
reheat, 638  
volume control, 637

## CHAPTER 1 TERMINOLOGY

Glossary of Physical and Heating, Ventilating, Refrigerating  
and Air Conditioning Terms Used in the Text

**Absolute Zero**: The zero from which absolute temperature is reckoned. Approximately -273.15 Cor -459.67 F. These values were established by the Tenth General Conference on Weights and Measures, 1954.

**Absorbent**: A sorbent which changes physically or chemically, or both, during the sorption process.

**Absorption**: The action of a material in extracting one or more substances present in an atmosphere or mixture of gases or liquids; accompanied by physical change, chemical change, or both, of the sorbent.

**Acceleration**: The time rate of change of velocity, i.e., the derivative of velocity with respect to time. In the cgs system the unit of acceleration is the centimeter per (second) (second); in the fps system the unit is the foot per (second) (second),  $a = \frac{dv}{dt}$ .

**Acceleration Due to Gravity**: The rate of gain in velocity of a freely falling body the value of which varies with latitude and elevation. The international gravity standard has the value of 980.665 cm per (sec) (sec) or 32.174 ft per (sec) (sec) which is the actual value of this acceleration at sea level and about 45 deg latitude.

**Adiabatic**: An adjective descriptive of a process such that no heat is added to, or taken from, a substance or system undergoing the process.

**Adsorbent**: A sorbent which does not change physically or chemically during the sorption process.

**Adsorption**: The action, associated with surface adherence, of a material in extracting one or more substances present in an atmosphere or mixture of gases and liquids, unaccompanied by physical or chemical change. Commercial adsorbent materials have enormous internal surfaces.

**Aerosol**: An assemblage of small particles, solid or liquid, suspended in air. The diameters of the particles may vary from 100 microns down to 0.01 micron or less, e.g., dust, fog, smoke.

**Air Cleaner**: A device designed for the purpose of removing airborne impurities such as dusts, gases, vapors, fumes and smokes. (Air cleaners include air washers, air filters, electrostatic precipitators and charcoal filters.)

**Air Conditioning**: The simultaneous control of all, or at least the first three, of the following factors affecting both the physical and chemical conditions of the atmosphere within a structure: temperature, humidity, motion, distribution, pressure, dust, bacteria, odors, toxic gases, and ionization.

**Air, Dry**: In psychrometry; air unmixed with, or containing no, water vapor.

**Air, Saturated**: A mixture of dry air and saturated water vapor, all at the same dry-bulb temperature.

**Air, Standard**: Air with a density of 0.075 lb per cu ft and an absolute viscosity of  $1.22 \times 10^{-4}$  lb mass per (ft) (sec). This is substantially equivalent to dry air at 70 F and 29.92 in. (Hg) barometer.

**Air Washer**: An enclosure in which air is drawn or forced through a spray of water in order to cleanse, humidify, or dehumidify the air.

**Anemometer**: An instrument for measuring the velocity of a fluid.

**Aspect Ratio**: In air distribution outlets, the ratio of the length of the core of a grille, face or register to the width.

In rectangular ducts, the ratio of the width to the depth.

**Atmospheric Pressure**: The pressure of the atmosphere to be measured by means of the barometer. *Standard Atmospheric Pressure* or *Standard Atmosphere* is exactly 1,013,250 dynes per square centimeter by recent action of the Tenth General Conference on Weights and Measures (1954). It is approximately the pressure exerted by a column of mercury 76 cm high at standard gravitational acceleration, 980.665

cm per (sec) (sec), the mercury having a density of 13.5951 grams per cubic centimeter. It is equivalent to 14.696 psi or 29.921 in. of mercury at 32 F.

**Baffle:** A surface used for deflecting fluids, usually in the form of a plate or wall.

**Blast Heater:** A set of heat transfer coils or sections used to heat air which is drawn or forced through it by a fan.

**Blow (throw):** In air distribution, the distance an air stream travels from an outlet to a position at which air motion along the axis reduces to a velocity of 50 fpm.

For unit heaters, the distance an air stream travels from a heater without a perceptible rise due to temperature difference and loss of velocity.

**Boiler Heating Surface:** That portion of the surface of the heat-transfer apparatus in contact with the fluid being heated on one side and the gas or refractory being cooled on the other, in which the fluid being heated forms part of the circulating system; this surface shall be measured on the side receiving heat. This includes the boiler, water walls, water screens, and water floor. (ASME Power Test Codes, Series 1929.)

**Direct Heating Surface** is generally understood to be the boiler heating surface subject to direct radiation from the surface of the grate, or from the surfaces of oil or gas burners.

**Indirect Heating Surface** is the boiler heating surface within the flues.

**Boiler Horsepower:** The equivalent evaporation of 34.5 lb of water per hr from and at 212 F. This is equal to a heat output of  $970.3 \times 34.5 = 33,475$  Btu per hr.

**British Thermal Unit (Btu):** The Btu is defined as 778.177 foot-pounds if it is related to the IT calorie in such a way that 1 IT calorie per (kg) (C deg) = 1 Btu per (lb) (F deg), with 1 lb = 453.5924 grams. The Ninth General Conference on Weights and Measures (1948) recommended the absolute joule as the fundamental unit of energy thereby, in effect, liquidating the old international electrical units. This calls for a redefinition of the International Tables calorie (IT cal) according to the following conversion factor: 4.18684 joule per IT calorie.

**Calorie (Gram Calorie):** The IT gram calorie is equivalent to 0.003968 Btu. (See definition of Btu.)

**Central Fan System:** A mechanical indirect system of heating, ventilating, or air conditioning, in which the air is treated or handled by equipment located outside the rooms served, usually at a central location, and is conveyed to and from the rooms by means of a fan and a system of distributing ducts. (See Chapter 30.)

**Chimney Effect:** The tendency of air or gas in a duct or other vertical passage to rise when heated due to its lower density compared with that of the surrounding air or gas. In buildings, the tendency toward displacement (caused by the difference in temperature) of internal heated air by unheated outside air due to the difference in density of outside and inside air.

**Comfort Air Conditioning:** The process by which simultaneously the temperature, moisture content, movement and quality of the air in enclosed spaces intended for human occupancy may be maintained within required limits. (See also general definition of *Air Conditioning* on page 1 of this chapter.)

**Comfort Line:** A line on the comfort chart showing relation between the effective temperature and the percentage of adults feeling comfortable.

**Comfort Zone (Average):** The range of effective temperatures over which the majority (50 percent or more) of adults feel comfortable. (See Chapter 6.)

**Condensate:** The liquid formed by condensation of a vapor. In steam heating, water condensed from steam; in air conditioning, water extracted from air, as by condensation on the cooling coil of a refrigeration machine.

**Condensation:** The process of changing a vapor into liquid by the extraction of heat. Condensation of steam or water vapor is effected in either steam condensers or in dehumidifying coils and the resulting water is called *condensate*.

**Conductance, Surface (Unit):** The amount of heat transferred by radiation, conduction, and convection from unit area of a surface to the air or other fluid in contact with it, or vice versa, in unit time for a unit difference in temperature between the surface and the fluid. The common unit is: Btu per (hour) (square foot) (Fahrenheit degree). Symbol  $f$ . The temperature of the fluid should be taken in a plane sufficiently far from the surface that it will not be affected by the temperature of the surface.

**Conductance, Thermal:** The time rate of heat flow through unit area of a body, of given size and shape, per unit temperature difference. Common unit is: Btu per (hour) (square foot) (Fahrenheit degree). Symbol  $C$ .

**Conduction, Thermal:** The process of heat transfer through a material medium in

which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

**Conductivity, Thermal:** The time rate of heat flow through unit area of a homogeneous substance under the influence of a unit temperature gradient. Common units are: Btu per (hour) (square foot) (Fahrenheit degree per inch). Symbol  $k$ .

**Conductor, Thermal:** A material which readily transmits heat by means of conduction.

**Convection:** The motion resulting in a fluid from the differences in density and the action of gravity. In heat transmission this meaning has been extended to include both forced and natural motion or circulation.

**Convective Heat Transfer:** The transmission of heat by either natural or forced motion of a fluid (liquid or gas).

**Convactor:** An agency of convection. In heat transfer, a surface designed to transfer its heat to a surrounding fluid largely or wholly by convection. The heated fluid may be removed mechanically or by gravity (Gravity Convactor). Such a surface may or may not be enclosed or concealed. When concealed and enclosed the resulting device is sometimes referred to as a concealed radiator. (See also definition of *Radiator*.) (See also Chapter 23.)

**Decibel:** A unit used to express the relation between two amounts of power. By definition the difference in decibels between two powers  $P_1$  and  $P_2$ ,  $P_1$  being the larger, is: db difference =  $10 \log_{10} P_2/P_1$ .

In acoustics the threshold of hearing at 1,000 cycles per sec has been standardized at  $10^{-16}$  watts per sq cm. If  $P_2$  is the power in watts per square centimeter of a measured sound, then  $10 \log_{10} P_2/10^{-16}$  is the db difference above the threshold and is known as the *intensity level*. This is a definite recognized way of describing the intensity of a sound.

**Declination of Sun:** The angle above or below equatorial plane. It is plus if north of the plane, and minus if below. Celestial objects are located by declination.

**Degree-Day:** A unit, based upon temperature difference and time, used in estimating fuel consumption and specifying nominal heating load of a building in winter. For any one day, when the mean temperature is less than 65 F, there exists as many degree-days as there are Fahrenheit degrees difference in temperature between the mean temperature for the day and 65 F.

**Dehumidify:** To reduce by any process, the quantity of water vapor within a given space.

**Dehydrate:** To remove water in all forms from matter. Liquid water, hygroscopic water, and water of crystallization or water of hydration are included.

**Density:** The ratio of the mass of a specimen of a substance to the volume of the specimen. The mass of a unit volume of a substance. When weight can be used without confusion, as synonymous with mass, density is the weight per unit volume.

**Dew-Point:** See *Temperature, Dew-Point*.

**Diffusivity, Thermal:** Thermal conductivity divided by product of density and specific heat =  $k/\rho c$ . Expressed in units of square feet per hour.

**Direct-Indirect Heating Unit:** A heating unit located in the room or space to be heated and partially enclosed; the enclosed portion being used to heat air which enters from outside the room.

**Direct-Return System (Hot Water):** A hot water system in which the water, after it has passed through a heating unit is returned to the boiler along a direct path so that the total distance traveled by the water is the shortest feasible, and so that there are considerable differences in the lengths of the several circuits composing the system.

**Down-Feed One-Pipe Riser (Steam):** A pipe which carries steam downward to the heating units and into which the condensate from the heating units drains.

**Down-Feed System (Steam):** A steam heating system in which the supply mains are above the level of the heating units which they serve.

**Draft:** A current of air. Usually refers to the pressure difference which causes a current of air or gases to flow through a flue, chimney, heater or space.

**Draft Head (Side Outlet Enclosure):** The height of a gravity convactor between the bottom of the heating unit and the bottom of the air outlet opening. (*Top Outlet Enclosure*): The height of a gravity convactor between the bottom of the heating unit and the top of the enclosure.

**Drip:** A pipe, or a steam trap and a pipe considered as a unit, which conducts condensation from the steam side of a piping system to the water or return side of the system.

**Dry:** To separate or remove a liquid or vapor from another substance. The liquid may be water, but the term is also used for the removal of liquid or vapor forms of other substances.

**Dust:** An air suspension (aerosol) of solid particles of any material. (See also Chapter 8.)

**Enthalpy:** A term used in lieu of *total heat* or *heat content*. Expressible in Btu per pound. Mathematically defined as  $h = u + pv/J$ . When a change occurs at constant pressure, as when water is boiled, the change in enthalpy is equal to the heat added; in this case latent heat.

**Enthalpy, Free:** A thermodynamic property which serves as a measure of the available energy of a system with respect to surroundings at the same temperature and same pressure as that of the system. No process involving an increase in available energy can occur spontaneously.

**Enthalpy, Specific:** A term sometimes applied to enthalpy per unit weight, the English unit being Btu per pound.

**Entropy:** The ratio of the heat added to a substance to the absolute temperature at which it is added. Mathematically, for a reversible process,  $dS = dq/T$  or  $S = \int dq/T$ .

These formulas are applicable when temperature is not constant. During a reversible adiabatic change, entropy is constant. During a reversible isothermal change, the heat absorbed by the substance is equal to the product of the absolute temperature of the substance and its change of entropy.

**Entropy, Specific:** A term sometimes applied to entropy per unit weight, the English unit being Btu per (Fahrenheit degree, absolute) (pound).

**Equivalent Evaporation:** The amount of water a boiler would evaporate, in pounds per hour, if it received feed water at 212 F and vaporized it at the same temperature and corresponding atmospheric pressure.

**Fan Furnace System:** See *Warm Air Heating System*.

**Fog:** Suspended liquid droplets generated by condensation from the gaseous to the liquid state, or by breaking up a liquid into a dispersed state, such as by splashing, foaming, and atomizing. (See also Chapter 8.)

**Force:** The action on a body which tends to change its relative condition as to rest or motion.

**Fumes:** Smoke; aromatic smoke; odor emitted, as of flowers; a smoky or vaporous exhalation, usually odorless, as that from concentrated nitric acid. The word *fumes* is so broad and inclusive that its usefulness as a technical term is very limited. Its principal definitive characteristic is that it implies an odor. The terms vapor, smoke, fog, etc., which can be more strictly defined, should be used whenever possible.

Also defined as solid particles generated by condensation from the gaseous state, generally, after volatilization from molten metals, etc., and often accompanied by a chemical reaction such as oxidation. Fumes flocculate and sometimes coalesce. (See also Chapter 8.)

**Furnace:** That part of a boiler or warm air heating plant in which combustion takes place. Also a complete heating unit for transferring heat from fuel being burned to the air supplied to a heating system.

**Furnace Volume (Total):** The total furnace volume for horizontal-return tubular boilers and water-tube boilers is the cubical contents of the furnace between the grate and the first plane of entry into or between tubes. It therefore includes the volume behind the bridge wall as in ordinary horizontal-return tubular boiler settings, unless manifestly ineffective (i.e., no gas flow taking place through it), as in the case of waste-heat boilers with auxiliary coal furnaces, where one part of the furnace is out of action when the other is being used. For Scotch or other internally-fired boilers, it is the cubical contents of the furnace, flues and combustion chamber, up to the plane of first entry into the tubes. (ASME Power Test Codes, Series 1929.)

**Grate Area:** The area of the grate surface, measured in square feet, to be used in estimating the rate of burning fuel. This area is construed to mean the area measured in the plane of the top surface of the grate, except that with special furnaces, such as those having magazine feed, or special shapes, the grate area shall be the mean area of the active part of the fuel bed taken perpendicular to the path of the gases through it. For furnaces having a secondary grate, such as those in double-grate down-draft boilers, the effective area shall be taken as the area of the upper grate plus one-eighth of the area of the lower grate, both areas being estimated as previously defined.

**Gravity, Specific:** The ratio of the mass of a unit volume of a substance to the mass of the same volume of a standard substance at a standard temperature. Water

at 39.2 F is the standard substance usually referred to. For gases, dry air at the same temperature and pressure as the gas, is often taken as the standard substance.

**Gravity Warm Air Heating System:** See *Warm Air Heating System*.

**Head, Dynamic:** Same as Total Pressure expressed in height of liquid.

**Heat:** That form of energy which transfers from one system to another, by virtue of the temperature difference which exists between the two systems, when they are placed in communication.

**Heat, Humid:** Ratio of increase of enthalpy per pound of dry air to rise of temperature under conditions of constant pressure and constant humidity ratio.

**Heat, Latent:** A term used to express the energy involved in a change of state.

**Heat, Sensible:** A term used in heating and cooling to indicate any portion of heat which changes only the temperature of the substances involved.

**Heat of the Liquid:** The increase in enthalpy per unit weight of a saturated liquid as its temperature increases from a chosen base temperature. For water, the base temperature is usually taken as 32 F.

**Heat, Specific:** The heat absorbed (or given up) by a unit mass of a substance when its temperature is increased (or decreased) by 1 deg. Common Units: Btu per (pound) (Fahrenheit degree), calories per (gram) (Centigrade degree). For gases, both specific heat at constant pressure ( $c_p$ ) and specific heat at constant volume ( $c_v$ ) are frequently used. In air conditioning,  $c_p$  is usually used.

**Heat, Total:** See *Enthalpy*.

**Heat Transmission, Coefficient:** Any one of a number of coefficients used in the calculation of heat transmission by conduction, convection, and radiation, through various materials and structures. (See thermal conductance, thermal conductivity, thermal resistance, thermal resistivity, thermal transmittance, etc.)

**Heating Element, Electric:** A unit assembly consisting of a resistor, insulated supports, and terminals for connecting the resistor to electric power.

**Heating Unit, Electric:** A structure containing one or more heating elements, electrical terminals or leads, electric insulation, and a frame or casing, all assembled together in one unit.

**Hot Water Heating System:** A heating system in which water is used as the medium by which heat is carried from the boiler to the heating units.

**Humidify:** To increase, by any process, the density of water vapor within a given space.

**Humidistat:** A regulatory device, actuated by changes in humidity, used for the automatic control of relative humidity.

**Humidity:** Water vapor within a given space.

**Humidity, Absolute:** The weight of water vapor per unit volume, pounds per cubic foot or grams per cubic centimeter.

**Humidity, Relative:** The ratio of the mol fraction of water vapor in a mixture to the mol fraction of water vapor in saturated air at the same dry-bulb temperature and barometric pressure. (See discussion in Chapter 3.) Also defined in various texts as the ratio of the actual partial pressure of the water vapor in a space to the saturation pressure of pure water at the same temperature.

**Humidity Ratio:** In a mixture of water vapor and air, the weight of water vapor per pound of dry air. Symbol,  $W$ . Also called *Specific Humidity*.

**Humidity, Specific:** See *Humidity Ratio*.

**Hygostat:** Same as *Humidistat*.

**Inch of Water:** A unit of pressure equal to the pressure exerted by a column of liquid water 1 in. high at a standard temperature. The standard temperature is sometimes taken as 0 C and sometimes as 62 F. One inch of water at 62 F = 5.197 lb per sq ft.

**Insulation (Thermal):** A material having a relatively high resistance to heat flow, and used principally to retard the flow of heat.

**Isobaric:** An adjective used to indicate a change taking place at constant pressure.

**Isothermal:** An adjective used to indicate a change taking place at constant temperature.

**Load, Estimated Design:** In a heating or cooling system, the sum of the useful heat transfer, plus heat transfer from or to the connected piping, plus heat transfer occurring in any auxiliary apparatus connected to the system. The units are Btu per hour or, in heating, equivalent direct radiation (EDR).

**Load, Estimated Maximum:** In a heating or cooling system, the calculated maximum heat transfer that the system will be called upon to provide.

**Manometer:** An instrument for measuring pressures; essentially a U-tube partially filled with a liquid, usually water, mercury, or a light oil; so constructed that the amount of displacement of the liquid indicates the pressure being exerted on the instrument.

**Mass:** A measure of the inertia of a body. It also measures the quantity of matter in a body. Since the only general property of a given portion of matter that cannot be changed is its inertia, it is this property by which quantities of matter are defined. Two bodies which have equal inertias are said to have equal masses, or to contain equal quantities of matter. (This definition fails at velocities approaching the velocity of light.) The mass of a body is numerically equal to the ratio of the force required to give the body a given acceleration, to the acceleration:  $m = F/a$ . The common units of mass are the gram and the pound.

**Mechanical Equivalent of Heat:** The quantity of mechanical energy equal to one unit of heat.  $J = 778.177 \text{ ft-lb per Btu} = 4.1858 \times 10^7 \text{ ergs per gram-calorie}$ .

**Medium, Heating:** A substance such as water, steam, air or furnace gas used to convey heat from the boiler, furnace or other source of heat or energy to the heating unit from which the heat is dissipated.

**Micron:** A unit of length, the thousandth part of 1 mm or the millionth of a meter.

**Millimeter of Mercury:** A unit of pressure equal to the pressure exerted by a column of mercury 1 mm high at a temperature of 0 C. One millimeter of mercury at 0 C =  $1.934 \times 10^{-2} \text{ psi}$ .

**Mol:** A weight of a substance numerically equal to its molecular weight. If the weight is in pounds the unit is a *Pound Mol*, in grams the unit is a *Gram Mol*. For perfect gases the volume of 1 mol is constant for all gases at the same temperature and pressure. For real gases this is approximately true at moderate pressures. At 32 F and zero-pressure the value of the product, pressure times specific volume, is  $359.045 \pm 0.006$  atmosphere cubic feet (atm ft<sup>3</sup>), for 1 mol of any gas. For dry air at 32 F and standard atmospheric pressure, the specific volume is 358.83 cu ft per mol (ft<sup>3</sup> per mol).

**One-Pipe Supply Riser—(Steam):** A pipe which carries steam vertically to a heating unit, and which also carries the condensate from the heating unit. In an up-feed system, steam and condensate flow in opposite directions; in an overhead or down-feed system, they flow in the same direction.

**One-Pipe System—(Steam):** A steam heating system in which a single main serves the dual purpose of supplying steam to the heating unit and conveying condensate from it. Ordinarily to each heating unit there is but one connection which must serve as both the supply and the return, although separate supply and return connections may be used. (Hot Water)—A hot water system in which the cooled water from the heating units is returned to the supply main. Consequently, the heating units farthest from the boiler are supplied with cooler water than those near the boiler in the same circuit.

**Overhead System:** Any steam or hot water system in which the supply main is above the heating unit. In a steam system the return must be below the heating units; in a water system the return may be above or below the heating units.

**Panel Heating:** A heating system in which heat is transmitted by both radiation and convection from panel surfaces to both air and surrounding surfaces.

**Panel Radiator:** A heating unit placed on or flush with a flat wall surface, and intended to function essentially as a radiator.

**Perimeter System:** See *Warm Air Heating System*.

**Plenum Chamber:** An air compartment maintained under pressure, and connected to one or more distributing ducts.

**Potentiometer:** An instrument for comparing small electromotive forces, or for measuring small electromotive forces by comparison with a known electromotive force. Its principal advantage is that during the measurement, no current flows through the source of electromotive force.

**Power:** The rate of performing work. Common units are horsepower, Btu per hour, and watts.

**Pressure:** Force per unit area. Common units are pounds per square inch, gram per square centimeter, inch of water, millimeter of mercury.

**Pressure, Absolute:** The sum of the gage pressure and the barometric pressure.

**Pressure, Dynamic:** Same as *Total Pressure*.

**Pressure, Gage:** Pressure measured from atmospheric pressure as a base. Gage pressure may be indicated by a manometer which has one leg connected to the pressure source and the other exposed to atmospheric pressure.

**Pressure, Saturation:** The saturation pressure for a pure substance for any given temperature is that pressure at which vapor and liquid, or vapor and solid, can co-exist in stable equilibrium.

**Pressure, Static:** The normal force per unit area that would be exerted by a moving fluid on a small body immersed in it if the body were carried along with the fluid. Practically, it is the normal force per unit area at a small hole in a wall of the duct through which the fluid flows (piezometer) or on the surface of a stationary tube at a point where the disturbances, created by inserting the tube, cancel. It is supposed that the thermo-dynamic properties of a moving fluid depend on static pressure in exactly the same manner as those of the same fluid at rest depend upon its uniform hydrostatic pressure.

**Pressure, Total:** In the theory of the flow of fluids; the sum of the static pressure and the velocity pressure at the point of measurement.

**Pressure, Vapor:** The pressure exerted by a vapor. If a vapor is kept in confinement over its liquid so that the vapor can accumulate above the liquid, the temperature being held constant, the vapor pressure approaches a fixed limit called the maximum, or saturated, vapor pressure, dependent only on the temperature and the liquid. The term *vapor pressure* is sometimes used as synonymous with *saturated vapor pressure*.

**Pressure, Velocity:** In a moving fluid, the pressure capable of causing an equivalent velocity, if applied to move the same fluid through an orifice such that all pressure energy expended is converted into kinetic energy.

**Psychrometer:** An instrument for ascertaining the humidity or hygrometric state of the atmosphere.

**Psychrometric:** Pertaining to psychrometry or the state of the atmosphere with reference to moisture.

**Psychrometric Chart:** A graphical representation of the thermodynamic properties of moist air.

**Psychrometry:** The branch of physics relating to the measurement or determination of atmospheric conditions, particularly regarding the moisture mixed with the air.

**Pyrometer:** An instrument for measuring high temperatures.

**Radiant Heating:** A heating system in which only the heat radiated from panels is effective in providing the heating requirements. The term *Radiant Heating* is frequently used to include both *Panel* and *Radiant Heating*.

**Radiation:** The transmission of energy by means of electromagnetic waves.

**Radiation, Thermal (Heat) Radiation:** The transmission of energy by means of electromagnetic waves of very long wave length. Radiant energy of any wave length may, when absorbed, become thermal energy and result in an increase in the temperature of the absorbing body.

**Radiation, Equivalent Direct (EDR):** A unit of heat delivery of 240 Btu per hr. It does not imply 144 sq. in. of surface.

**Radiator:** A heating unit exposed to view within the room or space to be heated. A radiator transfers heat by radiation to objects within visible range, and by conduction to the surrounding air which in turn is circulated by natural convection; a so-called radiator is also a convector, but the term radiator has been established by long usage.

**Radiator, Concealed:** A heating device located within, adjacent to, or exterior to the room being heated, but so covered or enclosed or concealed that the heat transfer surface of the device, which may be either a radiator or a convector, is not visible from the room. Such a device transfers its heat to the room largely by convection air currents.

**Radiator, Direct:** Same as *Radiator*.

**Radiator, Recessed:** A heating unit set back into a wall recess, but not enclosed.

**Radiator, Tube or Tubular:** A heating unit used as a radiator in which the heat transfer surfaces are principally tubes.

**Refrigerant:** A substance which produces a refrigerating effect by its absorption of heat while expanding or vaporizing.

**Refrigeration, Ton of:** The removal of heat at a rate of 200 Btu per min, 12,000 Btu per hr, or 288,000 Btu per 24 hr.

**Resistance, Thermal:** The reciprocal of thermal conductance. Symbol  $R$ .

**Resistivity, Thermal:** The reciprocal of thermal conductivity. Symbol  $r$ .

**Resistor, Electric:** A material used to produce heat by passing an electric current through it.

**Return, Dry:** A return pipe in a steam heating system which carries both water of condensation and air. The dry return is above the level of the water line in the boiler in a gravity system. (See *Return, Wet*.)

**Return, Wet:** That part of a return main of a steam heating system which is filled with water of condensation. The wet return usually is below the level of the water line in the boiler, although not necessarily so. (See *Return, Dry*.)

**Return Mains:** Pipes or conduits which return the heating or cooling medium from the heat transfer unit to the source of heat or refrigeration.

**Reversed-Return System:** A system in which the heating or cooling medium from several heat transfer units is returned along paths arranged so that all circuits composing the system or composing a major sub-division of it are of practically equal length.

**Sabin:** A unit of equivalent sound absorption equal to the equivalent absorption of one square foot of a surface of unit absorptivity (i.e., of one square foot of surface which absorbs all incident sound energy).

**Saturation:** The condition for co-existence in stable equilibrium of a vapor and liquid or a vapor and solid phase of the same substance. Example: Steam over the water from which it is being generated.

**Saturation, Degree of:** The ratio of the weight of water vapor associated with a pound of dry air to the weight of water vapor associated with a pound of dry air saturated at the same temperature.

**Smoke:** An air suspension (aerosol) of particles, usually but not necessarily solid, often originating in a solid nucleus, formed from combustion or sublimation. Also defined as carbon or soot particles less than 0.1 micron in size which result from the incomplete combustion of carbonaceous materials such as coal, oil, tar, and tobacco.

**Smokeless Arch:** An inverted baffle placed in an up-draft furnace toward the rear to aid in mixing the gases of combustion, and thereby to reduce the smoke produced.

**Solar Constant:** The solar intensity incident on a normal surface located outside the earth's atmosphere at a distance from the sun equal to the mean distance between the earth and the sun. Its value is 415, 445, or 430 Btu per (hr)<sup>2</sup> (sq ft) as the July, January, or mean value, respectively. At sea level in July the solar intensity value is about 300 Btu per (sq ft) (hr) since about 28 percent is absorbed in the earth's atmosphere.

**Sorbent:** A material which extracts one or more substances present in an atmosphere or mixture of gases or liquids with which it is in contact, due to an affinity for such substances.

**Sorption:** Adsorption or absorption.

**Split System:** A system in which the heating is accomplished by means of radiators or convectors supplemented by mechanical circulation of air (heated or unheated) from a central point. Ventilation may be provided by the same system.

**Square Foot of Heating Surface (Equivalent):** This term is synonymous with Equivalent Direct Radiation (EDR).

**Stack Height:** The height of a gravity convector between the bottom of the heating unit and the top of the outlet opening.

**Steam:** Water in the vapor phase. *Dry Saturated Steam* is steam at the saturation temperature corresponding to the pressure, and containing no water in suspension. *Wet Saturated Steam* is steam at the saturation temperature corresponding to the pressure, and containing water particles in suspension. *Superheated Steam* is steam at a temperature higher than the saturation temperature corresponding to the pressure.

**Steam Heating System:** A heating system in which heat is transferred from the boiler or other source of heat to the heating units by means of steam at, above, or below atmospheric pressure.

**Steam Trap:** A device for allowing the passage of condensate, or air and condensate, and preventing the passage of steam.

**Supply Mains:** The pipes through which the heating medium flows from the boiler or source of supply to the run-outs and risers leading to the heating units.

**Surface, Heating:** The exterior surface of a heating unit. *Extended heating surface (or extended surface):* Heating surface consisting of fins, pins or ribs which receive heat by conduction from the prime surface. *Prime Surface:* Heating surface having the heating medium on one side and air (or extended surface) on the other. (See also *Boiler Heating Surface*.)

## Terminology

**Temperature:** The thermal state of matter with reference to its tendency to communicate heat to matter in contact with it. If no heat flows upon contact, there is no difference in temperature.

**Temperature, Absolute:** Temperature expressed in degrees above absolute zero.

**Temperature, Dew-Point:** The temperature at which the condensation of water vapor in a space begins for a given state of humidity and pressure as the temperature of the vapor is reduced. The temperature corresponding to saturation (100 percent relative humidity) for a given absolute humidity at constant pressure.

**Temperature, Dry-Bulb:** The temperature of a gas or mixture of gases indicated by an accurate thermometer after correction for radiation.

**Temperature, Effective:** An arbitrary index which combines into a single value the effect of temperature, humidity, and air movement on the sensation of warmth or cold felt by the human body. The numerical value is that of the temperature of still, saturated air which would induce an identical sensation.

**Temperature, Mean Radiant (MRT):** The temperature of a uniform black enclosure in which a solid body or occupant would exchange the same amount of radiant heat as in the existing nonuniform environment.

**Temperature Scales.** Three temperature scales, Centigrade, Fahrenheit, and Reaumur, derive their degree values by dividing the difference between the ice point and steam points of water as follows: Centigrade 100, Fahrenheit 180, and Reaumur 80. Only the first two are important in the United States. The value of a Fahrenheit degree is therefore 5/9 of a Centigrade degree.

The Kelvin scale, sometimes called Centigrade absolute, has its zero point at the lowest attainable temperature 273.15 Centigrade degrees below the triple-point temperature of water and exactly 273.15 below the zero of the Centigrade scale.

The Rankine scale, sometimes called Fahrenheit absolute, has its zero at the lowest attainable temperature 459.688 Fahrenheit degrees below the triple-point temperature of water and exactly 459.67 F deg below the zero of the Fahrenheit scale.

To convert Centigrade to Kelvin temperature (generally designated K) add 273.15 deg.

To convert Fahrenheit to Rankine temperature (generally designated R) add 459.67 deg.

**Temperature, Wet-Bulb:** Thermodynamic wet-bulb temperature is the temperature at which liquid or solid water, by evaporating into air, can bring the air to saturation adiabatically at the same temperature. Wet-bulb temperature (without qualification) is the temperature indicated by a wet-bulb psychrometer constructed and used according to specifications. (ASME Power Test Codes, Series 1932, Instruments and Apparatus, Part 18.)

**Therm:** A quantity of heat equivalent to 100,000 Btu.

**Thermodynamics, Laws of:** Two laws upon which rest the classical theory of thermodynamics. These laws have been stated in many different, but equivalent ways. *The First Law:* (1) When work is expended in generating heat, the quantity of heat produced is proportional to the work expended; and conversely, when heat is employed in the performance of work, the quantity of heat which disappears is proportional to the work done. (Joule) (G.P.); (2) If a system is caused to change from an initial state to a final state by adiabatic means only, the work done is the same for all adiabatic paths connecting the two states. (Zemansky); (3) In any power cycle or refrigeration cycle the net heat absorbed by the working substance is exactly equal to the net work done. *The Second Law:* (1) It is impossible for a self-acting machine, unaided by any external agency, to convey heat from a body of lower to one of higher temperature. (Clausius) (G.P.); (2) It is impossible to derive mechanical work from heat taken from a body unless there is available a body of lower temperature into which the residue not so used may be discharged (Kelvin) (G.P.); (3) It is impossible to construct an engine that, operating in a cycle, will produce no effect other than the extraction of heat from a reservoir and the performance of an equivalent amount of work (Zemansky).

**Thermostat:** An instrument which responds to changes in temperature, and which directly or indirectly controls temperature.

**Transmittance, Thermal:** The time rate of heat flow, from the fluid on the warm side to the fluid on the cold side, per (square foot) (degree temperature difference between the two fluids). Sometimes called *Overall Coefficient of Heat Transfer*.

Common unit is Btu per (hour) (square foot) (Fahrenheit degree). Symbol *U*.

\* Names of authors who first stated laws are given in parentheses.

† From *Glossary of Physics*, by LeRoy Dougherty Weld (McGraw-Hill, 1937).

**Two-Pipe System (Steam or Water):** A heating system in which one pipe is used for the supply of the heating medium to the heating unit, and another for the return of the heating medium to the source of heat supply. The essential feature of a two-pipe system is that each heating unit receives a direct supply of the heating medium, which medium cannot have served a preceding heating unit.

**Up-Feed System:** A heating system in which the supply mains are below the level of the heating units which they serve.

**Vacuum Heating System:** A two-pipe steam heating system equipped with the necessary accessory apparatus which will permit operating the system below atmospheric pressure when desired.

**Vane Ratio:** In air distributing devices the ratio of depth of vane to shortest opening width between two adjacent grille bars.

**Vapor:** The gaseous form of substances which are normally in the solid or liquid state, and which can be changed to these states either by increasing the pressure or decreasing the temperature. Vapors diffuse. (ASA definition.)

**Vapor Heating System:** A steam heating system which operates under pressures at or near atmospheric and which returns the condensate to the boiler or receiver by gravity. Vapor systems have thermostatic traps or other means of resistance on the return ends of the heating units for preventing steam from entering the return mains; they also have a pressure-equalizing and air-eliminating device at the end of the dry-return.

**Velocity:** A vector quantity which denotes at once the time rate and the direction of a linear motion.  $V = \frac{ds}{dt}$ . For uniform linear motion  $V = \frac{s}{t}$ . Common units are: feet per second.

**Ventilation:** The process of supplying or removing air, by natural or mechanical means, to or from any space. Such air may or may not have been conditioned. (See *Air Conditioning*.)

**Viscosity:** That property of semi-fluids, fluids and gases by virtue of which they resist an instantaneous change of shape or arrangement of parts. It is the cause of fluid friction whenever adjacent layers of fluid move with relation to each other.

The coefficient of viscosity is the resistance offered by a layer of the fluid of unit area to the motion parallel to this area of another layer of the fluid at unit distance moving with unit velocity relative to the first layer. This coefficient is known as the *absolute viscosity*, and in cgs units is the force in dynes per square centimeter at a velocity of 1 cm per second at a distance of 1 cm. This unit of absolute viscosity is the *poise*. Values of absolute viscosity are frequently listed in centipoises, a centipoise being 1/100 of 1 poise.

In many formulas *absolute viscosity* is expressed in pounds per foot second or pounds per foot hour. Conversion from centipoises may be made as follows: viscosity in centipoises  $\times 0.000672$  = viscosity in pounds per foot second, or viscosity in centipoises  $\times 2.42$  = viscosity in pounds per foot hour.

**Kinematic viscosity** is the ratio of *absolute viscosity* to the density of a fluid. The unit is the stoke which equals one poise per cu cm per gram, or 1 sq cm per sec. For conversion to English units: kinematic viscosity in stokes  $\times 0.001076$  = kinematic viscosity in square feet per second.

**Volume, Specific:** The volume of a substance per unit mass; the reciprocal of density. Units: cubic feet per pound, cubic centimeters per gram, etc.

**Warm Air Heating System:** A warm air heating plant consists of a heating unit (fuel-burning furnace) enclosed in a casing, from which the heated air is distributed to various rooms of the building through ducts.

**Warm Air Heating System, Forced:** A warm air heating system in which circulation of air is effected by a fan. Such a system may include air cleaning devices.

**Warm Air Heating System, Gravity:** A warm air heating system in which the motive head producing flow depends on the difference in weight between the heated air leaving the casing and the cooler air entering the bottom of the casing.

**Warm Air Heating System, Perimeter:** A warm air heating system of the combination panel and convection type. Warm air ducts embedded in the concrete slab of a basementless house, around the perimeter, receive heated air from a furnace and deliver it to the heated space through registers placed in or near the floor. Air is returned to the furnace from registers near the ceiling.

## CHAPTER 2

ABBREVIATIONS, SYMBOLS,  
CONVERSION FACTORS

Standard Abbreviations; Standard Symbols; Greek Alphabet; Conversion Equations; Graphical Symbols for Piping, Ductwork, Heating and Ventilating, Refrigerating; Identification of Piping by Color

THIS chapter contains information regarding abbreviations, symbols, and conversion equations, which are of particular interest to the engineer engaged in heating, ventilating, and air conditioning.

## ABBREVIATIONS

Abbreviations are shortened forms of names and expressions employed in texts and tabulations, and should not generally be used as symbols in equations. Most of the following abbreviations have been compiled from a list of approved standards.<sup>1</sup> In general, the period has been omitted in all abbreviations, except where the omission results in the formation of an English word. Additional abbreviations applying to individual chapters will be found at the end of Chapters 3, 4, 13, 32, and 47.

Absolute.....abs  
Air horsepower.....air hp  
Alternating-current (as adjective).....a-c  
Ampere.....amp  
Ampere-hour.....amp-hr

Atmosphere.....atm  
Average.....avg  
Avoirdupois.....avdp  
Barometer.....bar  
Boiling point.....bp

Brake horsepower.....bhp  
Brake horsepower-hour.....bhp-hr  
British thermal unit.....Btu  
British thermal units per hour.....Btuh  
Calorie.....cal

Centigram.....cg  
Centimeter.....cm  
Centimeter-gram-second (system).....cgs  
Cubic.....cu  
Cubic centimeter.....cu cm or cc

Cubic foot.....cu ft  
Cubic feet per minute.....cfm  
Cubic feet per second.....cfs  
Decibel.....db  
Degree.....deg or °

Degree, Centigrade.....C  
Degree, Fahrenheit.....F  
Degree, Kelvin.....K  
Degree, Rankine.....R  
Diameter.....diam

<sup>1</sup> Abbreviations for Scientific and Engineering Terms, Z10.1-1941 (American Standards Association).

<sup>2</sup> It is recommended that the abbreviation for the temperature scale, F, C, K, R, be included in expressions for numerical temperatures but, wherever feasible, the abbreviation for degrees be omitted e.g., 68 F.

|                                       |        |
|---------------------------------------|--------|
| Direct-current (as adjective).....    | d-c    |
| Electromotive Force.....              | emf    |
| Feet per minute.....                  | fpm    |
| Feet per second.....                  | fps    |
| Foot.....                             | ft     |
| Foot-pound.....                       | ft-lb  |
| Foot-pound-second (system).....       | fps    |
| Freezing point.....                   | fp     |
| Gallon.....                           | gal    |
| Gallons per minute.....               | gpm    |
| Gallons per second.....               | gps    |

| Specific gravity.....                 | sp gr  |
| Specific heat.....                    | sp ht  |
| Square foot.....                      | sq ft  |
| Square inch.....                      | sq in. |
| Watt.....                             | w      |
| Watt-hour.....                        | whr    |

## SYMBOLS

A letter symbol is a single character, with subscript or superscript if required, used to designate a physical magnitude in mathematical equations and expressions. Two or more symbols together always represent a product. The following have been compiled from a selected list of approved standards.<sup>1</sup> Additional symbols and variations in the standard symbols

<sup>1</sup> Letter Symbols for Mechanics of Solid Bodies, Z10.3-1943, and Letter Symbols for Heat and Thermodynamics, Z10.4-1943 (American Standards Association).

found necessary in the individual chapters will be found in a list at the end of Chapters 3, 4, 13, 32, and 47.

|                                                       |                 |
|-------------------------------------------------------|-----------------|
| Acceleration, due to gravity.....                     | g               |
| Acceleration, linear.....                             | a               |
| Area.....                                             | A               |
| Change in specific volume during vaporization.....    | v <sub>12</sub> |
| Density, Weight per unit volume, Specific weight..... | d or ρ (rho)    |

$$d = \frac{1}{v}$$

|                                                                                                                                          |                        |
|------------------------------------------------------------------------------------------------------------------------------------------|------------------------|
| Distance, linear.....                                                                                                                    | s                      |
| Dry saturated vapor, Dry saturated gas at saturation pressure and temperature, vapor in contact with liquid.....                         | Subscript g            |
| Efficiency.....                                                                                                                          | η                      |
| Elevation above some datum.....                                                                                                          | z, Z                   |
| Emissivity.....                                                                                                                          | ε                      |
| Energy in general; work, total; work, molal.....                                                                                         | E                      |
| Entropy. (The capital should be used for any weight, and the small letter for unit weight).....                                          | S or s                 |
| Force, total load.....                                                                                                                   | F                      |
| Gas Constant, in equation $pV = nRT$ .....                                                                                               | R                      |
| Head.....                                                                                                                                | H or h                 |
| Heat content, Total heat, Enthalpy. (The capital should be used for any weight and the small letter for unit weight).....                | H or h                 |
| Heat content of saturated liquid, Total heat of saturated liquid, Enthalpy of saturated liquid, sometimes called heat of the liquid..... | h <sub>l</sub>         |
| Heat content of dry saturated vapor, Total heat of dry saturated vapor, Enthalpy of dry saturated vapor.....                             | h <sub>g</sub>         |
| Heat of vaporization at constant pressure.....                                                                                           | L or h <sub>fg</sub>   |
| Hydraulic radius.....                                                                                                                    | R <sub>a</sub>         |
| Internal energy, Intrinsic energy. (The capital should be used for any weight and the small letter for unit weight).....                 | U or u                 |
| Length of path of heat flow, thickness.....                                                                                              | L                      |
| Load, total.....                                                                                                                         | W                      |
| Mechanical efficiency.....                                                                                                               | e <sub>m</sub>         |
| Mechanical equivalent of heat.....                                                                                                       | J                      |
| Power, Horsepower, Work per unit time.....                                                                                               | P                      |
| Pressure, Absolute pressure, Gage pressure, Force per unit area.....                                                                     | p                      |
| Quantity (total) of fluid, water, gas, heat; Quantity by volume; Total quantity of heat transferred.....                                 | Q                      |
| Quality of steam, Pounds of dry steam per pound of mixture.....                                                                          | x                      |
| Reynolds Number.....                                                                                                                     | Re                     |
| Saturated liquid at saturation pressure and temperature, Liquid in contact with vapor.....                                               | Subscript f            |
| Specific heat.....                                                                                                                       | c                      |
| Specific heat at constant pressure.....                                                                                                  | c <sub>p</sub>         |
| Specific heat at constant volume.....                                                                                                    | c <sub>v</sub>         |
| Specific volume, Volume per unit weight, Volume per unit mass.....                                                                       | v                      |
| Temperature (ordinary) F or C. (Theta is used preferably only when t is used for Time in the same discussion).....                       | t or θ (theta)         |
| Temperature (absolute) F abs or K. (Capital theta is used preferably only when small theta is used for ordinary temperature).....        | T or Θ (capital theta) |
| Thermal conductance: heat transferred per (unit time) (degree).....                                                                      | C                      |

$$C = \frac{1}{R} = \frac{kA}{L} = \frac{q}{t_1 - t_2}$$

<sup>4</sup> Terms ending *totally* designate properties independent of size or shape, sometimes called *specific properties*. Examples: conductivity, resistivity. Terms ending *once* designate quantities depending not only on the material, but also upon size and shape, sometimes called *total quantities*. Examples: conductance, transmittance. Terms ending *ton* designate rate of heat transfer. Examples: conduction, transmission.

Thermal conductance per unit area, Unit conductance: heat transferred per (unit time) (unit area) (degree).....  $C_s$

$$C_s = \frac{C}{A} = \frac{1}{RA} = \frac{q}{A(t_1 - t_2)} = \frac{k}{L}$$

Thermal conductivity: heat transferred per (unit time) (unit area) (degree per unit length).....  $k$

$$k = \frac{\frac{q}{A}}{\frac{(t_1 - t_2)}{L}}$$

Surface coefficient of heat transfer, Film coefficient of heat transfer, Individual coefficient of heat transfer: heat transferred per (unit time) (unit area) (degree).....  $f$

$$f = \frac{\frac{q}{A}}{t_1 - t_2}$$

(In general  $f$  is not equal to  $k/L$ , where  $L$  is the actual thickness of the fluid film.)

Overall coefficient of heat transfer, Thermal transmittance per unit area: heat transferred per (unit time) (unit area) (degree overall).....  $U$

$$U = \frac{\frac{q}{A}}{t_1 - t_2}$$

Thermal transmission (heat transferred per unit time).....  $q$

$$q = \frac{Q}{t}$$

Thermal resistance (degree per unit of heat transferred per unit time).....  $R$

$$R = \frac{t_1 - t_2}{q} = \frac{L}{kA}$$

Thermal resistivity.....  $1/k$

Vaporization values at constant pressure, Differences between values for saturated vapor and saturated liquid at the same pressure..... *Subscript fg*

Velocity.....  $V$

Viscosity, absolute.....  $\mu$

Viscosity, kinematic.....  $\mu/\rho$

Volume (total).....  $V$

Volume per unit time, Rate at which quantity of material passes through a machine, Quantity of heat per unit time, Quantity of heat per unit weight.....  $q$

Weight of a major item, Total weight.....  $W$

Weight rate, Weight per unit of power, Weight per unit of time.....  $W$

Work (total).....  $W$

### CHAPTER 3

## THERMODYNAMICS

Mass and Energy Balances; Thermodynamic Properties of Moist Air; Formulas and Tables; Thermodynamic Properties of Water, Formulas and Tables; Degree of Saturation; A.S.H.V.E. Psychrometric Chart; Solution of Air Conditioning Problems by Use of Tables and Psychrometric Chart; U. S. Standard Atmosphere

**T**HERMODYNAMICS is that branch of natural science which deals with energy and its transformations into various forms. In this chapter the discussion will be limited to thermodynamics as it affects the arts of heating and air conditioning. This will necessarily presume some knowledge of the fundamentals of the science on the part of the reader who may also find it desirable to refer to a standard text on the subject, preferably one published after 1930.

### MASS AND ENERGY BALANCES

The First Law of Thermodynamics is a statement of the Principle of Conservation of Energy. It may be stated as follows: *The energy added to a system is equal to the increase or decrease of the energy stored in the system, plus the energy which leaves the system.* For a completely contained, or non-flow system, this may be restated as: The heat added to a non-flow system is equal to the change in the internal energy of the system, plus the work done by the system.

$$q_2 = U_2 - U_1 + w \quad (1)$$

For a constant pressure process

$$q_2 = H_2 - H_1 \quad (2)$$

where

$q_2$  = energy added between points 1 and 2.

$U$  = internal energy of system.

$w$  = work done by system.

$H$  = enthalpy of system.

Subscripts 1 and 2 refer to sections of the system between which a change takes place.

For engineering problems, a more important application of the First Law is its use in cases in which, in addition to energy, one or more fluids are crossing the boundaries of the system. The most simple of these is the steady flow system, in which the rates of energy and mass flow across the boundaries of the system are constant, and no mass or energy is stored or released by the system.

Consider a system as illustrated in Fig. 1. The fluid crossing the boundaries of the system carries with it potential energy by reason of its elevation above some convenient datum, kinetic energy by reason of its

velocity, and energy in the form of enthalpy. Additional energy may cross the boundaries of the system in the forms of heat or work. The various forms of energy crossing the boundaries between the sections under consideration may be equated by applying the First Law of Thermodynamics:

$$PE_1 + KE_1 + H_1 + {}_1q_2 = PE_2 + KE_2 + H_2 + w \quad (3)$$

where

$PE$  = potential energy, Btu per pound dry air.

$KE$  = kinetic energy, Btu per pound dry air.

$H$  = enthalpy, Btu per pound dry air.

${}_1q_2$  = heat added between sections 1 and 2, Btu per pound dry air.

$w$  = shaft work withdrawn between sections 1 and 2, Btu per pound of dry air.

FIG. 1. ENERGY CHANGE BETWEEN TWO SECTIONS OF A SYSTEM

For most psychrometric problems, since the change in the potential energy and kinetic energy terms is negligible compared to the enthalpy change, Equation 3 may be simplified to

$$H_1 + {}_1q_2 = H_2 + w \quad (4)$$

where

$H$  = enthalpy of the flowing medium, Btu per pound of dry air.

The enthalpy of the entire system may be broken down into constituent parts, thus:

$$GH = Gh + Lh_{w1} + Sh_{w2} \quad (5)$$

where

$h$  = enthalpy of moist air, Btu per pound of dry air.

$h_{w1}$  = enthalpy of liquid water, Btu per pound.

$h_{w2}$  = enthalpy of solid water, Btu per pound.

$L$  = flow rate of liquid water, pounds per hour.

$S$  = flow rate of solid water, pounds per hour.

$G$  = flow rate of dry air, pounds per hour.

Similarly, an equation expressing the conservation of mass may be written thus:

$$\sum_{in} [G(1 + W) + L + S] = \sum_{out} [G(1 + W) + L + S] \quad (6)$$

where

$W$  = humidity ratio, pounds of water vapor per pound of dry air.

### THERMODYNAMIC PROPERTIES OF MOIST AIR

The working substance of the air conditioning engineer is moist air. Air is actually a mixture of oxygen, nitrogen, carbon dioxide, water vapor, and traces of other gases.

The mixture consisting of the components other than water vapor is known as *dry air*. Its composition remains essentially constant under all conditions. In moist air the amount of water vapor varies considerably. To allow for this variation the specific properties of moist air are developed in terms of the relative amounts of water vapor and dry air. Accepted air conditioning practice is to express this in terms of the amount of water vapor per pound of dry air.

Terms frequently used in describing the condition of a mixture of air and water vapor are *humidity ratio*, *relative humidity*, *degree of saturation*, *dry-bulb temperature*, *thermodynamic wet-bulb temperature*, and *dew-point temperature*. These terms are defined in following paragraphs.

**Humidity Ratio.** Weight of water vapor associated with unit weight of dry air, pounds of water vapor per pound of dry air. Humidity ratio has also been called *specific humidity*, and this term is still used in many places.

**Relative Humidity.** Ratio of the mol fraction of water vapor in the actual mixture to the mol fraction of water vapor in saturated air at the same dry-bulb temperature and barometric pressure.

**Degree of Saturation.** Ratio of the actual humidity ratio to the humidity ratio of saturated air at the same dry-bulb temperature and barometric pressure.

Relative humidity and degree of saturation are related according to the identity:

$$\phi = \frac{\mu}{1 - (1 - \mu)f_s \frac{P_s}{P_a}} \quad (7)$$

where

$\phi$  = relative humidity, expressed as a decimal.

$\mu$  = degree of saturation, expressed as a decimal.

$P_a$  = observed (or barometric) pressure of the moist air.

$P_s$  = saturation pressure of pure water at the prevailing temperature, expressed in the same units as  $P_a$ .

$f_s$  = a dimensionless factor which may be regarded as accounting for influences arising when air and water are intermixed. Magnitudes of  $f_s$  have been reported by Goff and Gratch<sup>1</sup> and by Goff.<sup>2</sup> Table 1 gives values of  $f_s$  for a limited range of conditions.

**Dry-Bulb Temperature.** The temperature indicated by any type of thermometer or thermocouple not affected by the water vapor content of the air, or by radiation.

**Thermodynamic Wet-Bulb Temperature.** The temperature at which liquid or solid water, by evaporating into air, can bring the air to saturation adiabatically at the same temperature.

Consider an adiabatic system as shown in Fig. 2. Unsaturated air at the state  $h_1, W_1$ , enters the system at section 1, and saturated air at the state  $h^*, W^*$ , leaves the system at section 2. Liquid water at the state  $h_w^*$ , corresponding to the temperature of the saturated air leaving the system is supplied. Then, since no work is done and the system is strictly adiabatic, the energy equation becomes

$$h_1 + (W^* - W_1)h_w^* = h^* \quad (8)$$

where

\* indicates condition at thermodynamic wet-bulb temperature.

TABLE 1. MAGNITUDES OF  $f_s$  FOR THE RANGE 0 TO 125 F  
(Standard Barometric Pressure, 29.921 in. Hg)

| TEMP. F | $f_s$  | TEMP. F | $f_s$  |
|---------|--------|---------|--------|
| 0       | 1.0048 | 70      | 1.0045 |
| 10      | 1.0046 | 80      | 1.0047 |
| 20      | 1.0046 | 90      | 1.0048 |
| 30      | 1.0045 | 100     | 1.0050 |
| 40      | 1.0044 | 110     | 1.0053 |
| 50      | 1.0044 | 120     | 1.0055 |
| 60      | 1.0044 | 125     | 1.0057 |

Note: The original source gives  $f_s$  to seven significant figures over the temperature range -203 F to +202 F and over the pressure range 20 to 35 in. Hg.

The temperature corresponding to  $h^*$  for given values of  $h_1$  and  $W_1$  is called the thermodynamic wet-bulb temperature, or the temperature of adiabatic saturation.

The temperature indicated by an ordinary wet-bulb thermometer is affected by a number of factors not accounted for in Equation 8, and hence, may be quite different from the theoretical temperature obtained from its use. The measured wet-bulb temperature is influenced by (a) radiation from the surroundings to the wick; (b) conduction of heat along the stem of the thermometer; and (c) impact of the air on the wick or bulb of the thermometer. Arnold<sup>2</sup> has developed a theory which makes possible the calculation of the true thermodynamic wet-bulb temperature from observed data through the use of suitable corrections to be applied to the readings of the wet-bulb thermometer. However, unless extreme precision is required, the observed temperature may be taken equal to the theoretical temperature for most engineering problems, if no attempt is made to shield the wick from radiation and the air velocity past the wick is about 1000 fpm.

**Dew-Point Temperature.** The saturation temperature corresponding to a given combination of humidity ratio  $W$  and barometric pressure is called the dew-point temperature. It is the lowest temperature at which the

given humidity ratio can exist at the corresponding barometric pressure. At this temperature condensation will first start to form when moist air is cooled.

### Perfect Gas Relationships

Hypotheses, based on experimental observation of the physical behavior of gases, which were advanced by Boyle, Charles, Gay-Lussac, Dalton, Gibbs, Joule, Kelvin and others, were reduced to reasonably simple mathematical expressions and came to be regarded as physical laws. However, as scientific knowledge increased, and as more precise methods of measurement were developed, it became apparent that these simple equations did not describe the behavior of the mixtures of actual gases and vapors accurately.

The original statements have been found to be useful tools, nevertheless, in many cases. For example, the behavior of common diatomic and tria-

FIG. 2. ILLUSTRATION OF ADIABATIC SATURATION

tomic gases at low pressures follows these equations closely enough so that they may be used for some types of engineering problems. Many useful engineering works have been constructed through the use of approximations. The degree of approximation, however, which may be tolerated in engineering design must be decided by the engineer, based upon his study and experience in the field.

**Boyle's Law.** One of the original observations of the physical behavior of gases was made by Robert Boyle who noted that, if a constant weight of gas is compressed with the temperature held constant, the volume  $V$  varied inversely as the absolute pressure  $P$ . Stated mathematically,

$$PV = \text{constant} \quad (\text{temperature constant}) \quad (9)$$

**Charles' Law.** Experiments made independently by Charles and Gay-Lussac led to the formulation of what is now known as Charles' Law: If a constant weight of gas is heated or cooled at constant volume, the absolute pressure  $P$  varies as the absolute temperature  $T$ ; if a constant weight of

gas is heated or cooled at constant pressure, the volume  $V$  varies as the absolute temperature  $T$ . Stated mathematically,

$$\frac{P}{T} = \text{constant} \quad (\text{volume constant}) \quad (10)$$

$$\frac{V}{T} = \text{constant} \quad (\text{pressure constant}) \quad (11)$$

Boyle's Law and Charles' Law may be combined to form the equation of state for the ideal or perfect gas,

$$PV = RT \quad (12)$$

where

$R$  is a constant whose value depends on the units selected for  $P$ ,  $V$ , and  $T$ .

**Dalton's Rule.** Dalton stated that each gas in a mixture occupies the total volume of the mixture just as though the other gases were not present. Gibbs later expanded this statement for perfect gases into the following principles:

1. The pressure of a mixture of gases is the sum of the partial pressures of the individual gases when they exist at the total volume and temperature of the mixture.
2. The internal energy, enthalpy, and entropy of a mixture of gases are respectively equal to the sums of the individual internal energies, enthalpies, and entropies of the components when they exist at the total volume and temperature of the mixture.

While these relationships do not hold exactly for all systems of real gases, they may be used with a good degree of precision for many engineering applications at low pressures. Moreover, since water vapor very closely follows the perfect gas relationships in the range usually encountered in air conditioning, the Gibbs-Dalton Rule may frequently be applied to mixtures of dry air and water vapor.

Thus,

$$V_m = V_a = V_w \quad (13)$$

$$T_m = T_a = T_w \quad (14)$$

$$p_m = p_a + p_w \quad (15)$$

$$m_m h = m_a h_a + m_w h_w \quad (16)$$

where

Subscript  $m$  denotes mixture; subscript  $a$  denotes dry air; subscript  $w$  denotes water vapor.

Symbol  $m$  = weight of dry air crossing any duct section, pounds per minute.

Using Equations 12, 13, 14, and 15, the relation is obtained as follows:

$$v_r = \frac{n_a RT}{p_a} = \frac{n_w RT}{p_w} = \frac{(n_a + n_w) RT}{p} \quad (17)$$

where

$v_r$  = total volume, cubic feet.

$n_a$  = number of mols of dry air.

## Thermodynamics

$n_w$  = number of mols of water vapor.

$R$  = universal gas constant, 1545 foot-pounds per (Fahrenheit degree) (mol).

$p_a$  = partial pressure of dry air.

$p_w$  = partial pressure of water vapor.

$T$  = absolute temperature, Fahrenheit degrees.

The partial pressure of water vapor in the mixture is then

$$p_w = \frac{n_w}{n_a + n_w} p \quad (18)$$

or, the partial pressure of the water vapor in moist air is equal to the product of the mol fraction of the water vapor and the observed pressure of the mixture. A similar expression is obtained for the dry air.

Assuming that the perfect gas laws can be applied to water vapor at saturation at low pressures, the partial pressure of water vapor in a saturated mixture may be written as

$$p_w = \frac{n_s}{n_a + n_s} p \quad (19)$$

where

$n_s$  = number of mols of water vapor at saturation.

The relative humidity may be obtained by combining Equations 18 and 19 and solving for the ratio of mol fractions. Thus, using perfect gas relationships,

$$\phi = \frac{p_w}{p_s} \quad (20)$$

The humidity ratio  $W$  may be obtained from Equation 17:

$$W = \frac{18.016}{28.966} \frac{p_w}{p_a} = 0.622 \frac{p_w}{p - p_w} \quad (21)$$

where 18.016 and 28.966 are the molecular weights of water and dry air, respectively.

Equation 16 may be rewritten as

$$h = h_a + W h_w \quad (22)$$

where

$h$  = enthalpy, Btu per pound of dry air.

In relating the enthalpy to the state of the moist air, the fact that in all applications only differences in enthalpy are involved, allows the arbitrary selection of a datum or zero enthalpy point. Accordingly, from perfect gas relationships, it is possible to write for any temperature of  $t$ , Fahrenheit greater than 0 F

$$h_a = 0.24 t \quad (23)$$

where it is assumed that the same arbitrary datum of 0 F is used as in determining the properties of moist air in Table 2.

## Tables of Thermodynamic Properties of Moist Air

Research work conducted at the *University of Pennsylvania* and at other institutions has shown that the Gibbs-Dalton Rule is inaccurate in varying degrees, depending on temperature, pressure and the amount of water

vapor present. The probable reasons for this inaccuracy are due to the effect of:

1. Chemical solution of gas molecules in the water vapor.
2. The finite size of the molecules causing interference with the free passage of other molecules toward the boundaries of the system.
3. Intermolecular forces of attraction and repulsion.

Many attempts have been made to develop an equation of state which would predict the true states of real gases and vapors. The Van der Waal, Maxwell, and Beattie-Bridgman equations are probably the best known. Unfortunately, these expressions rapidly become much too complicated to be used in everyday calculations and, therefore, engineers find it more convenient to use tables of thermodynamic properties for specific working substances, as these can be prepared by physicists using the best laboratory equipment and all the refinements of mathematics.

Mechanical engineers have long been familiar with such tables for the properties of steam. Tables of the properties of moist air, as prepared by Goodenough and others, have been available for some time, but the latest and most precise of such tables are those which have resulted from a co-operative research agreement between the AMERICAN SOCIETY OF HEATING AND AIR-CONDITIONING ENGINEERS and the *Towne Scientific School of the University of Pennsylvania*. These properties are published herein as Table 2, and are taken from a research report by Goff and Gratch.<sup>4</sup> Table 2, which experimentally and mathematically takes into account deviations from perfect gas behavior, such as those listed above, makes the application of the Gibbs-Dalton Rule a less frequent necessity.

In Table 2 there are 15 columns of figures, each column being headed by a suitable symbol. In the following sub-paragraphs brief explanations are given of the data in Table 2 under the appropriate column headings.

$t(F)$  = Fahrenheit temperature defined in terms of absolute temperature  $T$  by the relation,

$$T = t + 459.67 \quad (24)$$

$W_s$  = humidity ratio at saturation. Saturation is the condition at which the vapor phase (moist air) may exist in equilibrium with a condensed phase (liquid or solid) at the given temperature and pressure (standard atmospheric pressure in the case of Table 2). At given values of temperature and pressure, the humidity ratio  $W$  can have any value from zero to  $W_s$ .

$v_a$  = specific volume of dry air, cubic feet per pound.

$v_{sa} = v_s - v_a$ , the difference between the volume of moist air at saturation, per pound of dry air, and the specific volume of the dry air itself, cubic feet per pound of dry air.

$v_s$  = specific volume of moist air at saturation per pound of dry air, cubic feet per pound of dry air.

$h_a$  = specific enthalpy of dry air, Btu per pound of dry air. The specific enthalpy of dry air has been assigned the value zero at 0 F, standard atmospheric pressure. The energy unit Btu is related to the foot-pound by definition, as follows: 1 Btu = 778.3 ft-lb.

$h_{sa} = h_s - h_a$ , the difference between the enthalpy of moist air at saturation, per pound of dry air, and the specific enthalpy of the dry air itself, Btu per pound of dry air.

$h_s$  = enthalpy of moist air at saturation per pound of dry air, Btu per pound of dry air.

$s_a$  = specific entropy of dry air, Btu per (pound) (Fahrenheit degree). It will be

noticed that the specific entropy of dry air has been assigned the value zero at 0 F and standard atmospheric pressure.

$s_{sa} = s_s - s_a$ , the difference between the entropy of moist air at saturation, per pound of dry air, and the specific entropy of the dry air itself, Btu per (pound of dry air) (Fahrenheit degree).

$s_s$  = entropy of moist air at saturation per pound of dry air, Btu per (pound of dry air) (Fahrenheit degree).

$h_w$  = specific enthalpy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per pound of water. The specific enthalpy of liquid water has been assigned the value zero at 32 F, saturation pressure (0.088586 psia).

$s_w$  = specific entropy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per (pound of water) (Fahrenheit degree). The specific entropy of liquid water has been assigned the value zero at 32 F, saturation pressure (0.088586 psia).

$p_s$  = saturation pressure of pure water vapor, pounds per square inch or inches of Hg (absolute pressure). At a given pressure, moist air can be saturated at any temperature, though this requires that it have a definite humidity ratio  $W_s$ , and that the coexisting condensed phase contain a definite, but very small, quantity of dissolved air. On the other hand, pure water vapor (steam) below the critical temperature, can be saturated at only one temperature for a given pressure. The values of saturation pressure listed in Table 2 have been computed from the formulas of Goff and Gratch.

### THERMODYNAMIC PROPERTIES OF WATER AT SATURATION

Since water vapor at low pressures acts almost as a perfect gas, the enthalpy of water vapor should also be a function only of the temperature within these limits. Therefore, the enthalpy of the water vapor may be expressed as being approximately equal to the enthalpy of saturated vapor at the dry-bulb temperature of the mixture. Substituting these values in Equation 22, the enthalpy of the mixture becomes

$$h = 0.24 t + Wh_s \quad (25)$$

where  $h_s$  is the value of the enthalpy of saturated vapor at the temperature  $t$ , and is obtained from Table 3.

Table 3 offers revisions to existing steam table data with extensions downward to -160 F. These revisions and extensions were a necessary preliminary to the construction of Table 2. A detailed explanation of the methods employed in the construction of Table 3 is given in a paper by John A. Goff and S. Gratch.<sup>5</sup>

As in Table 2, the temperature scale used as argument in Table 3 is the Fahrenheit scale defined in terms of absolute temperature  $T$  by Equation 24. The symbols used as column headings in Table 3 are the same as those used in steam tables, and have the same meanings.

Properties of water above 212 F from Keenan and Keyes<sup>6</sup> are given in Table 4.

### DEGREE OF SATURATION

Degree of saturation has previously been defined as the ratio of the actual humidity ratio to the humidity ratio of saturated air at the same dry-bulb temperature and barometric pressure. This may be stated mathematically as

$$\mu = \frac{W}{W_s} \quad (26)$$

Obviously the degree of saturation  $\mu$  can have any value from zero (dry air) to unity (moist air at saturation). The degree of saturation is con-

veniently used to interpolate values for the enthalpy, specific volume, and entropy of moist air from the data of Table 2. Within the estimated precision of the data of Table 2, at temperatures below 150 F, the volume  $v$ , enthalpy  $h$ , and entropy  $s$ , of moist air *per pound of dry air* at any degree of saturation  $\mu$  may be computed from the simple relations:

$$v = v_a + \mu v_{sa} \quad (27)$$

$$h = h_a + \mu h_{sa} \quad (28)$$

$$s = s_a + \mu s_{sa} \quad (29)$$

Thus, the degree of saturation is used in conjunction with Table 2 in the same manner as the quality is used with tables of the thermodynamic properties of steam.

#### Correction of Table 2 for Temperatures Above 150 F

The simple relations expressed in Equations 27, 28, and 29 give the properties of unsaturated air with satisfactory precision for most engineering-design problems. Above 150 F, when greater precision than obtained by Table 2 is required, these simple relations can be adjusted by the addition of supplementary terms.

To correct the volume, it is necessary to add a correction term  $\bar{v}$  which is defined as

$$\bar{v} = \frac{\mu(1-\mu)A}{1 + aW_{sa}} \quad (30)$$

where  $a$  denotes the ratio of the apparent molecular weight of dry air (28.966) to the molecular weight of water (18.016) and is equal to 1.6078. Table 5 gives the values of the coefficient  $A$  for several higher temperatures, the value of  $\mu$  at which the correction term  $\bar{v}$  attains its maximum value, and the maximum value of  $\bar{v}$  term there attained.

The correction term for the enthalpy is

$$\bar{h} = \frac{\mu(1-\mu)B}{1 + aW_{sa}} \quad (31)$$

TABLE 5. COEFFICIENTS A, B, C APPEARING IN EQUATIONS 30, 31, 32, MAXIMUM VALUES OF CORRECTIONS DEFINED BY EQUATIONS 30, 31, 32. DEGREE OF SATURATION AT WHICH THESE MAXIMA OCCUR,  $\bar{\mu}_m$ . Table 5 gives the values of the coefficient B and maximum values of  $\bar{h}$ , the maximum values occurring at the same degree of saturation as  $\bar{v}$ .

Corrections for the entropy consist of two terms:  $\bar{s}$  which is defined as

$$\bar{s} = \frac{\mu(1-\mu)C}{1 + aW_{sa}} \quad (32)$$

and  $\bar{s}$ , the so-called *mixing entropy*, which contributes the larger part of the error. The *mixing entropy* is defined as

$$\bar{s} = 0.1579 [(1 + \mu a W_{sa}) \log_{10}(1 + \mu a W_{sa}) - \mu a W_{sa} \log_{10}(\mu) - \mu(1 + a W_{sa}) \log_{10}(1 + a W_{sa})] \quad (33)$$

Table 5 lists the values of the coefficient C, the maximum values of  $\bar{s}$  and  $\bar{s}$  and the values of  $\mu$  at which they occur. The maximum  $\bar{s}$  occurs at the same degree of saturation as the maximum values of  $\bar{v}$  and  $\bar{h}$ .

FIG. 3. BASIC COORDINATES OF A.S.H.A.E. PSYCHROMETRIC CHART

#### THE ASHAE PSYCHROMETRIC CHART

A psychrometric chart is a graphical representation of the thermodynamic properties of moist air. To be of real value in the solution of engineering problems, it must have distinctive features which aid in problem analysis.

An examination of psychrometric mass and energy balances shows that no properties other than *enthalpy* and *humidity ratio* are required for the solution of problems. It is logical, then, to use these properties as the coordinates of a psychrometric chart. This was initially done by Mollier in 1923,<sup>7, 8</sup> and is the arrangement followed in the chart included with THE GUIDE. The A.S.H.A.E. Psychrometric Chart is based on the best thermodynamic data available today, namely, those of Goff and Gratch, as given in Table 2. The chart is plotted on oblique coordinates of enthalpy and humidity ratio; the enthalpy axis making an angle of approximately 40 deg with the humidity ratio axis. This is shown in Fig. 3.

For practical use, the inclusion of dry-bulb and wet-bulb temperatures, volumes, and indices of the condition of the air in relation to saturation, is necessary for locating and describing states on the chart. The arrange-

ment of the families of curves of constant dry-bulb temperature, wet-bulb temperature, volume, relative humidity and degree of saturation, are shown in Fig. 4.

Mass and energy balances deal only with net changes between definite states; the detailed history of a change is not involved. A chart used to facilitate such calculations must primarily aid in clearly establishing states. Lines drawn on the chart to connect different states need have

FIG. 4. ARRANGEMENT OF FAMILIES OF CURVES ON A.S.H.A.E. PSYCHROMETRIC CHART

no other significance than being loci lines; that is, lines which contain the two terminal points of a change according to the particular overall conditions imposed. Loci lines are commonly called *condition lines* for the processes concerned. On the A.S.H.A.E. chart a condition line is characterized by the ratio  $(h_2 - h_1)/(W_2 - W_1)$ .

An abridgment of the A.S.H.A.E. Psychrometric Chart appears in Fig. 5. A large size (24 x 32) chart will be found on the inside of the back cover.

The chart is drawn for standard atmospheric pressure. Steady flow changes commonly involve pressure drops with the flow, but so long as these pressure drops remain a small fraction of the barometric pressure, no appreciable errors need arise from using a constant pressure chart. For many design problems, the use of the standard pressure chart will not incur any undue error up to about 2000 ft above sea level.

The region above the saturation curve is a two-phase region giving equilibrium states for water in both the liquid and vapor phases. The ordinate of a point in this region is the weight of water in both phases per pound of dry air in the vapor phase, neglecting any dissolved air

FIG. 5. ABRIDGMENT OF A.S.H.A.E. PSYCHROMETRIC CHART

in the condensed phase. The ordinate at the saturation curve, or the point at which the break in the isotherm through the point in question occurs, is the weight of water per pound of dry air in the vapor phase. Consequently, the difference between the two ordinates is the weight of condensed moisture per pound of dry air in the vapor phase.

The shaded solid-liquid-vapor region at 32 F is an isothermal three-phase zone, and separates the liquid-vapor zone from the solid-vapor zone. The temperature is 32 F throughout the shaded area.

It is possible to obtain two values for the wet-bulb temperature when this temperature is below 32 F. If the bulb of a thermometer is dipped into water at a temperature slightly above 32 F and held in a stream of air whose wet-bulb temperature is below 32 F, the temperature indicated by the thermometer will drop rapidly until a minimum is reached below 32 F. This will be accomplished without the formation of ice on the bulb of the thermometer. After reaching this minimum temperature, the reading will jump back to 32 F and remain there until the water on the bulb is frozen, after which it will slowly drop again until equilibrium is reached. The final temperature may be higher or lower than the first minimum reading, or it may be the same depending on the amount of moisture present in the mixture. In the absence of reliable data on the wet-bulb temperature over sub-cooled water, the chart, below 32 F, has been drawn for the equilibrium condition, that is, the values plotted on the A.S.H.A.E. chart are for the condition where the minimum temperature is reached with ice on the bulb of the thermometer.

#### USE OF TABLE 2 AND THE A.S.H.A.E. PSYCHROMETRIC CHART

The use of Table 2 and the A.S.H.A.E. Psychrometric Chart in analyzing typical air conditioning problems, is best explained by means of illustrative examples. In each of the following it is to be understood that the processes in question take place at a constant pressure of 29.921 in. Hg, *i.e.*, standard atmospheric pressure.

**Example 1:** Determine the enthalpy of moist air at 80 F dry-bulb temperature and 0.40 degree of saturation.

**Solution a:** From the data of Table 2, at 80 F,  $h_a = 19.221$  Btu per lb of dry air and  $h_{sa} = 24.47$  Btu per lb of dry air. Then  $h$  at the specified conditions is  $19.221 + 0.40(24.47) = 29.01$  Btu per lb of dry air.

**Solution b:** From the A.S.H.A.E. Chart. Follow the 80 F dry-bulb line vertically until it intersects the 0.40 degree of saturation line. From this intersection, follow the line of constant enthalpy to the enthalpy scale and read 29.00 Btu per lb of dry air.

**Example 2:** Determine the thermodynamic wet-bulb temperature of moist air at the conditions of Example 1.

**Solution a:** From the data of Table 2. Applying Equation 8,  $h_1 = 29.01$  Btu per lb of dry air (Example 1). As a first approximation this is  $h^*$ , the enthalpy at saturation at the thermodynamic wet-bulb temperature which is, therefore, approximately 63.5 F.  $W^*$  at 63.5 F is  $12.57 \times 10^{-3}$  lb of water vapor per lb of dry air, and  $W_1$  is  $0.02233 \times 0.40 = 0.00893$  lb of water vapor per lb of dry air. The specific enthalpy of liquid water at 63.5 F is 31.58 Btu per lb of water. As a second approximation,  $h^* = 29.01 + (0.01257 - 0.00893)(31.58) = 29.12$  Btu per lb of dry air. Interpolation in Table 2 gives as the final answer  $t^* = 63.64$  F.

**Solution b:** From the A.S.H.A.E. Chart. At the intersection of the 80 F dry-bulb temperature line and the 0.40 degree of saturation line, read the thermodynamic wet-bulb temperature.

#### Heating of Moist Air at Constant Pressure Without Addition of Moisture

**Example 3:** Air initially at 20 F, 0.80 degree of saturation, is heated to 120 F. Find the quantity of heat required to process 20,000 cfm of heated air.

The process is diagrammatically illustrated in Fig. 6. The energy equation for the process is

$$Gh_1 + \dot{q}_2 = Gh_2$$

$$\dot{q}_2 = G(h_2 - h_1)$$

FIG. 6. ILLUSTRATION OF PROCESS OF EXAMPLE 3

**Solution a:** From the data of Table 2. The initial humidity ratio, which is the same as the final humidity ratio, is  $0.80(0.002152) = 0.001722$  lb of water vapor per lb of dry air; the initial enthalpy is  $4.804 + 0.80(2.302) = 6.646$  Btu per lb of dry air; the final degree of saturation is  $0.001722/0.03149 = 0.02113$ ; the final enthalpy is  $28.841 + 0.02113(90.70) = 30.757$  Btu per lb of dry air; the final volume is  $14.611 + 0.02113(1.905) = 14.651$  cu ft per lb of dry air. Since 20,000 cfm of heated air are to be processed, the total quantity of heat required is

$$\dot{q}_2 = (20,000/14.651) \times 24.111 = 32,914 \text{ Btu per min.}$$

**Solution b:** From the A.S.H.A.E. Chart. The process is represented by the horizontal line 1-2, Fig. 7. The initial enthalpy, at 20 F dry-bulb temperature and 0.80 degree of saturation, is 6.65 Btu per lb of dry air. Since the final humidity ratio is the same as the initial humidity ratio, the ratio  $(h_2 - h_1)/(W_2 - W_1) = \infty$ . The horizontal line 1-2, Fig. 7, then represents the condition line for the process, and the final state of the moist air must lie on this line. The final state is located at the point at which the 120 F dry-bulb temperature line crosses the condition line, and is labeled point 2 on the figure. At this condition the final enthalpy is 30.8 Btu per lb of dry air and the final specific volume is 14.65 cu ft per lb of dry air. Substituting these values in the energy equation,

$$\dot{q}_2 = (20,000/14.65) \times (30.8 - 6.65) = 32,950 \text{ Btu per min.}$$

#### Cooling of Moist Air at Constant Pressure with Condensation of Water

Referring to Fig. 8, moist air cooled from state 1 passes through successive states along the line  $W = W_1 = \text{constant}$  until the saturation line is intersected. The

FIG. 7. SOLUTION OF EXAMPLE 3 ON A.S.H.V.E. PSYCHROMETRIC CHART

$$\frac{20.270 - h_2}{h_2 - 0.668} = \frac{0.003164 - W_2}{W_2 - 0.000630} = \frac{1}{4}$$

from which  $h_2 = 16.350$  and  $W_2 = 0.002657$ . The enthalpy of the final mixture may also be expressed by Equation 28:

$$h_2 = h_a + \mu h_{w2}$$

Since  $\mu$  by definition is  $W_2/W_a$ , Equation 28 may be rewritten as

$$16.350 = h_a + (0.002657/W_a) \times h_{w2}$$

At 56 F the right side of the equation is 16.332, and at 57 F it is 16.582. Interpolation gives as the final dry-bulb temperature of the mixture 56.07 F. At this temperature the humidity ratio at saturation is 0.00960 lb of water vapor per lb of dry air. Therefore, the final degree of saturation is

$$\mu = 0.002657/0.00960 = 0.277$$

**Solution b.** From the A.S.H.A.E. Chart, Equation 34 indicates that the state point of the resulting mixture lies on a straight line connecting the state points of

FIG. 10. ILLUSTRATION OF MIXING OF TWO STEADY FLOW STREAMS AT CONSTANT PRESSURE

the two streams being mixed, and divides this line into two segments whose respective lengths are inversely proportional to the rates of dry air flow in the corresponding streams. This is illustrated in Fig. 11. Points 1 and 2 are located and connected by a straight line. The state of the final mixture is set so that

$$\frac{G_1}{G_2} = \frac{D_{2-1}}{D_{1-1}} = \frac{1}{4}$$

Scaling the distances on the chart, the required solution to Example 5 is 56 F dry-bulb temperature and 0.28 degree of saturation.

#### Addition of Moisture to an Adiabatic Stream

Consider a stream of moist air flowing adiabatically between two sections, 1 and 2, as in Fig. 12, with moisture addition at the rate  $G_1(W_2 - W_1)$  and the moisture having the enthalpy  $h_w$  Btu per pound of moisture.

An energy balance yields

$$G_1 h_1 + G_1(W_2 - W_1)h_w = G_2 h_2 \quad (35)$$

**Example 6:** Liquid water chilled to 40 F is injected into an air stream initially at

FIG. 11. SOLUTION OF EXAMPLE 5 ON A.S.H.V.E. PSYCHROMETRIC CHART

95 F dry-bulb temperature and 80 F thermodynamic wet-bulb temperature. At what temperature will saturation be reached? How much water must be evaporated to reach saturation?

**Solution a:** From the data of Table 2. The solution of Equation 35 for  $h_2$  yields

$$h_2 = h_1 + (W_2 - W_1)h_w$$

The initial enthalpy of the moist air  $h_1$  must be found from Equation 8,

$$h_1 = h^* - (W^* - W_1)h_w^*$$

from which  $\mu = 0.511$ .

$$\begin{aligned} \text{Hence, } h_1 &= 22.827 + 0.511(40.49) \\ &= 43.52 \text{ Btu per lb of dry air} \\ \text{and } W_1 &= 0.03673(0.511) \\ &= 0.01877 \text{ lb per lb of dry air.} \end{aligned}$$

The solution of Equation 35 is

$$h_2 = 43.52 + (W_2 - 0.01877)(8.09)$$

By trial and error, this equation will be satisfied at the temperature 79.87 F. At this temperature the humidity ratio  $W_2$  is 0.02223. The weight of water evaporated is therefore  $0.02223 - 0.01877 = 0.00346$  lb per lb of dry air.

FIG. 12. ILLUSTRATION OF ADDITION OF MOISTURE TO AN ADIABATIC STREAM

**Solution b:** From the A.S.H.A.E. Chart. Solution of Equation 35 for the ratio  $(h_2 - h_1)/(W_2 - W_1)$  yields

$$\frac{h_2 - h_1}{W_2 - W_1} = h_w \quad (36)$$

The slope of the condition line is therefore determined by the enthalpy of the water which is supplied. This slope is established on the chart by connecting the center of the protractor on the psychrometric chart with the value of  $h_w$  on the protractor. Draw a line parallel to this reference line through the initial point 1 (Fig. 13). The second line is the condition line for the process. Since the conditions of the problem require the final point to lie on the saturation line, the intersection of the condition line with the saturation line gives the desired solution.

### Adiabatic Saturation

Adiabatic saturation is the designation given any process in which the state of moist air is changed from some initial unsaturated condition to a saturated one with-

FIG. 13. SOLUTION OF EXAMPLE 6 ON A.S.H.A.E. PSYCHROMETRIC CHART

out the addition or removal of heat. According to this definition, the addition of moisture to an adiabatic stream may become an adiabatic saturation process. *Example 6* is an illustration.

A type of adiabatic saturation of further practical interest is the use of continually recirculated spray water in a saturating air washer. Here the spray water will ultimately come to the same temperature as the saturated leaving air; this temperature is, by definition, the thermodynamic wet-bulb temperature. Hence, adiabatic saturation in this manner will have the final state point on the saturation curve, with the same thermodynamic wet-bulb temperature as the original state point.

In a process such as this, the moist air enthalpy changes very slightly. The moisture added and temperature change may be obtained from the psychrometric chart as sketched in Fig. 14.

**Example 7:** Moist air at 75 F dry-bulb temperature and 0.60 degree of saturation, is saturated adiabatically with recirculating spray water. Find the amount of water added and the change in enthalpy.

**Solution a:** From the data of Table 2. As previously stated, the final temperature of the mixture will be the thermodynamic wet-bulb temperature at the initial state. This must first be determined by the method of *Example 2*, and is 65.51 F. At this temperature the humidity ratio at saturation and enthalpy at saturation are 0.01350 and 30.45, respectively. The humidity ratio at the initial state is 0.60 (0.01882) = 0.01129; the initial enthalpy is  $0.60(20.59) + 18.018 = 30.372$ . The weight of water

FIG. 14. MOISTURE ADDED AND TEMPERATURE CHANGE

added is therefore  $0.01350 - 0.01129 = 0.00221$  lb per lb of dry air; the enthalpy change is  $30.45 - 30.372 = 0.078$  Btu per lb of dry air.

**Solution b:** From the A.S.H.A.E. Chart. Since the initial and final states have the same thermodynamic wet-bulb temperature, the results may be read directly from the chart.

### Addition of Heat and Water Vapor to an Air Stream in Steady Flow

Fig. 15 is a schematic representation of a system operating at constant pressure, where

$G_1$  is the rate of flow of dry air, pounds per minute.

$G_w$  is the rate of evaporation of the water, pounds per minute.

$h_w$  is the enthalpy of the liquid water entering, Btu per pound.

$Q$  is the rate of heat addition, Btu per minute.

An energy balance for the system gives

$$G_1 h_1 + Q + G_w h_w = G_2 h_2 \quad (37)$$

A mass balance gives

$$G_1 + G_1 W_1 + G_w = G_2 + G_2 W_2$$

or

$$G_1 W_1 + G_w = G_2 W_2 \quad (38)$$

FIG. 15. ILLUSTRATION OF ADDITION OF HEAT AND WATER VAPOR TO AN AIR STREAM IN STEADY FLOW

Combining equations 37 and 38 and solving for the ratio  $(h_2 - h_1)/(W_2 - W_1)$ ,

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{Q}{G_w} + h_w \quad (39)$$

**Example 8:** Moist air at 20 F dry-bulb temperature and 0.80 degree of saturation is heated and humidified until it is at 120 F dry-bulb temperature and 71.5 F thermodynamic wet-bulb temperature. Water at 55 F is supplied. If the air flow rate is 20,000 cfm at the initial conditions, how much heat is required?

**Solution a:** From the data of Table 2. The initial humidity ratio is 0.80(0.002152) = 0.00172; the initial enthalpy is 4.804 + 0.80(2.302) = 6.6456; the initial specific volume is 12.084 + 0.80(0.042) = 12.118. The degree of saturation at the final state may be determined from Equation 8 which may be rewritten as

$$h_{a2} + \mu h_{a2} + h_w^*(W^* - \mu W_{a2}) = h^*$$

FIG. 16. SOLUTION OF EXAMPLE 8 ON A.S.H.A.E. PSYCHROMETRIC CHART

The values of these properties are:  $h^* = 35.39$ ;  $W^* = 0.01668$ ;  $h_w^* = 39.61$ ;  $h_{a2} = 90.70$ ;  $W_{a2} = 0.08149$ ;  $h_{a1} = 28.84$ .

Making the proper substitutions and solving for degree of saturation,

$$\mu = 0.0681.$$

The final humidity ratio is therefore 0.0681(0.08149) = 0.005549; the final enthalpy is 28.84 + 0.0681(90.70) = 35.02 Btu per lb dry air.

The rate of water addition is obtained from Equation 38.

$$G_w = \frac{20,000}{12.12} (0.005549 - 0.00172) \\ = 6.32 \text{ lb per min.}$$

The heat supplied is obtained from Equation 37.

$$Q = G_1(h_2 - h_1) - G_w h_w \\ = \frac{20,000}{12.12} (35.02 - 6.65) - 6.32(28.08) \\ = 46,667 \text{ Btu per min.}$$

**Solution b:** From the A.S.H.A.E. Chart. Locate the initial and final states on the chart and connect them with a straight line. Through the reference point on the chart, draw a line parallel to the line connecting the initial and final state points, the condition line, and read the value of the ratio  $(h_2 - h_1)/(W_2 - W_1)$  as 7500 from

the protractor on the chart (Fig. 16). From Equation 39

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{Q}{G_w} + h_w = 7500$$

The rate of water supply was determined in *Solution a*, but will be found from the chart. It is

$$G_w = \frac{20,000}{12.1} (0.0055 - 0.0017) \\ = 6.28 \text{ lb per min} \\ Q = G_w(7500 - h_w) \\ = 6.28(7500 - 23) \\ = 46,900 \text{ Btu per min.}$$

TABLE 6. PRESSURE AND TEMPERATURE FOR ALTITUDES IN U. S. STANDARD ATMOSPHERE

### U. S. STANDARD ATMOSPHERE

The definition of the U. S. Standard Atmosphere is important to the air conditioning engineer as an essential standard of reference. The basic assumptions in defining the Standard Atmosphere are:

1. There is a linear decrease in temperature  $T$  with altitude up to the limit of the isothermal atmosphere at 35,332 ft. Thus,

$$T = T_0 - 0.003566 Z \quad (40)$$

2. The air is dry.

3. Air is a perfect gas obeying the laws of Charles and Boyle:

$$PV = RT$$

4. Gravity is constant at all altitudes with the standard value.

5. The temperature of the isothermal atmosphere is -66 F.

Standard values at sea level, which are part of the definition of the Standard Atmosphere, are:

|             |               |
|-------------|---------------|
| Pressure    | 29.921 in. Hg |
| Temperature | 59 F          |

|                      |                             |
|----------------------|-----------------------------|
| Absolute Temperature | 518.67 F Abs                |
| Gravity              | 32.1740 ft per (sec) (sec). |
| Density              | 0.076505 lb per cu ft       |

Values of pressure and temperature are listed in Table 6 for altitudes in the standard atmosphere from -1000 to 50,000 ft above sea level. For further explanation, References 9 and 10 should be consulted.

### LETTER SYMBOLS USED IN CHAPTER 3

- $\mu$  = degree of saturation (decimal).
- $\rho$  = density of fluid, pounds per cubic foot.
- $\phi$  = relative humidity (decimal).
- $\alpha$  = ratio of apparent molecular weight of dry air (28.966) to the molecular weight of water (18.016) = 1.6078.
- $A$  = coefficient from Table 5 for use in Equation 30 (obtained from Table 5).
- $B$  = coefficient to be used in Equation 31 (obtained from Table 5).
- $C$  = coefficient for use in Equation 32 (obtained from Table 5).
- $f_s$  = factor accounting for effect of mixing air and water, dimensionless.
- $G$  = flow rate of dry air, pounds per hour.
- $G_1$  = flow rate of dry air, pounds per minute.
- $G_w$  = rate of evaporation of water, pounds per minute.
- $H$  = enthalpy of the system.
- $H$  = enthalpy of the flowing medium, Btu per pound of dry air.
- $h$  = enthalpy of moist air, Btu per pound of dry air.
- $\bar{h}$  = enthalpy correction term to be added above 150 F, to enthalpy.
- $h_a$  = specific enthalpy of dry air, Btu per pound.
- $h_a = h_s - h_{sa}$  = the difference between the enthalpy of moist air at saturation per pound of dry air, and the specific enthalpy of the dry air itself, Btu per pound of dry air.
- $h_s$  = enthalpy of saturated water vapor, Btu per pound.
- $h_{sa}$  = enthalpy of moist air at saturation per pound of dry air, Btu per pound of dry air.
- $h_{sa}^*$  = enthalpy of moist air at saturation at thermodynamic wet-bulb temperature,  $t^*$ , Btu per pound of dry air.
- $h_w$  = specific enthalpy of condensed water (liquid or solid) at standard pressure, Btu per pound water.
- $h_w^*$  = specific enthalpy of water as added at the thermodynamic wet-bulb temperature  $t^*$ , Btu per pound of dry air.
- $h_{w1}$  = enthalpy of liquid water, Btu per pound.
- $h_{w2}$  = enthalpy of solid water, Btu per pound.
- $KE$  = average kinetic energy, Btu per pound.
- $\overline{KE}$  = average kinetic energy, Btu per pound.
- $L$  = flow rate of liquid water, pounds per hour.
- $m$  = weight of dry air crossing any duct section, pounds per minute.
- $n_a$  = mols dry air.
- $n_s$  = mols of water vapor at saturation.
- $n_w$  = mols of water vapor.
- $P$  = absolute pressure.
- $P_a$  = atmospheric pressure, inches Hg.

### LETTER SYMBOLS (Continued)

- $P_a$  = standard atmospheric pressure by definition 29.921 in. Hg.
- $P_s$  = saturation pressure of pure water at prevailing temperature.
- $p$  = total pressure of a mixture of air and water vapor, pounds per square inch or inches Hg.
- $p_a$  = partial pressure of dry air, pounds per square inch or inches Hg.
- $p_s$  = saturation pressure of pure water vapor, pounds per square inch or inches Hg.
- $p_w$  = partial pressure of water vapor in mixture of air and water vapor, pounds per square inch or inches Hg.
- $PE$  = potential energy, Btu per pound dry air.
- $\overline{PE}$  = average potential energy, Btu per pound dry air.
- $Q$  = total heat added or subtracted, between sections, Btu per minute.
- $q$  = ratio of energy added (or removed) to water added (or removed), Btu per pound. Also called specific enthalpy of water added.
- $q_1$  = energy added between points 1 and 2.
- $q_2$  = heat added between sections 1 and 2, Btu per pound dry air.
- $R$  = universal gas constant, 1545 foot-pounds per (Fahrenheit degree) (mol).
- $R_a$  = gas constant for dry air.
- $R_w$  = gas constant for water vapor.
- $S$  = flow rate of solid water, pounds per hour.
- $s$  = entropy of moist air per pound of dry air, Btu per (pound) (Fahrenheit degree).
- $\bar{s}$  = correction to be added to entropy of moist air obtained from Table 2.
- $\bar{s}$  = additional correction to be added to entropy because of "mixing entropy" (obtained from Table 5). Correction to be added to value of  $s$  obtained from Table 2.
- $s_a$  = specific entropy of dry air, Btu per (pound) (Fahrenheit degree, absolute).
- $s_{sa}$  = the difference between the entropy of moist air at saturation per pound of dry air, and the specific entropy of the dry air itself, Btu per (pound of dry air) (Fahrenheit degree, absolute).
- $s_s$  = entropy of moist air at saturation per pound of dry air, Btu per (pound of dry air) (Fahrenheit degree, absolute).
- $s_w$  = specific entropy of condensed water (liquid or solid) at standard atmospheric pressure, Btu per (pound of water) (Fahrenheit degree, absolute).
- $T$  = absolute temperature, Fahrenheit degrees.
- $T_a$  = standard atmospheric temperature, by definition 518.4 F absolute.
- $t$  = temperature, Fahrenheit degrees.
- $t^*$  = thermodynamic wet-bulb temperature, Fahrenheit degrees.
- $U$  = internal energy of system.
- $U$  = internal energy.
- $V$  = volume.
- $\bar{V}$  = average velocity, feet per minute.
- $v$  = volume of moist air per pound of dry air, cubic feet per pound.
- $v$  = correction to be added to volume of moist air per pound of dry air, above 150 F.
- $v_a$  = specific volume of dry air, cubic feet per pound.

## LETTER SYMBOLS (Concluded)

- $v_{a,s} = v_s - v_a$ , the difference between volume of moist air at saturation, per pound of dry air, and the volume of the dry air itself, cubic feet per pound of dry air.
- $v_s$  = volume of moist air at saturation per pound of dry air, cubic feet per pound of dry air.
- $v_T$  = total volume, cubic feet.
- $W$  = humidity ratio, of moist air, pounds of water per pound of dry air.
- $W_s$  = humidity ratio, at saturation, weight of water vapor per pound of dry air, pound per pound.
- $W_s^*$  = humidity ratio corresponding to thermodynamic wet-bulb temperature  $t^*$ , pounds of water per pound of dry air.
- $w$  = work done by system.
- $w$  = shaft work withdrawn between sections 1 and 2, Btu per pound of air.
- $Z$  = elevation above any datum, feet.
- $\bar{Z}$  = average elevation, feet.

Subscripts with symbols have following meanings: 1, 2, 3 indicate section of flow; a = air, w = water, wl = liquid water, ws = solid water, s = saturation, m = mixture; \* indicates that the value is at thermodynamic wet-bulb temperature.

## CHAPTER 4

## FLUID FLOW

Theory of Fluid Flow, Pressure Loss in Circular Pipes, Pressure Loss in Non-Circular Pipes; Flow of Compressible Fluids, Ideal Flow Through Nozzle or Orifice; Flow Measurement, Head Meters, Location of Head Meters and Pressure Taps Pitot Tube, Variable Area Flow Meters

THE flow of fluids is part of the branch of engineering science known as fluid mechanics, which will be discussed here insofar as it applies to the work of engineers in the fields of heating, ventilating, and air conditioning. Probably air is the most frequently handled fluid, but other gases and liquids are often involved. Compressible fluids (gases) and incompressible fluids (liquids) vary somewhat in behavior, though in cases where pressure and density changes are small, the gases may be treated as incompressible fluids.

## THEORY OF FLUID FLOW

The following energy equation for one dimensional steady flow processes will serve as a basis for the theory of the flow of fluids. This equation is presented in several ways in various texts, but a suitable form is

$$\frac{V_1^2}{2g_c} + J u_1 + p_1 v_1 + J q + \frac{g}{g_c} z_1 = \frac{V_2^2}{2g_c} + J u_2 + p_2 v_2 + W + \frac{g}{g_c} z_2 \quad (1)$$

where

- $V$  = velocity in feet per second.
- $g$  = gravitational acceleration, in feet per (second) (second).
- $g_c$  = gravitational conversion factor = 32.174 (pounds mass per pound force)  $\times$  ft per (second) (second).
- $J$  = mechanical equivalent of heat = 778 foot pounds per Btu.
- $u$  = internal energy, in Btu per pound of fluid.
- $p$  = pressure in pounds per square foot.
- $v$  = specific volume, in cubic feet per pound.
- $W$  = mechanical work done by the fluid in foot pounds per pound of fluid.
- $q$  = heat transferred to the fluid in Btu per pound of fluid flowing.
- $z$  = elevation above some arbitrary datum, in feet.
- Subscript 1 refers to the entrance, subscript 2 to the exit.

Introducing the enthalpy  $h$ , which by definition is  $u + \frac{pv}{J}$ , expressed in Btu per pound of fluid, Equation 1 becomes

$$\frac{V_1^2}{2g_c} + J h_1 + J q + \frac{g}{g_c} z_1 = \frac{V_2^2}{2g_c} + J h_2 + W + \frac{g}{g_c} z_2 \quad (2)$$

The equivalent differential form for energy Equation 1 is

$$\frac{1}{2g_c} dV^2 + J du + d(pv) + \frac{g}{g_c} dz - J dq + dW = 0 \quad (3)$$

Replacing  $v$  by its equal  $\dot{q}/g\rho$  (where  $\rho$  is density in pounds weight per cubic foot) and rearranging, Equation 3 becomes

$$\frac{1}{2g} dV^2 + \frac{1}{\rho} dp + dz + \frac{g_c}{g} [J du + p dv - J dq + dW] = 0 \quad (4)$$

In the case of flow through a pipe, no outside work is performed so that  $dW = 0$ . Furthermore,

$$J du + p dv = JT ds = J dq + JT ds' \quad (5)$$

where

$ds$  = total change in entropy.

$ds'$  = change in entropy due to internal irreversibility from turbulence and friction.

FIG. 1. RELATION OF VARIOUS FACTORS IN BERNOULLI EQUATION

Accordingly, Equation 4 may be written

$$\frac{1}{2g} dV^2 + \frac{dp}{\rho} + dz + \frac{g_c}{g} JT ds' = 0^* \quad (6)$$

In cases where there is no internal irreversibility,  $ds' = 0$ , and Equation 6 may be integrated to give

$$\frac{V_1^2}{2g} + \frac{p_1}{\rho_m} + z_1 = \frac{V_2^2}{2g} + \frac{p_2}{\rho_m} + z_2 \quad (7)$$

where  $\rho_m$  is the proper mean density.

This is commonly called the Bernoulli equation, named after the Swiss mathematician and physician who first propounded the theory.  $\frac{V^2}{2g}$  is

known as the velocity head,  $\frac{p}{\rho}$  is the pressure head, and  $z$  is the elevation head, all in feet of the fluid; the total head,  $h_t$  is the sum of the other three heads. Fig. 1 shows diagrammatically the relation of the various factors. The pressure at point 2 is lower than at point 1 because of the elevation of point 2 over point 1, and the velocity at point 2 is lower than at point 1 because of the larger pipe diameter at point 2. If the pipe

\* In the analysis of subsequent portions of this chapter the distinction between  $g$  and  $g_c$  will be omitted. Aside from the dimensional consistency the factor,  $g/g_c$ , is not in general significant in fluid flow analysis.

diameter were the same throughout, the velocity, and consequently the velocity head, would be the same at both points, but the higher elevation at point 2 would still be responsible for a loss in pressure. The utility of the equation is evident, though it should be remembered that in it the effects of friction and turbulence are neglected, and that Fig. 1 represents ideal conditions. It should also be noted that care must be taken in determining the proper mean density. Accordingly, the Bernoulli equation is applied most conveniently to incompressible fluids for which density is constant.

FIG. 2. RELATION OF KINEMATIC VISCOSITY TO TEMPERATURE OF AIR

### Pressure Loss in Circular Pipes

The pressure loss in circular pipes is customarily expressed by the formula:

$$h_f = \frac{f l V^2}{2g d} \quad (8)$$

where

$h_f$  = the loss in head of the fluid under conditions of flow, in feet.

$l$  = the length of the pipe, in feet.

$V$  = the velocity, in feet per second.

$g$  = the acceleration due to gravity = 32.174 ft per (second) (second).

$d$  = the internal diameter of the pipe, in feet.

$f$  = a dimensionless friction coefficient.

The formula is generally known by the name of Darcy or Fanning, though it seems to have been originated by d'Aubisson de Voisins in 1834.

The factor  $f$  is a function of the Reynolds number,

$$N_{Re} = \frac{d V \rho}{\mu} \quad (9)$$

where

$N_{Re}$  = Reynolds number.

$\rho$  = the density in pounds per cubic foot.

$\mu$  = the absolute viscosity in pounds per foot-second.

Both  $f$  and the Reynolds number are dimensionless. To aid in computing the Reynolds number, values of  $\frac{\mu}{\rho}$ , the kinematic viscosity, are shown as a function of temperature for air in Fig. 2, and for water in Fig. 3.

Fig. 4 shows the relation between  $f$  and the Reynolds number, adapted from a review by Moody.<sup>1</sup> The straight line sloping downward at the left of the chart supplies the values of  $f$  for laminar flow determined by the formula:

FIG. 3. RELATION OF KINEMATIC VISCOSITY TO TEMPERATURE OF WATER

$$f = \frac{64}{N_{Re}} \quad (10)$$

With laminar flow, the velocity profile is a parabola, having the formula:

$$V = \frac{\rho h_1}{4\mu L} (r^2 - L^2) \quad (11)$$

where

$r$  = the radius of the pipe in feet.

$L$  = distance perpendicularly from the axis of the pipe, in feet.

Accordingly, the maximum velocity occurs at the center of the pipe and is twice the average velocity; the average velocity is found when  $L = 0.707 r$ . It is worth noting that roughness of the pipe wall has no effect on the loss in head for laminar flow.

Between values of the Reynolds number of 2000 and 4000, there is an

<sup>1</sup> Superior numbers refer to the references at the end of chapter.

unstable region where the flow changes from laminar to turbulent, or vice versa. The actual value is impossible of prediction for any conditions of flow, though in general it may be said that the prevailing type of flow persists into the unstable region; however, once the change starts, it proceeds very rapidly.

When the flow is turbulent, the velocity profile is essentially parabolic over four-fifths of the pipe diameter, but near the pipe walls, the effect of friction becomes evident, and in the boundary layer at the pipe wall the flow is laminar. Fig. 5 compares the velocity profiles for three different Reynolds numbers, but for the same average velocity.

The lower curve in the turbulent region in Fig. 4 represents the relation of  $f$  to the Reynolds number for smooth pipe, such as drawn brass tubing

FIG. 4. RELATION BETWEEN FRICTION FACTOR AND REYNOLDS NUMBER  
NOTE: The straight line at left shows values of Friction Factor for laminar flow.

or glass tubing. The effect of roughness on  $f$ , an effect which is considerable in turbulent flow, is open to some conjecture; artificially roughened pipes, for instance, give results at variance with actual tests. The curves above the smooth pipe curve of Fig. 4 represent a summary of tests on rough pipe, each of them identified by a value of  $e/d$ , with  $e$  signifying the absolute roughness in feet. Values of  $e$  for different pipes are given in Table 1.

To find the friction loss for any pipe, follow the curve with the proper value of  $e/d$ , to the pertinent value of  $N_{Re}$ , and from this point proceed horizontally to left margin to find the value of  $f$  for use in Equation 8.

The curves in Fig. 4 may be approximated very closely by the empirical formula:<sup>1</sup>

$$f = 0.0055 \left[ 1 + \left( 20,000 \frac{e}{d} + \frac{10^6}{N_{Re}} \right)^{1/2} \right]$$

Equation 8 is applicable to all liquids, and to gases when the pressure loss is less than 10 percent of the initial pressure. When the loss in head is high, the formula to be used for gases is

$$\frac{p_1^2 - p_2^2}{p_1^2} = \frac{fLV_1^2}{gd p_1 v_1} \quad (13)$$

which may be arranged to give the loss in pressure,

$$p_1 - p_2 = p_1 \left[ 1 - \sqrt{1 - \frac{fLV_1^2}{gd p_1 v_1}} \right] \quad (14)$$

FIG. 5. COMPARISON OF VELOCITY PROFILES FOR 3 DIFFERENT REYNOLDS NUMBERS BUT FOR SAME AVERAGE VELOCITY

#### Pressure Loss in Non-Circular Pipes

The formulas for friction loss in pipes are based on the use of pipes of circular cross-section. The same formulas may be extended to non-circular sections, by suitable modification. In the basic formula, Equation 8, the internal diameter  $d$  is to be replaced by the hydraulic diameter  $d_H$  defined by the equation:

$$d_H = \frac{4 \times \text{area of cross-section}}{\text{wetted perimeter of cross-section}} \quad (15)$$

For example, in a rectangular duct, 1 ft by 2 ft, the cross-section area is 2 sq ft, and the perimeter 6 ft. Then the hydraulic diameter will be  $d_H = (4 \times 2)/6 = 1\frac{1}{3}$  ft.

In the case of a round pipe,

$$d_H = \frac{4 \times \pi d^2/4}{\pi d} = d \quad (16)$$

In computing the Reynolds number, and from that the friction factor, the hydraulic diameter is not to be used. A better approximate procedure is to replace the length in the Reynolds number by the shortest dimension plus one-fourth of the hydraulic diameter. Thus, in a duct of dimension  $a \times b$  where  $a < b$ ,  $N_{Re}$ , for the purposes of calculating friction factors, is

$$N_{Re} = (a + 0.25d_H)V\rho/\mu \quad (17)$$

TABLE 1. VALUES OF  $e$  FOR DIFFERENT KINDS OF PIPE

| TYPE OF PIPE                          | $e$             |
|---------------------------------------|-----------------|
| Smooth drawn tubing.....              | 0.00005         |
| Commercial steel or wrought iron..... | 0.00015         |
| Asphalted cast-iron.....              | 0.0004          |
| Galvanized iron.....                  | 0.0005          |
| Cast-iron.....                        | 0.00085         |
| Wood stave.....                       | 0.0008 to 0.003 |
| Concrete.....                         | 0.001 to 0.01   |
| Riveted steel.....                    | 0.003 to 0.03   |

This value of  $N_{Re}$  may be used in Equation 10 for laminar flow, and in Equation 12 or Fig. 4 for turbulent flow. The error in the approximation is somewhat greater for laminar than for turbulent flow. In the former case, the relative error may be as much as 10 percent, while in the latter it almost always is less than 3 percent.

#### FLOW OF COMPRESSIBLE FLUIDS

In the flow of compressible fluids, the large density variations make impracticable the use of the Bernoulli equation, (Equation 7). In certain special cases, however, the exact equations for compressible flow may be stated. If flow occurs with no friction or other internal irreversibility, Equation 6 becomes

$$\frac{1}{2g} dV^2 + \frac{dp}{\rho} = 0 \quad (18)$$

If, in addition, the flow is adiabatic,

$$pp^{-k} = p_1 p_1^{-k} \quad (19)$$

so that Equation 18 becomes

$$\frac{1}{2g} dV^2 + \frac{p_1^{1/k}}{\rho_1} \frac{dp}{p^{1/k}} = 0 \quad (20)$$

or by integration,

$$\frac{1}{2g} (V_2^2 - V_1^2) + \frac{k}{k-1} \frac{p_1}{\rho_1} \left[ \left( \frac{p_2}{p_1} \right)^{\frac{k-1}{k}} - 1 \right] = 0 \quad (21)$$

This extension to compressible flow of Bernoulli's equation reduces to the more familiar form if the pressure change is small.

The ratio of specific heats,  $k$ , is used extensively in fluid dynamics; values of  $k$  for various gases are given in Table 2.

TABLE 2. RATIO OF SPECIFIC HEAT AT CONSTANT PRESSURE TO SPECIFIC HEAT AT CONSTANT VOLUME FOR COMPRESSIBLE FLUIDS

| COMPRESSIBLE FLUID                                                                                        | RATIO $k = c_p/c_v$ |
|-----------------------------------------------------------------------------------------------------------|---------------------|
| Helium and other monatomic gases.....                                                                     | 1.66                |
| Air and other diatomic gases.....                                                                         | 1.40                |
| Ammonia and hydrogen sulfide.....                                                                         | 1.34                |
| Carbon dioxide, methane, natural gas, superheated steam, moist steam down to a quality of 97 percent..... | 1.28 to 1.32        |
| Sulfur dioxide, ethylene, acetylene.....                                                                  | 1.24 to 1.26        |

It is convenient in the analysis of compressible flow to introduce the velocity of propagation of pressure impulses or, more familiarly, the sonic velocity,  $a$ . For perfect gases this is given by the equation:

$$a^2 = kgp/\rho = kgRT \quad (22)$$

Accordingly, Equation 21 may be written

$$\frac{1}{2}(V_2^2 - V_1^2) + \frac{a_1^2}{k-1} \left[ \left( \frac{p_2}{p_1} \right)^{\frac{k-1}{k}} - 1 \right] = 0 \quad (23)$$

or, by rearrangement,

$$\frac{p_2}{p_1} = \left[ 1 - \frac{k-1}{a_1^2} \left( \frac{V_2^2 - V_1^2}{2} \right) \right]^{\frac{k}{k-1}} \quad (24)$$

which permits the calculation of the ratio of pressures at entrance and exit of the steady flow device—pipe, orifice, or nozzle. From Equations 19 and 22 it follows that

$$\frac{a_2^2}{a_1^2} = \frac{T_2}{T_1} = \left( \frac{p_2}{p_1} \right)^{\frac{k-1}{k}} \quad (25)$$

so that

$$\frac{k-1}{2} (V_2^2 - V_1^2) + a_2^2 - a_1^2 = 0 \quad (26)$$

and

$$\frac{a_2^2}{a_1^2} = \frac{1 + \frac{k-1}{2} \frac{V_1^2}{a_1^2}}{1 + \frac{k-1}{2} \frac{V_2^2}{a_2^2}} \quad (27)$$

The ratio of flow velocity to sonic velocity is known as the Mach number,

$$M = V/a$$

This parameter is particularly useful in compressible flow analysis. In general, if  $M \leq 0.1$  the flow may be considered to be incompressible. This is generally true in heating and ventilating air ducts.

In terms of the Mach number

$$\frac{a_2^2}{a_1^2} = \frac{T_2}{T_1} = \frac{1 + \frac{k-1}{2} M_1^2}{1 + \frac{k-1}{2} M_2^2} \quad (28)$$

and

$$\frac{p_2}{p_1} = \left( \frac{1 + \frac{k-1}{2} M_1^2}{1 + \frac{k-1}{2} M_2^2} \right)^{\frac{k}{k-1}} \quad (29)$$

The quantity,

$$p^0 = p \left( 1 + \frac{k-1}{2} M^2 \right)^{\frac{k}{k-1}} \quad (30)$$

is called the stagnation pressure, and gives a measure of pressure energy. For incompressible flow

$$p^0 = p + \frac{1}{2g} \rho V^2 = p + q \quad (31)$$

where

$$q = \frac{1}{2g} \rho V^2 \quad (32)$$

and is the dynamic pressure. A total head tube measures stagnation pressure directly.

From Equation 29 it follows that for frictionless, adiabatic flow

$$p^0 = p_1^0 \quad (33)$$

This represents another extension of the Bernoulli equation to compressible flow. Friction will cause a loss in pressure energy.

#### Ideal Flow through Nozzle or Orifice

The majority of low-head measuring systems depend upon a correlation between pressure drop, area, and quantity of flow. The basic formulas may be stated on the assumption that the flow is frictionless and adiabatic. Designating the main stream by station 1, and flow at some measuring restriction by station 2, the flow in pounds per second is

$$w = \rho_1 A_1 V_1 = \rho_2 A_2 V_2 \quad (34)$$

or, in terms of Mach number,

$$w = A_2 M_2 \sqrt{k g p_2 \rho_2} \quad (35)$$

According to Equation 29

$$\left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} = \frac{1 + \frac{k-1}{2} M_1^2}{1 + \frac{k-1}{2} M_2^2} \quad (36)$$

from which

$$M_2^2 = \frac{2}{k-1} \left( \frac{1 + \frac{k-1}{2} M_1^2}{1 - M_1^2/M_2^2} \right) \left[ \left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} - 1 \right] \quad (37)$$

so that

$$w = A_2 \sqrt{\frac{1 + \frac{k-1}{2} M_1^2}{1 - M_1^2/M_2^2}} \sqrt{\frac{2k g p_2 \rho_2}{k-1} \left[ \left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} - 1 \right]} \quad (38)$$

If the initial velocity is sufficiently small,  $M_1^2$  will be negligible so that

$$w = A_2 \sqrt{\frac{2k g p_2 \rho_2}{k-1} \left[ \left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} - 1 \right]} = A_2 \sqrt{\frac{2k g p_1 \rho_1}{k-1} \left( \frac{p_2}{p_1} \right)^{\frac{k+1}{k}} \left[ \left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} - 1 \right]} \quad (39)$$

If this is computed and the figures are plotted, the curved line (partly

solid and partly broken) of Fig. 6 is found. The maximum value of  $\frac{p_2}{p_1}$  may be computed by differentiating  $w$  with respect to  $p_2$  and equating the result to zero. This operation produces the formula:

$$\frac{p_2}{p_1} = \left( \frac{2}{k+1} \right)^{\frac{k}{k-1}} \quad (40)$$

For air, with  $k = 1.40$ ,  $\frac{p_2}{p_1} = 0.53$ .

Actually, the broken part of the curve is not attained for the flow in the nozzle. If the ratio of  $p_2$  to  $p_1$  is decreased from unity, the mass rate of discharge, as well as the volume, increases from zero to a maximum, as shown by the solid section of the curve in Fig. 6; thereafter, as  $p_2/p_1$  is decreased further, the discharge is constant, as indicated by the horizontal line. The value of  $p_2$  at the maximum point is called the critical pressure, or  $p_c$ , and it is seen that  $p_c$  is approximately 53 percent of  $p_1$  when air is flowing.

FIG. 6. RELATION OF FLOW OF GAS TO PRESSURE DROP IN A CONVERGING TUBE

To find the velocity at the critical pressure, it is assumed that the upstream velocity  $V_1$  is so small as to be negligible. Using the subscript  $c$  to indicate conditions at the critical point, from Equation 29

$$\frac{p_c}{p_1} = \frac{1}{\left( 1 + \frac{k-1}{2} M_c^2 \right)^{\frac{k}{k-1}}} \quad (41)$$

or

$$M_c = \sqrt{\frac{2}{k-1} \left[ \left( \frac{p_1}{p_c} \right)^{\frac{k-1}{k}} - 1 \right]} \quad (42)$$

Substituting the critical pressure ratio from Equation 40 it follows that

$$M_c = 1 \quad (43)$$

or that the velocity at the throat is equal to the local sonic velocity.

In developing the working equations for orifices and nozzles, it is customary to start with the incompressible form of the flow Equation 38. In this case both  $M_1$  and  $M_2$  are small quantities,  $p_1 = p_2$ , and  $(p_1 - p_2)/p_1 = \Delta p/p_1$  is small. Retaining only first order terms, it follows from Equation 35 that

$$\frac{M_1}{M_2} = \frac{A_2}{A_1} \quad (44)$$

so that

$$\sqrt{\frac{1 + \frac{k-1}{2} M_1^2}{1 - M_1^2/M_2^2}} \approx \frac{1}{\sqrt{1 - (A_2/A_1)^2}} = \frac{1}{\sqrt{1 - \beta^2}} \quad (45)$$

where  $\beta = D_2/D_1$ . The quantity  $1/\sqrt{1 - \beta^2}$  is the velocity of approach

FIG. 7. DIMENSIONS AND FLOW COEFFICIENT FOR STANDARD SQUARE-EDGED ORIFICE WITH CORNER TAPS OR ANNULAR SLITS  
(Coefficient shown as a function of Reynolds Number and Ratio,  $A_1/A_2$ )

NOTE: From Reference 4. Used by permission.

factor as generally used, with  $\beta$  being the ratio of the throat or orifice diameter to the pipe diameter.

Since  $\Delta p/p_1$  is small

$$\frac{2k}{k-1} \left[ \left( \frac{p_1}{p_2} \right)^{\frac{k-1}{k}} - 1 \right] \approx \frac{2\Delta p}{p_2} \quad (46)$$

and the mass flow is

$$w = \frac{A_2}{\sqrt{1 - \beta^2}} \sqrt{2g\rho\Delta p} \quad (47)$$

The volume flow is then

$$Q = A_2 \frac{1}{\sqrt{1 - \beta^2}} \sqrt{2g\Delta p/\rho} = A_2 \frac{1}{\sqrt{1 - \beta^2}} \sqrt{2gh_1} \quad (48)$$

## FLOW MEASUREMENT

The measurement of quantity of flow of fluids is generally accomplished either by making observations on the change of state due to flow-system configuration, such as the pressure drop across a metering orifice, or by the displacement of some device, such as a rotating vane system. The selection of the metering system will be determined by the type of fluid, the precision of measurement desired, the cost of equipment and installation, the range of flow quantity, the ease of maintenance, and the method of observation and recording.

Fluid meters may be classified as follows: (1) *Head Meters* (Pressure Sensitive), which may be of *Venturi*, *flow nozzle*, *orifice plate*, or *Pilot tube* types; (2) *Area Meters*, which may be of *gate*, *tapered tube*, or *tapered plug* types; (3) *Force Meters*, which may be of *vane*, *propellor*, or *turbine* types; (4) *Quantity Meters*, which may be of *weighing tank*, *reciprocating piston*, or *geared impeller* types.

Rate meters are generally of the first three groups, although rates are

FIG. 8. DIMENSIONS FOR INTERNATIONAL STANDARDS ASSOCIATION FLOW NOZZLE

NOTE: From Reference 3. Used by permission of A.S.M.E.

obtainable from timed observations of quantity meters. Similar quantity measurements can be obtained by suitable integration of rate meter indications.

## Head Meters

The head meter is of sufficient flexibility so that almost any type of flow measuring problem can be handled. For this reason, standard and reference measurements are usually made in this way. With proper care, extreme precision can be obtained. Also, an inexpensive installation can be made to give moderate precision. In general, a head meter requires fairly competent installation and maintenance to give satisfactory service.

Among the types of head meters, the Venturi has the advantage of having a low pressure loss, but requires considerable length of space. The orifice plate reduces the required length to a minimum at the cost of considerable pressure drop. The flow nozzle represents a compromise, but must be calibrated individually, or made with extreme care from standard specifications, to obtain a good precision of measurement. Standard configurations for representative orifice plates and flow nozzles, are shown in Figs. 7 and 8, respectively. Additional specifications are given in References 2, 3, and 4 at end of chapter.

The measurement of flow in head meters is dependent upon observations

## Fluid Flow

NOTE: From Table 7 of Reference 2.

of a static pressure difference between two parts of the system. Standard locations for these static pressure measurements are illustrated in Figs. 8 and 16. In general, there exists a reduction in area, either by a smooth contour as in the case of a Venturi or flow nozzle, or by a vena contracta following an orifice. In either case, the flow will be given by a suitable modification of Equations 47 and 48. Adding a correction term, these become

$$w = \frac{A_2 C}{\sqrt{1 - \beta^4}} \sqrt{2g\rho\Delta p} \quad (49)$$

FIG. 12. FLOW COEFFICIENT FOR INTERNATIONAL STANDARDS ASSOCIATION FLOW NOZZLE SHOWN IN FIG. 8 AS A FUNCTION OF AREA RATIO  $(D_2/D_1)^2$  AND THE REYNOLDS NUMBER  $N_{Re}$ .

NOTE: From Reference 3. Used by permission of ASME

and

$$Q = \frac{A_2 C}{\sqrt{1 - \beta^4}} \sqrt{2gh_1} \quad (50)$$

In all cases,  $A_2$  refers to the minimum area of the Venturi, nozzle, or orifice. The correction factor  $C$  is introduced to account for any loss due to departure from isentropic flow, and for any deviation between the downstream measured pressure and the actual pressure at the minimum section. Since these corrections are usually dependent on configuration, as described by the ratio of upstream to minimum area  $A_1/A_2$ , it is often convenient to introduce a combined flow coefficient,  $K$  which is

$$K = \frac{C}{\sqrt{1 - \beta^4}} \quad (51)$$

so that

$$w = KA_2 \sqrt{2g\rho\Delta p} \quad (52)$$

and

$$Q = KA_2 \sqrt{2gh_1} \quad (53)$$

The coefficients  $K$  and  $C$  will be determined by the area ratio  $A_1/A_2$ , or by the diameter ratio  $D_1/D_2$  and the Reynolds number. Extensive data are available from various sources.<sup>2,4</sup> Figs. 9, 10, 11, 12 show representative values of  $K$  based on  $N_{Re}$ , the Reynolds number, and the ratio of diameter of the orifice or nozzle throat to pipe diameter.

In any specific application, numerical values for areas, densities, and pressure units can be substituted in Equations 52 and 53 to obtain compact working formulas. In planning flow measurements, standard flow meter

FIG. 13. RELATION OF EXPANSION FACTOR,  $\phi$ , FOR NOZZLES TO DIAMETER RATIO AND PRESSURE LOSS FOR AIR AND OTHER DIATOMIC GASES

dimensions and standard pressure tap locations should preferably be used so that published flow coefficients can be used for accurate determination of flow rates.

In measuring the flow of compressible fluids, the approximate Equations 52 and 53 must be corrected for density variations. The need for such correction is evident by comparing Equations 35 and 38 with Equation 47. Introducing a multiplicative correction factor  $\phi$  the equation for flow with no loss becomes:

$$w = \frac{A_2 \phi}{\sqrt{1 - \beta^4}} \sqrt{2g\rho_1(p_1 - p_2)} \quad (54)$$

By comparison with Equation 35,

$$\phi = \sqrt{\frac{k p_2 M_2^2 (1 - \beta^4)}{2 p_1 (p_1/p_2) - 1}} \quad (55)$$

From Equations 34 and 35,

$$M_1^2/M_2^2 = \beta^4(p_2/p_1)^{1/k} \quad (56)$$

Hence, by Equation 38 for a small value of  $M_1$ ,

$$\phi = \sqrt{\left(\frac{p_2}{p_1}\right)^{1/k} \left(\frac{k}{k-1}\right) \frac{\left(\frac{p_1}{p_2}\right)^{(k-1)/k} - 1}{\left(\frac{p_1}{p_2}\right) - 1} \frac{1 - \beta^4}{1 - \beta^4 \left(\frac{p_2}{p_1}\right)^{2k}}} \quad (57)$$

From Equations 37 and 56, if  $M_1$  is not too large,

$$\frac{2}{k} \frac{1}{M_1^2} \left(\frac{p_1}{p_2} - 1\right) \approx 1 - \beta^4 + \frac{1}{2} [1 - 2(k-2)\beta^4] M_1^2 \quad (58)$$

so that, approximately,

$$\phi \approx 1 - \frac{3}{8} \left[ 1 + \left(1 - \frac{2k}{3}\right) \beta^4 \right] M_1^2 \quad (59)$$

FIG. 14. RELATION OF EXPANSION FACTOR,  $\phi$ , FOR NOZZLES TO DIAMETER RATIO AND PRESSURE LOSS FOR STEAM, CARBON DIOXIDE AND NATURAL GAS

where to the same degree of approximation from Equation 36

$$M_1^2 = 2 \frac{p_1 - p_2}{k p_1} \quad (60)$$

Values of  $\phi$  are also given by Figs. 13 and 14.

While  $\phi$  may be used for smooth nozzles and Venturi tubes, it is necessary in the case of orifices, where the departure from ideal flow is significant, to replace  $\phi$  by an empirical factor  $Y$  obtained by the equation

$$Y = 1 - (0.41 + 0.35\beta^4) \left( \frac{p_1 - p_2}{p_1} \right) \quad (61)$$

When this correction is used, the flow will be given by the equation

$$w = K A_2 Y \sqrt{2 g \rho_1 (p_1 - p_2)} \quad (62)$$

#### Location of Head Meters and Pressure Taps

In the installation of Venturis, orifices, and nozzles, care must be taken in regard to upstream and downstream flow conditions. Recommended

practice, with reference to fittings and valves, is shown by Fig. 15. If these conditions cannot be met, some flexibility is possible by introducing straightening vanes, as described more fully in References 2 and 5.

The static pressure difference across the head meter is measured by suitably located static pressure taps. For orifices, the different sets of pressure taps are called flange taps, radius taps, vena contracta taps, and pipe or full-flow taps. The relative locations of the first three of these are shown in Fig. 16.

The flow coefficients in Figs. 9, 10 and 11 apply only to measurements made with these pressure tap locations. The need for applying suitable

FIG. 15. MINIMUM CONDITIONS TO BE OBSERVED WHEN INSTALLING ORIFICES AND NOZZLES BETWEEN FITTINGS AND VALVES

coefficients to measurements obtained by means of the different taps, is indicated by the curve of change, in pressure of the flowing fluid, shown in the lower part of Fig. 16. Pipe taps are located  $2\frac{1}{2}$  pipe diameters upstream and 8 pipe diameters downstream (both distances being measured from the upstream face of the orifice plate) so that pressures are measured before the orifice plate has had any effect on the flow, and after the recovery in pressure has been completed. The use of pipe or full-flow taps has been limited to the metering of natural fuel gas in certain areas. As they are not suited to use in heating and ventilating work, no data for them are given in this chapter.

Still another type of pressure tap, the corner tap, is used in European practice. Pressures are taken from recesses in the flange connected to annular slits in the corners formed by the pipe wall and the orifice plate.

Coefficients for these taps have been adopted by the *International Standards Association*, but are not used commercially in America.

It will be noted that the location of the downstream pressure tap of the vena contracta arrangement is variable. Vena contracta is the term applied to the minimum cross-section of the jet from the orifice, where the static pressure is at a minimum. Its location, and the location of the downstream vena contracta tap, vary with the ratio of orifice to pipe diameter, and with rate of flow, as shown in Fig. 17; the tap is generally located in accordance with the mean curve in the figure.

Similar precautions are required when using flow nozzles and Venturi tubes. In many cases, these will be supplied ready for installation. In such cases, the manufacturer's instructions should be followed with care

FIG. 16. RELATIVE LOCATION OF FLANGE, RADIUS AND VENA CONTRACTA TAPS

in order to avoid serious errors. Further information on such systems is given in References 2, 3, and 5.

#### Pitot Tube

In certain cases, such as in rectangular ducts, it is impracticable to use standard orifices, and consequently, either a specially designed orifice must be calibrated, or an independent flow device must be used. In either case, the Pitot tube is useful. It consists essentially of an inner bent tube with its open end pointing upstream so as to measure total pressure, and an outer tube having small holes on the side for communicating static pressure to a manometer. (See Fig. 3, Chapter 52). The difference in liquid level in the manometer will be proportional to the square of the velocity, for incompressible flow, so that in general

$$V = \sqrt{2gh_1} \quad (63)$$

For compressible flow, the differential head is to be divided by the correction  $F_c$  from Equation 64,

$$F_c = 1 + \frac{1}{2}M^2 + \frac{1}{4}M^4 \quad (64)$$

where

$$M^2 = 2 \frac{p_0 - p}{\rho p} \quad (65)$$

In the use of a Pitot tube system, care is required in obtaining correct total and static pressures. The total pressure tube must be smoothly constructed, and should point directly upstream. The static pressure tap must be located so that local flow interferences will not reduce the value. In any case, it is better to obtain an independent calibration, or use a specially designed and manufactured probe. A number of such Pitot tube probes are available, and can be used without calibration.

In using Pitot tubes to obtain flow rates, it is necessary to make a traverse of the pipe and thereby to obtain one of the profiles of Fig. 5.

FIG. 17. LOCATION OF VENA CONTRACTA IN RELATION TO RATIO OF ORIFICE TO PIPE DIAMETER AND TO RATE OF FLOW

In rectangular ducts or near valves or fittings, a disturbed flow pattern would be obtained, and therefore, in such cases, a fairly complete survey should be made. The flow in such cases will be computed from the average of the local velocities, as obtained by Equation 63.

#### Variable Area Flow Meters

For permanent installations where high precision, ruggedness, and ease of operation are important, the variable area flow meter has proved very satisfactory. Its most frequent use is in measurement of liquids or gases in small diameter pipes. For ducts or pipes over 6 in. in diameter, the expense of this meter may not be warranted. In large systems, however, the meter might be placed in a by-pass line and used in conjunction with an orifice.

In its most common form, the variable area meter, Fig. 18, consists essentially of a float which is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus

formed between the float and inside wall of the tube. At any particular rate of flow, the float assumes a definite position in the tube, its location being indicated by means of a calibrated scale on the tube.

The position of the float is established by a balance between the fluid pressure forces across the annulus and the weight of the float itself. The buoyant force which must support the float,  $v_f(\rho_f - \rho)$ , is balanced by the pressure difference acting on the cross-section area of the float,  $A_f \Delta p$ , where  $\rho_f$ ,  $A_f$ ,  $v_f$ , are, respectively, the float density, float cross-section area, and float volume. Accordingly, the difference in head across the annulus is given by

$$h_f = \frac{\Delta p}{\rho} = \frac{v_f(\rho_f - \rho)}{A_f \rho} \quad (66)$$

FIG. 18. SCHEMATIC DIAGRAM OF VARIABLE AREA FLOW METER

The volume flow follows from equation (53) as

$$Q = KA_2 \sqrt{2g v_f (\rho_f - \rho) / \rho A_1} \quad (67)$$

and the mass flow as

$$w = \rho Q = KA_2 \sqrt{2g v_f (\rho_f - \rho) \cdot \rho / A_1} \quad (68)$$

The flow for any selected fluid is, accordingly, very nearly proportional to the area, so that a convenient calibration of the tube may be obtained. The behavior of the flow coefficient,  $K$ , has been investigated<sup>6</sup> and the action of the flow meter as just outlined, experimentally confirmed. The flow coefficient variation for any float must be known in order to use the meter for different fluids. Some developments have been carried on in the design of the float to reduce the variation of the flow coefficient with Reynolds number, and also with regard to float materials, to reduce the dependence of mass flow calibration on fluid density.

This type of flow meter is usually furnished in standard sizes calibrated

for specific fluids by the manufacturer. The compactness, reliability, and ease of installation are particularly advantageous when many measurements of essentially the same type are to be made.

#### LETTER SYMBOLS USED IN CHAPTER 4

- $\beta$  = ratio, throat or orifice diameter to pipe diameter.
- $\mu$  = absolute viscosity, pounds per foot second.
- $\mu/\rho$  = kinematic viscosity, square feet per second.
- $\rho$  = density of flowing fluid, pounds per cubic foot.
- $\rho_m$  = proper mean density.
- $\rho_w$  = density of water at 60 F (62.37 lb per cubic foot).
- $\rho_f$  = density of float in variable area meters.
- $\phi$  = expansion factor for nozzles.
- $a$  = velocity of sound, feet per second.
- $A$  = cross-sectional area of flow, square feet.
- $C$  = correction factor (coefficient of discharge) for flow through orifice, nozzle or Venturi.
- $c_p$  = specific heat of gas at constant pressure.
- $c_v$  = specific heat of gas at constant volume.
- $D$  = diameter of fluid stream, feet.
- $d$  = internal diameter of pipe, feet.
- $d_H$  = hydraulic diameter, feet.
- $e$  = absolute roughness of pipe surface, feet.
- $F_c$  = correction factor for differential head in compressible flow.
- $f$  = dimensionless friction coefficient.
- $g$  = gravitational acceleration, feet per (second) (second).
- $g_c$  = gravitational conversion factor = 32.174 (pounds mass per pound force)  $\times$  feet per (second) (second).
- $h$  = enthalpy, Btu per pound of fluid.
- $h_f$  = loss of head, feet of fluid.
- $h_t$  = total head, feet of fluid.
- $J$  = mechanical equivalent of heat = 778 foot pounds per Btu.
- $K$  = flow coefficient (correction factor), including velocity of approach correction factor, for flow through orifice, nozzle or Venturi.
- $k$  = ratio of specific heat at constant pressure to specific heat at constant volume.
- $L$  = perpendicular distance from axis of pipe, feet.
- $l$  = length of pipe, feet.
- $M$  = Mach number.
- $N_{Re}$  = Reynolds number.
- $p$  = pressure, pounds per square foot.
- $p^0$  = stagnation pressure.
- $p_c$  = critical pressure.
- $Q$  = discharge rate, cubic feet per second.
- $q$  = heat transferred to the fluid per pound of fluid flowing.
- $R$  = gas constant.
- $r$  = radius of pipe in feet.
- $s$  = entropy of fluid in Btu per (pound) (Fahrenheit degree).
- $T$  = temperature, Fahrenheit degrees, absolute.
- $u$  = internal energy, Btu per pound of fluid.
- $V$  = velocity, feet per second.
- $V_c$  = critical velocity, feet per second.
- $v$  = specific volume, cubic feet per pound.
- $W$  = mechanical work, foot pounds per pound of fluid flowing.
- $w$  = mass flow of gas, pounds per second.
- $Y$  = expansion factor—correcting for expansion of gas under reduced downstream pressure.
- $z$  = elevation above some arbitrary datum, feet.

## CHAPTER 5

## HEAT TRANSFER

Conduction, Convection, Radiation; Equations for Conduction, Convection, Radiation and Combined Convection and Radiation; Heat-Flow Resistance, in Series and Parallel; Practical Heat Transfer Problems; Periodic and Transient Heat Flow

HEAT is the form of energy that is transferred by virtue of an existing temperature difference. The temperature difference is the potential which causes the transfer, the latter in turn being resisted by the thermal properties of the material combined in a single term known as the resistance. Energy exchange associated with evaporation, condensation, etc., is treated elsewhere such as in the section on *cooling tower design* in Chapter 35. The objectives of this chapter are to:

1. Describe the mechanisms and present the rate equations for the different modes of heat transfer.
2. Illustrate the application of the basic concepts to steady-state problems (temperature independent of time or a cyclic variable thereof) by means of several typical solutions of heat transfer systems.
3. Present concise summaries of available methods of analysis for transient and periodic heat transfer problems.

Further applications to specific systems will be found throughout THE GUIDE.

## CONDUCTION, CONVECTION AND RADIATION

*Thermal conduction* is the term applied to the mechanism of heat transfer whereby the molecules of higher kinetic energy transmit part of their energy to adjacent molecules of lower kinetic energy by direct molecular action. Since the temperature is proportional to the average kinetic energy of the molecules, thermal transfer will occur in the direction of decreasing temperature. The motion of the molecules is random; there is no net material flow associated with the conduction mechanism. In the case of flowing fluids, thermal conduction is significant in the region very close to a solid boundary or wall, for in this region the flow is laminar, parallel with the wall surface, and there are practically no cross currents in the direction of the heat transfer across the solid fluid boundary. In solid bodies the significant mechanism of heat transfer is always thermal conduction.

Contrasted to the thermal conduction mechanism, *thermal convection* involves energy transfer by eddy mixing and diffusion<sup>1</sup> in addition to conduction. This is shown schematically in Fig. 1 which exhibits transfer from a pipe wall at surface temperature  $t_s$  to a colder fluid at a bulk temperature  $t_f$ . (Bulk temperature is that which would be attained if the fluid stream were drawn off at a certain section and mixed. It is therefore somewhat higher than the lowest temperature in the stream.) In the laminar sublayer, immediately adjacent to the wall, the heat transfer occurs by thermal conduction; in the *transition* region, which is called the buffer layer, eddy mixing as well as conduction effects are significant;

in the *eddy* or *turbulent* region the major fraction of the transfer occurs by eddy mixing.

In most commercial equipment the main body of the fluid is in turbulent flow, and the laminar film exists at the solid walls only, as shown in Fig. 1, but in cases of low-velocity flow in small tubes, or with viscous liquids such as heavy oil (low Reynolds numbers), the entire flow may be laminar. In these latter cases there is no transition or eddy region.

When the fluid currents are produced by sources external to the heat transfer region, as for example by a pump, the described solid to fluid heat transfer is termed *forced convection*. In contrast, if the fluid currents are generated internally, as a result of non-homogeneous densities arising from the temperature variations, the heat transfer is termed *free convection*.

In the conduction and convection mechanisms, the transfer of heat is associated with matter. For *radiant heat transfer*, however, a change in

FIG. 1. THERMAL CONVECTION CONDITIONS

energy form takes place, from internal energy at the source to electromagnetic energy for transmission, then back to internal energy at the receiver.

The rate of heat transfer, corresponding to the three transfer mechanisms previously described, may be expressed by three rate equations. These are similar to Ohm's Law for electrical flow, the current flow through a resistance being proportional to the potential. The convection and radiation flow rate expressions may be approximated by a potential (temperature difference) and a resistance in order that heat transfer calculations may be effected more conveniently and rapidly.

#### Thermal Conduction Equation

Equation 1 states symbolically that the thermal conduction per unit transfer area normal to the flow,  $q/A$ , Btu per (hour) (square foot), is proportional to the temperature gradient  $(dt)/(dL)$ , Fahrenheit degrees per foot. The proportionality factor is termed the *thermal conductivity*,  $k$ , Btu per (hour) (square foot) (Fahrenheit degree per foot of thickness).

$$\frac{q}{A} = -k \frac{dt}{dL} \quad (1)$$

The minus sign on the right side of the equation is introduced to indicate positive transfer in the direction of decreasing temperature. Fig. 2 shows the physical significance of the indicated quantities.

It should be emphasized that the thermal conductivity used should be expressed in consistent units; either using the inch or foot throughout.

Expressions of conductivity used in the heating field are usually inconsistent in this sense, in that it is customary to refer to the conductivity *per square foot* but for one inch of thickness. This custom has been adopted for the reason that wall thicknesses are usually expressed in inches, whereas if expressed in feet, decimal or fractional thicknesses would result. When dealing with flat walls, no complication is involved in using the inconsistent expression of conductivity. However, where curved or spherical walls are concerned, considerable complication is involved. Therefore, in this discussion the consistent units of conductivity expressed in *Btu per (hour) (square foot) (Fahrenheit degrees per one foot thickness)* are used throughout. Conductivity values obtained from Chapter 9 or Table 1 in this chapter, must therefore be converted for use in the calculations of this chapter by dividing by 12. As an example, the conductivity of brick listed as 5.0 in Table 2 of Chapter 9, becomes 0.42 when used in the calculations of this chapter.

FIG. 2. THERMAL CONDUCTION IN A FLAT SLAB

Also, it should be emphasized that in order to make the calculations and applications consistent in this chapter, *all dimensions of thickness must be expressed in feet*.

#### Thermal Convection Equation

$$\frac{q}{A} = h_c(t_s - t_f) \quad (2)$$

This rate equation states that the thermal convection per unit transfer area ( $q/A$ ), Btu per (hour) (square foot) is proportional to the tem-

perature difference ( $t_s - t_f$ ) which is the temperature of the surface less that of the fluid. The particular fluid temperature to use for a given system will be noted under the discussion of that system. The proportionality factor is termed the *unit thermal convective conductance* (sometimes called the film coefficient for convection),  $h_c$ , Btu per (hour) (square foot) (Fahrenheit degree). Fig. 1 shows the conditions associated with convection.

The heat transmission by free or natural convection for objects surrounded by air can be conveniently expressed as in Equation 2a:

$$\frac{q}{A} = C \left( \frac{1}{D} \right)^{0.3} \left( \frac{1}{T_{av}} \right)^{0.181} (t_s - t_f)^{1.17} \quad (2a)$$

where

$\frac{q}{A}$  = heat transmission by convection, Btu per (square foot) (hour).

$C$  = a constant depending upon the shape of the surface.

$D$  = diameter of pipe or circular duct or height of vertical wall, inches. (Effect of diameter or height becomes constant at 24 in.)

$T_{av}$  = average of wall surface and surrounding air temperature, Fahrenheit degrees absolute.

$t_s - t_f$  = temperature excess between wall surface and surrounding air, Fahrenheit degrees.

For horizontal cylinders, the value of  $C = 1.02$  has been well established by various investigations. For vertical plates, the value of  $C = 1.39$  has been fairly well established. Suggested values<sup>2</sup> of  $C$  for horizontal plates warmer than the surrounding air are 1.79 when facing upward, and 0.89 when facing downward.

Problems in either forced convection or natural convection may be solved by the simple first-power equation if the convection coefficient is expressed as a unit conductance:

$$q = h_c A (t_1 - t_2) \quad (2b)$$

where

$q$  = heat transmission by convection, Btu per hour.

$A$  = surface area, square feet.

$t_1 - t_2$  = temperature difference between the surface and the fluid, Fahrenheit degrees.

$h_c$  = unit convective conductance, from Table 2, Btu per (square foot) (hour) (Fahrenheit degree temperature difference).

### Thermal Radiation Equation

The relation given by Equation 3 is applicable to systems in which radiant exchange takes place between the surfaces of solids, as schemati-

$$q_r = \sigma A_1 F_A F_E (T_1^4 - T_2^4) \quad (3)$$

cally shown in Fig. 3. Gaseous and luminous radiation are not considered in this discussion. Equation 3 states that the net radiation per unit transfer area of surface 1,  $q_r/A$  Btu per (hour) (square foot), which sees surface 2 through a non-absorbing medium, is proportional to the difference of the

<sup>a</sup> Fluid properties should be evaluated at the arithmetic mean fluid temperature,  $t_f = (t_{\text{surface}} + t_{\text{fluid}}) / 2$ .

<sup>b</sup> These expressions are suitable approximations to longitudinal flow in other than right circular cylinders provided the hydraulic diameter is employed as the conduit dimension parameter. For non-circular cross sections, the hydraulic diameter is equal to four times the cross-sectional area divided by the wetted perimeter.

<sup>c</sup> For low rates of heat transfer by free convection the exponent decreases towards zero, and for higher rates, increases towards 0.33. The above equations employing an exponent equal to 0.25 are applicable in the intermediate range indicated.

## NOMENCLATURE AND DIMENSIONS FOR TABLE 2

$c_p$  = heat capacity at constant pressure, Btu per (pound) (Fahrenheit degree)  
 $D$  = cylinder diameter, feet.  
 $f$  = subscript denoting film.

$g$  = body force per unit mass, feet per hour per hour. (For static system on earth,  $g = 32.2 \times 3600^2$  feet per hour per hour.)

$G = 3600 u_{mp}$  = mass flow per unit cross-sectional area normal to flow, pounds per (hour) (square foot of flow cross-section).

$N_{Gr}$  = Grashof modulus, dimensionless ( $N_{Gr} = D^3 \rho^2 g \Delta t / \mu^2$ ).

$h_o$  = average unit thermal convective conductance from the leading edge of surface to the position  $x$ , Btu per (hour) (square foot) (Fahrenheit degree).

$h_{cx}$  = local unit thermal convective conductance, at the position  $x$  from the leading edge of surface, Btu per (hour) (square foot) (Fahrenheit degree).

$k$  = thermal conductivity, Btu per (hour) (square foot) (Fahrenheit degree per foot thickness).

$l$  = a dimension of the system, feet.

$m$  = a subscript denoting mean.

$P$  = pressure, atmospheres.

$P_o$  = pressure (atmospheric) atmospheres.

$t$  = temperature, Fahrenheit.

$T$  = temperature, Fahrenheit, absolute.

$u$  = fluid velocity, feet per second.

$V$  = volume, cubic feet.

$x$  = a dimension of the system, feet.

$\beta$  = coefficient of cubical expansion ( $\beta = \frac{1}{V} \left( \frac{dV}{dT} \right) \rho$ ); for perfect gases  $\beta = 1/T$ .

$\Delta t$  = difference between wall and fluid temperatures, Fahrenheit degrees.

$\mu$  = fluid viscosity, pounds per (hour) (foot).

$\rho$  = density, pounds per cubic foot.

$\infty$  = infinity, referring the quantity to a point not directly affected by the phenomenon in question.

<sup>a</sup> Emissivities of other materials may be found in Reference 4. <sup>\*</sup> Reflects about 3 percent.

fourth powers of the absolute surface temperatures ( $T_1^4 - T_2^4$ ). The proportionality factor ( $\sigma F_A F_E$ ) may be conveniently separated into three parts (excepting in some problems involving interreflections, where it is not possible to divide the product ( $F_A F_E$ ) into separate terms):

$\sigma$  = the Stefan-Boltzmann radiation constant =  $1730 \times 10^{-12}$  Btu per (hour) (square foot) (Fahrenheit degree absolute temperature to the fourth power).  
 $F_A$  = the geometrical factor which is dimensionless and  $\leq 1$ . This factor accounts for the shape and relative position of the two surfaces. The value of  $F_A = 1$  may be used in the cases of large parallel planes, long concentric cylinders or smaller bodies in large enclosures.

$F_E$  = the emissivity factor which is also dimensionless and  $\leq 1$ . This factor accounts for the absorption and emission characteristics of the surfaces for the

FIG. 3. RADIATION BETWEEN SURFACES

radiation which exists. Emissivities or absorptivities ( $\epsilon$ ) for many common surfaces, are given in Table 3. The value of  $F_g$  for large parallel planes, long concentric cylinders, or large enclosed bodies is  $1 + (1/\epsilon_1 + 1/\epsilon_2 - 1)$ .

The radiation under black-body conditions, or for an emissivity of 1.0, is given in Table 4<sup>7</sup> for cold surfaces as low as -39 F to warmer surfaces as high as 139 F. Some net radiation exchange solutions for several common radiation systems are given in Table 5.

There are several methods by which the geometrical factors  $F_A$  can be determined. One method involves the use of a mechanical geometrical integrator (Reference 8). Photographic and other methods are given in References 9 and 10.

#### Equivalent Conductance for Radiation

Although Equation 3 is a suitable equation for describing radiant exchange, it is not convenient for computations where other modes of energy transfer are operative. For such cases, it is convenient to define an equivalent conductance for radiation by the equation:

$$q_r = h_r A (t_1 - t_2) \quad (4)$$

FIG. 6. GEOMETRICAL FACTOR  $F$  FOR DIRECT RADIATION BETWEEN OPPOSED PARALLEL RECTANGLE AND DISCS OF EQUAL SIZE\*

\* From Radiant Heat Transmission, by H. C. Hottel (Mechanical Engineering, July 1930, pp. 700 to 702)

The conductance  $h_r$ , thus defined is a function of the shape-emissivity factor, as well as the temperatures of the radiator and receiver. Fig. 7 shows a plot of the equivalent conductance for two black bodies (i.e., with emissivities equal to unity) which exchange energy only with one another.

### Combined Convection and Radiation

It should be noted that the previous equations and tables give the heat transfer by convection and by radiation computed separately. In many practical cases it is desirable to treat convection and radiation as a single combined process, using a first-power equation:

$$q_{rc} = h_{rc} A (t_1 - t_2) \quad (5)$$

where  $q_{rc}$  is the total heat flow due to radiation and convection, in Btu per hour. Values of  $h_{rc}$ , the surface or film conductance for combined

FIG. 7. EQUIVALENT CONDUCTANCE FOR RADIATION BETWEEN TWO BLACK BODIES EXCHANGING ENERGY ONLY WITH ONE ANOTHER

radiation and convection, are given in Chapter 9, (Table 1 and Fig. 4). Complete tables for the combined heat transfer of steam and hot water radiators, pipes, coverings, etc., will be found in the appropriate chapters.

### HEAT-FLOW RESISTANCE

In most of the steady-state heat transfer problems encountered in air conditioning applications, more than one of the heat transfer mechanisms are effective, and the thermal current flows through several resistances in series or in parallel. In using the resistance concept, the calculations involved are analogous to the application of Ohm's Law in electricity, viz., the heat flow or thermal current is directly proportional to the thermal potential or temperature difference, and inversely proportional to the thermal resistance:

$$q_{rc} = \frac{t_1 - t_2}{R} \quad (6)$$

Following the electrical analogy, when there is a thermal current flowing through several *resistances in series*, the resistances are additive:

$$R_T = R_1 + R_2 + R_3 + \dots + R_n \quad (7)$$

Similarly, conductance is the reciprocal of resistance, and for heat flow through several *resistances in parallel*, the conductances are additive:

$$C_T = \frac{1}{R_T} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots + \frac{1}{R_n} \quad (8)$$

### Practical Heat Transfer Problems

The use of these relations for resistance and conductance makes possible the solution of many practical heat transfer problems. As discussed in Chapters 9, 28 and 36, the practical analyses of heat transfer in building walls, in fin-tube coils and in pipe coverings, are usually computed by this method. The same resistance analysis may be applied to complicated

FIG. 8. HEAT TRANSFER CONDITIONS IN AN INSULATED COLD WATER LINE

steady-state *conduction* problems. Table 6 gives the resistances in six common cases of steady-state conduction.

A complete analysis by the resistance method is well illustrated by considering the heat transfer from the air outside to the cold water inside of an insulated pipe. The temperature gradients and the nature of the resistance analysis are indicated by the two sketches of Fig. 8.

Since air is sensibly transparent to radiation, there will be some heat transfer by both radiation and convection to the outer insulation surface. The mechanisms act in parallel on the air side. The total transfer by radiation and convection then passes through the insulating layer and the pipe wall by thermal conduction, and thence by convection and radiation into main cold water streams. (Radiation is not significant on the water side as liquids are sensibly opaque to radiation, although water transmits energy in the visible region). The contact resistance between the insulation and the pipe wall is presumed to be equal to zero.

Referring to Fig. 8, the heat transferred for a given length  $N$  of pipe,  $q_{re}$ , Btu per hour, may be thought of as flowing through the parallel resistances  $R_i$  and  $R_o$ , associated with the insulation surface radiation and convection transfer. Then the flow is through the resistance offered to thermal conduction by the insulation,  $R_s$ , through the pipe wall resistance,

<sup>a</sup> The dimensions to be employed in these solutions are: length of dimension  $p$ ,  $L$ ,  $r$  = feet; units of  $k$  = Btu per (hour) (square foot) (Fahrenheit degree for one foot thickness); units of  $h$ , Btu per (hour) (square foot) (Fahrenheit degree); units of area,  $A$  = square feet.

<sup>b</sup> The thermal conductivity,  $k$ , in these solutions should be taken at the average material temperature.

<sup>c</sup>  $\log_e x = 2.303 \log_{10} x$ .

<sup>d</sup> This expression can also be employed as an approximation for tapered fins or of annular fins by employing average magnitudes of  $A$  and  $p$ .

<sup>e</sup>  $\tanh$  is the hyperbolic tangent.

$R_2$ , and into the water stream through the convection resistance,  $R_1$ . Note the analogy to the direct current electrical circuit problem. A temperature (potential) drop is required to overcome these resistances to the flow of thermal current. The total resistance to heat transfer,  $R_t$ , hour Fahrenheit degrees per Btu, is the summation of the individual resistances:

$$R_t = R_1 + R_2 + R_3 + R_4 \quad (9)$$

where the resultant parallel resistance  $R_4$  is obtained from

$$\frac{1}{R_4} = \frac{1}{R_r} + \frac{1}{R_o} \quad (10)$$

Provided the individual resistances may be evaluated, the total resistance can be obtained from this relation. Then the heat transfer for the length of pipe ( $N$ , ft) can be established by the relation

$$q_{re} \text{ (Btu per hour)} = \frac{(t_o - t_i)}{R_t} \quad (11)$$

For a unit length of the pipe the heat transfer rate is

$$\frac{q_{re}}{N} \text{ Btu per (hour) (foot)} = \frac{(t_o - t_i)}{R_t N} \quad (12)$$

The temperature drop,  $\Delta t$ , through an individual resistance may then be calculated from the relation:

$$\Delta t = R q_{re} \quad (13)$$

where  $R$  is the resistance in question.

The problem is now reduced to one of evaluating the individual resistances of the system. This entails suitable manipulation of the rate Equations 1, 2 and 3 to produce expressions of the form:

$$q = \frac{\Delta t}{R} \quad (14)$$

where  $q$  is the heat transfer rate, and  $\Delta t$  is the potential drop or temperature difference through the resistance  $R$ . Table 6 lists such solutions for six different conduction systems. Table 2 in Chapter 9 and Table 1 of this chapter indicate the magnitudes of the thermal conductivities,  $k$ , to be employed in the expressions of Table 6, after dividing  $k$  by 12.

The solution applicable to the problem depicted in Fig. 8, for the calculation of  $R_2$  and  $R_3$ , is case 2 in Table 6. Thus for a 1 ft length of 2 in. nominal size pipe (I. D. = 2.067 in., O. D. = 2.375 in.) insulated with 1 in. of material having a conductivity of 0.025:

$$R_2 = \frac{\log_e \frac{1.188}{1.033}}{2\pi \times 26 \times 1} = 8.5 \times 10^{-4} \text{ (hr) (F deg) per Btu.}$$

$$R_3 = \frac{\log_e \frac{2.188}{1.188}}{2\pi \times 0.025 \times 1} = 3.9 \text{ (hr) (F deg) per Btu.}$$

The convection resistances to heat transfer from the pipe wall to the cold water,  $R_1$ , and from the air to the surface of the insulating material,  $R_o$ , are dependent on the flow conditions prevailing at these surfaces, and on the thermal properties of the fluids. These resistances are also directly dependent upon the temperature distribution, and for this reason it is necessary first, to guess on the basis of the problem statement, a temperature distribution upon which to base the initial calculations. Since the values of  $h_o$  for heat transfer between water and pipe walls are relatively high in this temperature range, it is logical to assume only a small temperature difference between the temperature of the fluid body and the temperature of the pipe wall. For the purpose of an initial guess, this temperature difference will be assumed to be 2 deg. On the other hand,  $h_o$  for heat transfer from air to a body is relatively small, and a higher temperature difference would be expected between these masses. The value initially assumed here will be 20 deg. In summary, the temperature distribution in the system is assumed as follows:

Fluid temperature = 34 F.

Inner pipe wall temperature = 36 F.

Outer insulation surface temperature = 100 F.

Ambient air temperature = 120 F.

With these assumptions and the problem statement, it is now possible to calculate values for the convective resistances. If it is found in the ultimate solution of the problem that the temperature distribution is different from that assumed, it will then be necessary to repeat the solution procedure.

If reference now be made to Table 2, it is found that Case 3 of this table is a system similar to that encountered in the convection between the water and the pipe wall. The equation for this case is the following:

$$h_o = 13.9(t_o)^{0.44} \frac{u_m^{0.8}}{D^{0.2}} \quad (15)$$

where

$$u_m = 5 \text{ fps}$$

$$D = \frac{2.067}{12} = 0.1725 \text{ ft}$$

$$t_i = \frac{34 + 36}{2} = 35 \text{ F}$$

$$h_o = \frac{13.9 \times 6.9 \times 3.62}{0.703} = 494 \text{ Btu per (hr) (sq ft) (F deg).}$$

This heat transfer rate is through the inner surface of the pipe and it is, therefore, this area that determines the resistance  $R_1$ .

$$A = \pi D = 0.542 \text{ sq ft per unit length of pipe,}$$

and therefore

$$R_1 = \frac{1}{h_o A} = \frac{1}{494 \times 0.542}$$

$$R_1 = 3.73 \times 10^{-4} \text{ (hr) (F deg) per Btu.}$$

Case 11 of Table 2 fits the conditions of the problem if only free convection heating of the pipe is assumed. The equation in this case is as follows:

$$h_c = 0.271 \left( \frac{P}{P_o} \right)^{0.5} \left( \frac{\Delta t}{D} \right)^{0.25} \quad (16)$$

where

$$\begin{aligned} \Delta t &= 20 \text{ F} \\ D &= 0.364 \text{ ft} \\ P &= P_o = \text{one atmosphere} \end{aligned}$$

therefore,

$$\begin{aligned} h_c &= 0.271 \left( \frac{20}{0.364} \right)^{0.25} \\ h_c &= 0.737 \text{ Btu per (hr) (sq ft) (F deg).} \end{aligned}$$

Using the surface area of the insulation, the value of the resistance per unit length is determined.

$$A = \pi \left( \frac{4.375}{12} \right) \times 1 = 1.14 \text{ sq ft}$$

$$R_c = \frac{1}{h_c A} = \frac{1}{0.737 \times 1.14}$$

$$R_c = 1.19 \text{ (hr) (F deg) per Btu.}$$

This result may not be deemed conservative inasmuch as the expression is for still air. If, however, the air is not still, but flows at approximately 5 mph or 7 fps, the heat transfer equation for forced convection would apply. This equation is Case 5 of Table 2.

$$h_{c(\text{average})} = 0.211 (T_f)^{0.4} \frac{(u_{\infty} \rho)^{0.5}}{D^{0.4}} \quad (17)$$

$$T_f = \frac{100 + 120}{2} + 460 = 570 \text{ Rankine (Fahrenheit absolute)}$$

$$u_{\infty} = 7 \text{ fps}$$

$$\rho = 0.076 \left( \frac{520}{570} \right) = 0.0694 \text{ lb per cu ft}$$

$$D = 0.364 \text{ ft}$$

$$h_{c(\text{average})} = \frac{0.211(570)^{0.4}(7 \times 0.0694)^{0.5}}{(0.364)^{0.4}}$$

$$h_{c(\text{average})} = 2.73 \text{ Btu per (hr) (sq ft) (F deg)}$$

and

$$R_c (\text{Forced Convection}) = \frac{1}{h_c A} = \frac{1}{2.73 \times 1.14}$$

$$R_c = 0.321 \text{ (hr) (F deg) per Btu.}$$

The radiation resistance,  $R_r$ , which acts in parallel with the resistance just calculated, can be computed with the aid of Fig. 7. The pipe wall, assumed at 100 F sees the surroundings at 120 F. If these two tempera-

tures are used with Fig. 7, a value for  $\frac{h_r}{F_A F_E}$  is determined directly.

$$\frac{h_r}{F_A F_E} = 1.4 \text{ Btu per (hr) (F deg) (sq ft).}$$

The angle factor,  $F_A$ , is unity, and for an estimated surface emissivity of 0.95 (see Table 3),  $F_E = 0.95$ . Therefore,

$$h_r = 1.4 F_A F_E = 1.4 \times 1 \times 0.95$$

$$h_r = 1.33 \text{ Btu per (hr) (F deg) (sq ft)}$$

and the radiation resistance,  $R_r$ , is then the following:

$$R_r = \frac{1}{h_r A} = \frac{1}{1.33 \times 1.14}$$

$$R_r = 0.659 \text{ (hr) (F deg) per Btu.}$$

The resultant resistance of  $R_c$  and  $R_r$  acting in parallel (see Fig. 8) can now be evaluated as:

$$\frac{1}{R_t} = \frac{1}{R_c} + \frac{1}{R_r} = \frac{1}{0.321} + \frac{1}{0.659} = 4.54 \text{ Btu per (hr) (F deg)}$$

$$R_t = 0.216 \text{ (hr) (F deg) per Btu.}$$

The overall resistance,  $R_T$ , surroundings to cold water, is the sum of  $R_1 + R_2 + R_3 + R_t = 4.12 \text{ (hr) (F deg) per Btu}$  for 1-ft length of pipe. Note that the controlling resistances are  $R_3$  and  $R_t$ , and that neglect of both  $R_1$  and  $R_2$  would not significantly influence the total resistance,  $R_T$ .

On the basis of this resistance calculation, the heat transfer from the surroundings to the cold water may be evaluated as:

$$\frac{q_{rc}}{N} = \frac{t_o - t_i}{R_T} = \frac{120 - 34}{4.12} = 20.8 \text{ Btu per (hr) (ft)}$$

or about 0.175 tons of refrigeration per 100 ft of pipe.

Since the calculation is based on a 1-ft pipe length,

$$q_{rc} = 20.8 \text{ Btu per hr.}$$

The temperature drops through the various resistances are now readily evaluated by Equation 14 as:

$$\Delta t = qR$$

$$t_o - t_{a3} (\text{air to insulation surface}) = qR_4 = 20.8 \times 0.216 = 4.49 \text{ F deg}$$

$$t_{a3} - t_{a2} (\text{through the insulation}) = qR_3 = 20.8 \times 3.9 = 81.2 \text{ F deg}$$

$$t_{a2} - t_{a1} (\text{through the pipe wall}) = qR_2 = 20.8 \times 8.5 \times 10^{-4} = 0.018 \text{ F deg}$$

$$t_{a1} - t_i (\text{pipe wall to cold water}) = qR_1 = 20.8 \times 3.73 \times 10^{-3} = 0.078 \text{ F deg}$$

This solution was obtained on the temperature distribution assumptions initially made. It is apparent that a better solution could be obtained if the whole problem were reiterated using the temperature distribution just calculated.

## PERIODIC AND TRANSIENT HEAT FLOW

The foregoing data and examples dealt with steady-state heat transfer (not varying with time). In most practical heat transfer problems the heat flow depends upon time. Such cases can usually be divided into two classes: periodic and transient. Periodic heat transfer repeats periodically in time. Transient heat transfer exhibits no periodicity. Graphical, analytical and numerical methods are available for solving transient or periodic heat flow problems.<sup>4,5,10,11,12</sup> Graphical and numerical methods are the most versatile, and can be applied with minimum mathematical training.

A large number of analytical solutions for the case of heat conduction in variously shaped solids are available in the literature. Table 7 gives a

FIG. 9. EXAMPLE OF A GRAPHICAL SOLUTION TO A PROBLEM IN TRANSIENT HEAT CONDUCTION.

summary of the cases reported and tabulated. Many more analytical solutions are available in the form of infinite series,<sup>11,12,18,19</sup> but are not tabulated. Certain complex cases may be treated by combining the simple analytical solutions as discussed in Reference 17. (See also Reference 20).

Frequently, transient heat flow problems in one dimension have boundary conditions which make the problem difficult to treat analytically. In such cases, recourse may be made to a graphical method of solution sometimes called the Schmidt method.<sup>4,10,19,21,22</sup> This method will be briefly outlined for the case of transient heat flow in a slab insulated on one face, and suddenly exposed on the other face through a fixed thermal resistance to a higher temperature. The technique is general, however, and methods may be devised for any boundary conditions<sup>5,21</sup> and also, for one dimensional (radial) heat flow in spheres and cylinders.<sup>22,23</sup>

|                                                                                                                                                |                                                                                                        | Heat flow at the surface as a function of time.<br>Reference: (10) p. 267.                                                         |

Consider the slab to be divided, as shown in Fig. 9, by  $n$  equidistant planes parallel to the slab surface and a distance  $\Delta x$  apart. Let the temperature of the slab at any plane and any time ( $\theta$ ) be denoted by  $T_{x,\theta}$ . Then the temperature of the slab at the two adjacent planes at the same

time will be denoted as  $T_{(x+\Delta x,\theta)}$  and  $T_{(x-\Delta x,\theta)}$ . In a similar manner the temperature of the  $x$  plane at a time  $\Delta\theta$  later will be  $T_{(x,\theta+\Delta\theta)}$ .

In accordance with this nomenclature, the temperature at any plane  $x$  and time  $\theta + \Delta\theta$  is given as

$$T_{(x,\theta+\Delta\theta)} = \frac{T_{(x+\Delta x,\theta)} + T_{(x-\Delta x,\theta)}}{2} \quad (18)$$

which may be interpreted as follows. The temperature of the slab at any plane,  $x$ , and any time,  $\theta$ , is equal to the average temperature of the two adjacent planes obtained at the time  $(\theta - \Delta\theta)$ .

The time interval  $\Delta\theta$  is determined by the equation

$$\Delta\theta = \frac{\Delta x^2}{2a} \quad (19)$$

Omitting the graphical construction at the slab boundaries, reference to Fig. 9 demonstrates the graphical method by means of which the temperature at each plane is determined at successive intervals of time in accordance with Equation 18.

For the problem stated, the boundary condition at the insulated surface is specified by the equation

$$\frac{\partial T}{\partial x} = 0$$

and at the uninsulated face by the equation

$$h(T_\infty - T) = -k \frac{\partial T}{\partial x}$$

In terms of finite differences these two equations (employing nomenclature established by Fig. 9) become.

$$\frac{T_F - T_E}{\Delta x} = 0 \quad \text{or} \quad T_F = T_E \quad \text{at} \quad x = L$$

and

$$h(T_\infty - T_A) = -k \frac{(T_B - T_A)}{\Delta x} \quad \text{at} \quad x = 0$$

or

$$\frac{T_\infty - T_A}{k/h} = - \frac{T_A - T_B}{\Delta x}$$

The details of the graphical construction are best obtained by inspection of Fig. 9. Note that the line  $(0,0,0')$  used to initiate the graphical construction, is the only one drawn to the slab boundary  $A'$ . The numbered points indicate temperatures at the sub-slab boundaries at 1,2,3, etc., time intervals  $(\Delta\theta)$  after the slab is exposed to the high temperature.

For transient heat flow in two dimensions, and also, for steady state conduction, numerical methods of solution are available in the literature.<sup>5,10,12,19</sup> These numerical methods are applicable to three dimensional problems, although the calculations involved normally become too tedious for most applications of the method. An additional technique of solution for one and two dimensional problems in transient conduction results from

the analogy of electrical resistance-capacitance networks to thermal systems.<sup>24</sup>

For two dimensional problems in steady state conduction, additional techniques of solution are found in flux plotting,<sup>5,19</sup> and in the use of a potential tank.<sup>5,19</sup> These methods are of most direct use in problems in which the boundaries of the two dimensional shape are made up of isothermal and adiabatic surfaces.

## CHAPTER 6 PHYSIOLOGICAL PRINCIPLES

Chemical Vitiating of Air, Physical Impurities in Air, Thermal Interchanges Between the Body and Its Environment, High Temperature Hazards, Acclimatization, Upper Limits of Heat for Men at Work, Application of Physiologic Principles to Air Conditioning Problems, Effective Temperature Index and Comfort Zones

**V**ENTILATION is defined in part as *the process of supplying air to, or removing air from, any space by natural or mechanical means*. The word in itself implies quantity, but air must be of the proper quality also. The term *air conditioning* in its broadest sense implies control of any or all of the physical or chemical qualities of the air. The A.S.H.V.E. Code of Minimum Requirements for Comfort Air Conditioning<sup>1</sup> defines it "as the process by which simultaneously the temperature, moisture content, movement and quality of the air in enclosed spaces intended for human occupancy may be maintained within required limits. If an installation cannot perform all of these functions, it shall be designated by a name that describes only the function or functions performed."

### CHEMICAL VITIATION OF AIR

People living indoors bring about certain physical and chemical changes in the air about them. The oxygen content of the air diminishes and the carbon dioxide increases, but these changes are too slight to be significant except in air tight spaces as in submarines. Organic matter which is usually perceived as odors, comes from the body or clothes. Moisture and heat are given off by the body. There is no evidence of any toxic volatile material given off by man to the ambient air. Stale air may be offensive because of odors and may induce loss of appetite and loss of energy. Objectionable body odors have the same effects. These reasons, whether esthetic or physiological, usually make it desirable in the design of air conditioning systems to provide for the elimination or control of odors arising from occupancy, cooking, or other sources. This may be accomplished by introducing odor-free air in sufficient quantities to reduce odor concentrations by dilution to a level which is not objectionable. Odor-free air may be outdoor air or air which has been cleared of odors by sorption, washing, or other appropriate means.

In the case of vitiating by a few hazardous gases such as carbon monoxide from heating, cooking, and certain industrial processes, no satisfactory chemical treatment for the elimination of the impurity has been found. The only satisfactory solution is elimination at the source by local exhaust ventilation; or, if this is impossible, reduction to a safe concentration by dilution. (See Chapter 8.) In the case of contamination by other matter, including volatile vapors and gases, chemical treatment for the removal or reduction of the impurities has been made available through air cleaning methods, which are discussed in Chapter 34.

When the only source of contamination is the human occupant, and overheating is not a problem, the minimum quantity of outdoor air needed appears to be that required to remove objectionable body odors, or tobacco smoke. The concentration of body odor in a room, in turn, depends

upon a number of factors, including the dietary and hygienic habits of the occupants (frequently reflecting their socio-economic status), the outdoor air supply, air space allowed per person, odor adsorbing capacity of air conditioning processes, and temperature and relative humidity. The intensity of odor sensation has been found to vary as the logarithm of the concentration of the odoriferous substance in the air, or inversely with the logarithmic function of the amount of outdoor air supplied and the air space per person.

The relation between air supply and occupancy has been reported by the Harvard School of Public Health<sup>2</sup> (Table 1) and the A.S.H.A.E. Research Laboratory.<sup>3</sup> Outdoor air requirements for removal of objectionable tobacco smoke odors are not accurately known, but available information and current practice indicate the need of 15 cfm per person or more.<sup>4</sup>

The total quantity of outdoor air to be circulated through an enclosure is often governed chiefly by physical considerations for controlling temperature, air distribution, and air velocity. Other factors which must be taken into consideration, include the type and usage of the building, locality, climate, height of rooms, floor area, window area, extent of occupancy, and the operation of the system distributing the air supply. Frequently, some of these factors, particularly the need for air movement and good distribution, may be satisfied by recirculation of inside air rather than outside air.

It will be noted that, with adequate air space, the rate of air change indicated in Table 1 is from 4 to 30 cfm per person. In rooms occupied by only a few persons, such an air change will be automatically attained in cold weather by normal leakage around doors and windows, and can easily be secured in warm weather by the opening of windows. With a space allotment of 400 cu ft per person, only  $1\frac{1}{2}$  air changes per hour are necessary to provide a ventilation rate of 10 cfm per person.

Therefore, in the ordinary dwelling with adequate cubic space allotment, no special provision for controlling chemical purity of the air is necessary (aside from removal of fumes from heating appliances). For such conditions, the control of air temperature is the major consideration.

In more crowded rooms (large offices, large workrooms, auditoriums), where the cubic space per person is less and it is usually impossible to admit untempered outside air without creating drafts, mechanical ventilation is essential.

The present data regarding the effect of cubic space on outdoor air requirements are not universally accepted. The Code of Minimum Requirements for Comfort Air Conditioning<sup>1</sup> prescribes definite minimum requirements which should be familiar to the designing engineer. It should be emphasized, however, that the code fixes *minimum*, rather than *adequate* requirements. (See also Tables 1 and 3 of Chapter 13.)

Notwithstanding the rapid advance made in air conditioning, some persons still believe there is a stimulating quality in outdoor air (particularly country, mountain and seashore air) under ideal weather conditions, which is lacking in artificially conditioned air. It is apparent, however, that modern air conditioning insures control of the phenomena of nature for the service and comfort of man independently of weather conditions. Freedom of movement, action and thought, together with the variability of stimuli experienced by persons under ideal conditions in the country, mountains or seashore, undoubtedly has some stimulating effect. Various experimenters have attempted to duplicate the invigorating qualities of

outdoor air by the use of ozone, ionization, or ultra-violet light, but results to date have been inconclusive or negative.<sup>6</sup>

Ozone in amounts of 0.01 to 0.05 ppm of air is allowable in comfort air conditioning. Above this limit there is a pungent, unpleasant odor and perhaps respiratory distress, depression, and stupor.<sup>6</sup>

## PHYSICAL IMPURITIES IN AIR

Dust particles of almost any type can produce irritation of the mucous membranes of the nose and throat, if present in high concentrations. Certain dusts may be very harmful, but coal dust is tolerated well. The effects of various industrial dusts, pollens, etc., are discussed in Chapter 8.

A certain part of the dissemination of disease in confined spaces may be due to pathogenic organisms floating in the air like dust particles. (See Chapter 7.)

While in some instances it may be possible to reduce the physical impurities of the air by dilution from a non-contaminated source, such a source is rarely available. Frequently, outdoor air contains a higher concentration of physical impurities than indoor air. Therefore, it is usually desirable to reduce the concentration of physical impurities by air cleaning methods. (See Chapter 34.)

## THERMAL INTERCHANGES WITH ENVIRONMENT

Body temperature depends upon the balance between heat production and heat loss. Heat resulting from oxidation in the body (metabolism)

maintains the body temperature well above that of the surrounding air in a cool or cold environment. At the same time, heat is constantly lost from the body by radiation, convection and evaporation. Since, under ordinary conditions, the body temperature is maintained at its normal level of about 98.6 F, the heat production must be balanced by the heat loss. During work, the body temperature may rise; in fact, afternoon temperatures of normal persons average 1 deg above the resting value of the morning whether working or not.

The fundamental thermodynamic processes concerned in heat interchanges between the body and its environment may be described by the equation:

$$M = \pm S + E \pm R \pm C \quad (1)$$

where

- $M$  = rate of metabolism, heat produced within the body.
- $S$  = rate of storage, change in intrinsic body heat.
- $E$  = rate of evaporative heat loss.
- $R$  = rate of radiative heat loss or gain.
- $C$  = rate of convective heat loss or gain.

The rate of metabolism,  $M$ , is always positive. The storage,  $S$ , may be either positive or negative, depending upon whether heat is being stored or depleted owing to a rise or fall in body temperature. Under ordinary circumstances (when the dew-point of the air is below the body surface temperature) the evaporation loss,  $E$ , is always positive; that is, heat from metabolism supplies this loss.  $R$  and  $C$  are positive when body surface temperature is above that of walls and air, and negative when it is below.

DuBois,<sup>7</sup> after careful calorimeter studies on a fasting, nude man, plotted the partition of body heat loss and heat production as a function of temperature. Fig. 1 shows some disparity between heat production and heat loss. This disparity is  $S$  in Equation 1. In the central range of the experiments  $S$  was quite low and no increase in heat loss by vaporization was apparent.

Within the range of 81-86 F air temperature, with still air, there is, for a resting nude man, a point at which his body has to take no particular action to maintain its heat balance. If he is clothed, or if he is active, this point will naturally lie at a lower level. At this point, which may be termed the *neutral point* for that individual, conditions are neither too hot nor too cold. If, through a fall in air temperature, or a rise in air movement, the rate of heat loss from the skin to the environment is increased, then the body must do something to counteract this heat loss. Over a certain range, the body can achieve this by decreasing the flow of blood through the skin. This will result in some cooling of the skin and subjacent tissues, but the temperature of the deep tissues will be preserved. The range of external conditions over which this may be achieved, may be termed the *zone of vaso-motor regulation against cold*. Beyond this range, the temperature of the superficial tissues will fall still further, and that of the deep tissues will fall as well, unless some other steps are taken. The body normally does react; it increases heat production by increasing muscular tension, by shivering, or by spontaneous increase in activity.<sup>8</sup> As long as these are adequate to meet the increased rate of heat loss to the environment, a fall in deep body temperature may be prevented. Such conditions may be said to lie in the *zone of metabolic regulation against cold*. Beyond

this point, the body enters the *zone of inevitable body cooling*. Once body temperature starts to fall, man is headed for disaster.

It will be seen that, in man, deep body temperature is preserved over an important range of cold external conditions, at the expense of (1) a fall in the temperature of the peripheral tissues, and (2) an increased expenditure of energy. As regards the first of these, the farther away superficial tissue lies from the central body mass, the more readily will its temperature fall.

On the hot side of the neutral point, there exists a *zone of vaso-motor regulation against heat*, corresponding to that against cold. The blood flow through the skin is increased when the opportunities for heat loss to the environment are restricted.<sup>9</sup> This increase in blood flow may double the conductance of the superficial tissues over that characteristic of the neutral point, and the temperature of the skin surface may rise until it is only three degrees below that of the deep tissues. If this increase in blood flow is

FIG. 1. HEAT LOSS FROM HUMAN BEING BY EVAPORATION, RADIATION, AND CONVECTION<sup>a</sup>

<sup>a</sup> Normal control, naked, in calorimeter at temperatures from 72.8 to 94.1 F. First column in each experiment represents heat production as determined by indirect calorimetry, the second column, heat elimination. The portion marked with vertical lines represents vaporization; the dotted area, convection; the unmarked area, radiation. The skin temperature represents the average reading of 18 spots on the surface.

unable to balance the restriction in heat loss, the body has entered the next zone. Once again, the normal body takes steps to prevent a change in its deep temperature; but they are not the counterpart of the steps taken under similar circumstances on the cold side. There is, in fact, very little change in heat production, beyond that resulting from a disinclination for exertion. The second line of defense, on the hot side, is a new and powerful method of promoting heat loss—the provision of water, by the operation of the sweat glands, for evaporative cooling. As long as evaporation is adequate to restore the desired heat loss, the body is in the *zone of evaporative regulation against heat*. When this ceases to be adequate, the body is in the *zone of inevitable body heating*. The body enjoys a little more latitude in this zone than it did in the corresponding zone on the cold side, but when the deep temperature rises more than 4 deg F, it loses its efficiency. All factors which affect the evaporation of water from the skin affect heat regulation in the zone of evaporative regulation. Atmospheric vapor pressure

and air motion are most important. With dry-bulb temperature above body temperature, air motion facilitates evaporative heat loss by removing hot humid air from contact with the skin and replacing it with relatively drier air.

Heat regulation in man requires an intact set of sensory nerves, a normal sympathetic nerve supply to sweat glands and blood vessels, a great many sweat glands, and a circulatory system capable of carrying heat from muscles and viscera to the skin by circulation of the blood.

Some of the phenomena of body temperature control are shown graphically in Fig. 2. The dotted curves, from a study at the John B. Pierce Laboratory of Hygiene,<sup>10</sup> are for subjects lightly clothed in a semi-reclining position, and give the relation between the dry-bulb temperature of the environment (with about 45 percent relative humidity) and the metabolic

FIG. 2. RELATION BETWEEN METABOLISM, STORAGE, EVAPORATION, RADIATION PLUS CONVECTION, AND TEMPERATURE FOR THE CLOTHED SUBJECT

rate (heat production), the rate of heat dissipation by radiation and convection combined, and the latent heat loss due to evaporation from the skin and the respiratory tract. The smooth line curves from the work of the A.S.H.A.E. Research Laboratory<sup>11</sup> give the same relationships for healthy, male subjects (18 to 24 years of age), seated at rest and dressed in customary winter indoor clothing. The Pierce Laboratory data for the semi-reclining subjects also include the rate of heat storage (either positive or negative) due to a rise or fall in body temperature. For the normally clothed subjects, a curve gives the total heat loss (that is, the sum of the radiation, convection and evaporative losses). Here, storage is given by the difference between the metabolism and total heat loss.

The small difference between the metabolic rates for the two groups of subjects may be accounted for by difference in activity. Heat exchange between the body and the environment by radiation and convection is greater for the lightly clothed subject, both for cool conditions where there is excessive heat loss, and for very warm conditions where there is transfer of heat from the atmosphere to the body. The two curves for

evaporative loss serve to show how physiological control uses evaporation of sweat to maintain equilibrium at high temperatures. Below 75 F, for the normally clothed subject, and below 85 F for the lightly clothed subject, evaporation loss is minimal and constant. Burch<sup>12</sup> has shown that this insensible perspiration reflects the permeability of the skin to the moisture of the body. Above these temperatures, control is obtained by the availability of sweat for evaporation. The difference in the curves above 75 F is probably largely determined by the difference in clothing and activity.

In the zone of evaporative heat regulation, air movement facilitates heat loss if the temperature of the air is not above that of the skin.<sup>13</sup> Under hot, dry conditions air movement may be of little advantage, or even of disadvantage, if it increases the addition of heat to the skin by conduction more than it promotes the loss of heat from the skin by evaporation.

## HIGH TEMPERATURE HAZARDS

Studies at the A.S.H.A.E. Research Laboratory<sup>14</sup> and elsewhere during the past two decades have made available much information dealing with the physiological effects of hot atmospheres on workers, and means of alleviating the distress and hazards associated therewith. Table 2 gives some of the physiological responses of men, at rest and at work, to hot environments. Frequent and continued exposure of workers to hot environments results in physiological derangement affecting the leucocyte count of the blood, and other factors dealing with man's mechanism of defense against infection.

Wherever *S* (Equation 1) becomes strongly positive and body temperature rises progressively, men will continue to work until body temperature reaches 103 F. When these body temperatures are exceeded, men work with declining efficiency and may be subject to heat stroke.

Heat exhaustion is a circulatory failure in which the venous return to the heart is reduced so that fainting results.<sup>15</sup> Early symptoms of heat exhaustion may include fatigue, headache, dizziness when erect, loss of appetite, nausea, abdominal distress, vomiting, shortness of breath, flushing of face and neck, pulse rate above 150, glazed eyes, and mental dis-

TABLE 3. UPPER LIMITS OF ENVIRONMENTAL CONDITIONS FOR ACCLIMATIZED, HEALTHY, YOUNG MEN IN MILITARY SERVICE

| ENVIRONMENT           | REACTIONS AT THE END OF 4 HR |            |
|-----------------------|------------------------------|------------|
|                       | Rectal Temp F                | Pulse rate |
| Relatively Easy ..... | Below 101                    | Below 130  |
| Difficult .....       | 101 to 102                   | 130 to 145 |
| Impossible .....      | Above 102                    | Over 145   |

turbances as apathy, poor judgment, and irritability which usually precede fainting (syncope). Recovery is usually prompt when the man is removed to a cool place and kept lying down for a time, unless he has some other illness such as heart disease.

Heat cramps are painful muscle spasms in extremities, back and abdomen due, at least in part, to excessive loss of salt in sweating. Formerly common in hot industries, this manifestation of illness due to heat is now greatly reduced by drinking water containing 0.1 percent salt, or by proper use of salt tablets. Heat cramps are readily alleviated by administration of salt solution intravenously.

Heat stroke is a serious effect of exposure to great heat. The body temperature climbs rapidly to excessive levels often above 105 F when for unknown reasons free sweating suddenly stops. At such high temperatures, coma appears and death may be imminent. Emergency measures are required to reduce the excessive body temperature by cooling quickly to avoid irreparable damage to the brain.<sup>16</sup>

The deleterious physiologic effects of high temperatures exert a powerful influence upon physical activity, accidents, sickness and mortality. Both laboratory and field data show that physical work in warm atmospheres is a great effort, and that production falls progressively as the temperature rises.

### ACCLIMATIZATION

When men move to deserts or to jungles some adaptation to the climate takes place. If work is gradually increased day by day, and if the men can get plenty of water and salt, and can sleep each night, acclimatization may be complete in 7 to 10 days. The acclimatized man works with a lower heart rate, lower skin and rectal temperature, and more stable blood pressure than when unacclimatized. The process of acclimatization requires work in the heat.<sup>17</sup> During the recent war, white troops lived and did hard physical work for long periods in tropical conditions when disease hazards were controlled.

In recent tests made at the A.S.H.A.E. Research Laboratory,<sup>18</sup> subjects were required to perform light work under very hot conditions for a 4-hr period each day. It was found that the ability of a new subject to endure these conditions showed daily improvement for a period of at least 2 weeks. However, after acclimatization was completed, a recess of several days had no effect on the endurance of the subject. Individuals differ widely in their capacity to acclimatize. Acclimatized men lose most of these improvements in a few weeks of temperate climate, even though they are vigorously active. In the course of acclimatization, the sweat glands come to secrete fluid less rich in salt.<sup>19</sup> For all except those carrying out really hard work in hot, dry atmospheres, this effects an important saving in

FIG. 3. HEAT ENDURANCE OF ACCLIMATIZED SUBJECTS WORKING AT A SPECIFIC RATE<sup>20</sup>

salt loss, and makes all the difference between being exposed and not being exposed to the risk of heat cramps.

The adaptive level changes somewhat with the season. There are also marked differences between the sexes. In the cold zone the thickness of thermal insulating tissues of women is almost double that of men, although the sensory responses to cold are similar. In the hot zone, the threshold of sweating is higher for women. The thickness and insulating value of the clothing worn are also important factors in the determination of the comfort level.

### UPPER LIMITS OF HEAT FOR MEN AT WORK

In very hot conditions humidity is the limiting factor, and the wet-bulb temperature assumes great importance. In 1905 Haldane recognized that 88 F wet-bulb was the limit of endurance for coal miners, and later observers have concurred.

A study was made at the Armored Medical Research Laboratory<sup>20</sup> to determine the upper limits of environmental conditions under which a man can perform certain work. Thirteen enlisted men, thoroughly acclimatized to the hot conditions, served as subjects. During each test, the subjects were required to march for 4 hr at the rate of 3 mph, carrying

FIG. 4. EFFECT OF MRT ELEVATION IN TERMS OF EFFECTIVE TEMPERATURE

20 lb packs under a wide range of environmental conditions which were rated as relatively easy, difficult, and impossible, on the basis of the physiological reactions of the subjects at the end of the 4-hr period as shown in Table 3 and Fig. 3.

Recognition of the need of air conditioning for workers in hot industries is growing rapidly. The choice of the type of system to be used in any given instance, must be determined by the air conditioning engineer after a study of conditions. In some hot industries where few workers are

FIG. 5. RELATION BETWEEN TOTAL HEAT LOSS FROM THE HUMAN BODY AND EFFECTIVE TEMPERATURE FOR STILL AIR<sup>14</sup>

\* Curve A—Persons working, metabolic rate 1310 Btu per hour. Curve B—Persons working, metabolic rate 850 Btu per hour. Curve C—Persons working, metabolic rate 660 Btu per hour. Curve D—Persons seated at rest, metabolic rate of 400 Btu per hour. Curves B and D based on test data covering a wide temperature range. All curves are averages of values for high and low relative humidities; variation due to humidity is small.

engaged in large spaces the worker himself, rather than the atmosphere, can be cooled by placing him in a small booth, and blowing cooled air over him, or by circulating cooled air through a loose-fitting suit.<sup>21</sup>

The A.S.H.A.E. Laboratory has studied the effects of walls of higher temperature than the air.<sup>18</sup> The findings are in part shown in Fig. 4. It will be seen that the importance of mean radiant temperature, as compared with that of the effective temperature, decreases as the effective temperature rises; and also, to a certain extent, as the mean radiant temperature itself rises. The lower of the two curves relates to conditions in which the MRT was kept approximately at the level of the DBT. If this curve is followed, it will be seen that, at 80 ET, a little more than 1 deg

rise in MRT produces the same effect as 1 deg rise in ET; but when the ET is 92 deg, it takes a rise of 11 F deg in the MRT to produce the same effect as 1 deg rise in ET. The upper curve relates to conditions in which the MRT was kept about 40 F deg higher than the DBT. It will be seen that under these conditions, a rise in MRT is less effective, even at low values of ET; and that it loses its relative effectiveness more rapidly as the ET rises. It should not be assumed, however, that MRT does not matter much. All that these comparisons indicate is that unit rise in MRT becomes less important as compared with unit rise in ET, as conditions get hotter. This may be due more to a growing importance of unit rise in ET than to a diminishing importance of unit rise in MRT. Under ordinary still air conditions the effects of air temperature and MRT appear to be interdependent. Various authorities give 0.3 to 1 deg increase of room temperature to compensate for 1 deg depression of the MRT.

FIG. 6. RELATION BETWEEN RADIATION AND CONVECTION LOSS FROM THE HUMAN BODY AND DRY-BULB TEMPERATURE FOR STILL AIR<sup>14</sup>

\* See footnote a, Fig. 5.

### APPLICATION OF PHYSIOLOGIC PRINCIPLES TO AIR CONDITIONING PROBLEMS

In order to estimate cooling loads in occupied spaces it is necessary to know the metabolic rate (heat production) of man. This has been studied extensively, and found to remain relatively constant per unit of body surface area in a subject fasting and resting quietly after a good night's sleep. The rate is high in children, and diminishes gradually with age; it increases in certain diseases and in the presence of fever. The metabolic rate is somewhat lower in women. Heat production goes up sharply with work and varies widely in different persons doing the same work. Figs. 5, 6, and 7 and Table 25 of Chapter 13 give sufficient basic data for estimating heat production and heat loss under various conditions.

## EFFECTIVE TEMPERATURE INDEX AND COMFORT ZONES

There is no precise physiologic observation by which comfort can be evaluated. Mean skin temperature offers some promise. The zone of thermal neutrality differs with clothing, season, activity, and all the other factors controlling heat production (Table 4). The comfort zone is very similar to the zone of thermal neutrality.

Sensations of warmth or cold depend not only on the temperature of the surrounding air as registered by a dry-bulb thermometer, but also upon the temperature indicated by a wet-bulb thermometer, upon air movement, and upon radiation effects. Dry air at a relatively high temperature may feel cooler than air of lower temperature with a high moisture content. Air motion makes any moderate condition feel cooler. Radiation to cold or from warm surfaces is another important factor under certain conditions affecting the comfort reaction of the individual.

Fig. 7. EVAPORATIVE HEAT AND MOISTURE LOSS FROM THE HUMAN BODY IN RELATION TO DRY-BULB TEMPERATURE FOR STILL AIR CONDITIONS<sup>14</sup>

<sup>14</sup> See footnote a, Fig. 5.

Combinations of temperature, humidity, and air movement which induce the same feeling of warmth are called thermo-equivalent conditions. A series of studies<sup>22</sup> at the A.S.H.A.E. Research Laboratory established the equivalent conditions for practical use. This scale of thermo-equivalent conditions not only indicates the sensation of warmth, but also to a considerable degree determines the physiological effects on the body induced by heat or cold. For this reason, it is called the *effective temperature* scale or index, and it denotes sensory heat level.

*Effective temperature* is an empirically determined index of the degree of warmth perceived on exposure to different combinations of temperature, humidity, and air movement. It was determined by trained subjects who compared the relative warmth of various air conditions in two adjoining conditioned rooms by passing back and forth from one room to the other.

The numerical value of the index for any given air conditions is fixed by the temperature of slowly moving (15 to 25 fpm air movement) saturated

air which induces a like sensation of warmth or cold. Thus, any air condition has an effective temperature of 60 deg when it induces a sensation of warmth like that experienced in slowly moving air at 60 F saturated with moisture. The *effective temperature index* cannot be measured directly, but is determined from dry- and wet-bulb temperatures and air motion observations by reference to an Effective Temperature Chart (see Figs. 8, 9, and 10) or tables.

Fig. 8 gives the effective temperature for any combination of dry- and wet-bulb temperatures for *still air* (15 to 25 fpm) conditions. Charts similar to Fig. 8 for air velocities of 100 and 300 fpm have been presented in earlier editions of THE GUIDE, e.g. 1939. Fig. 9 is another form of effective temperature chart embodying all three variables: dry-bulb and wet-bulb temperatures, and air velocity.

TABLE 4. COMPARISON OF COMFORT RANGES WITH ZONE OF THERMAL NEUTRALITY

As stated previously, effective temperature is an index of the degree of warmth experienced by the body. An effective temperature line is, therefore, a line defining the various combinations of conditions which will induce like sensations of warmth. It does not necessarily follow that like sensations of comfort will also be experienced along the entire length of an effective temperature line. Some degree of discomfort is likely to be experienced at very high or very low relative humidities, regardless of the effective temperature. It has also been found that the optimum effective temperature varies with the season, and is lower in winter than in summer.

Tests<sup>14</sup> made at the A.S.H.A.E. Research Laboratory in very hot conditions, with subjects doing light work, were in very close agreement with the effective temperature chart. Other work<sup>20</sup> under similar environmental conditions, but with subjects walking 3 mph and carrying 20 lb packs, indicated that the effective temperature lines should be more

nearly horizontal. It therefore appears that the slope of the ET lines may vary, depending upon the rate of work being performed.

Fig. 10 shows the A.S.H.A.E. Comfort Chart<sup>22</sup> as published since 1950. The areas and arrows indicating the summer and winter comfort zones on the previous charts have been removed. The summer comfort zone was removed because it extended to temperatures where too large a percentage of the people would be uncomfortable. The winter comfort zone was removed for the same reason, and because of inadequate data in later studies.

FIG. 8. PSYCHROMETRIC CHART, PERSONS AT REST, NORMALLY CLOTHED, IN STILL AIR

The distribution curve, showing the percent of people feeling comfortable at various effective temperatures in *summer*, indicates that a maximum of 98 percent of the people were comfortable at 71 ET. The study was conducted with relative humidities between 30 and 70 percent.

The distribution curve shown on the previously used chart, showing the percent of people feeling comfortable at various effective temperatures in the *winter*, was based on research prior to 1932. This curve indicated that at 66 ET a maximum number of people were comfortable. Later studies<sup>23</sup> by the A.S.H.A.E. Research Laboratory indicated that a maximum of 97.7 percent of the people were comfortable at 68 ET, and this finding has been confirmed by current practice.<sup>24</sup> However, adequate data from the later studies were available only for the ET range of 65 to 69,

FIG. 9. EFFECTIVE TEMPERATURE CHART SHOWING NORMAL SCALE OF EFFECTIVE TEMPERATURE, APPLICABLE TO INHABITANTS OF THE UNITED STATES UNDER FOLLOWING CONDITIONS:

*A. Clothing:* Customary indoor clothing. *B. Activity:* Sedentary or light muscular work. *C. Heating Methods:* Convection type, i.e., warm air, direct steam or hot water radiators, plenum systems.

as presented in Fig. 10. The studies should be extended to cover a wider range. The lighter weight clothing, probably worn in the later studies, accounts for the higher desirable ET.

Radiation from occupants to room surfaces, and between the occupants, has an important bearing on the feeling of warmth, and may alter to some

measurable degree the optimum conditions for comfort previously indicated. Since the mean radiant temperature of a space is affected by cold walls and windows, as well as by the warm surfaces of heating units placed within the room or imbedded in the walls, these factors must be

FIG. 10. A.S.H.A.E. COMFORT CHART FOR STILL AIR<sup>a,b</sup>

<sup>a</sup> Note.—Both summer and winter comfort lines apply to inhabitants of the United States only. Application of winter comfort line is further limited to rooms heated by central systems of the convection type. The line does not apply to rooms heated by radiant methods. Application of summer comfort line is limited to homes, offices and the like, where the occupants become fully adapted to the artificial air conditions. The line does not apply to theaters, department stores, and the like where the exposure is less than 3 hours. The line does not apply to theaters, department stores, and the like where the exposure is less than 3 hours. The line does not apply to theaters, department stores, and the like where the exposure is less than 3 hours. The line does not apply to theaters, department stores, and the like where the exposure is less than 3 hours.

<sup>b</sup> Dotted portion of winter comfort line was extrapolated beyond test data.

compensated. Likewise, in densely occupied spaces, such as classrooms, theaters and auditoriums, temperatures somewhat lower than those indicated by the comfort line may be desirable because of counter-radiation between the bodies of occupants in close proximity to each other. Such radiation will also elevate the mean radiant temperature of the room.

Many field studies<sup>22</sup> have been made to determine the optimum indoor effective temperature for both winter and summer in several metropolitan districts of the United States and Canada, in cooperation with the managements of offices employing large numbers of workers (Fig. 11). On the whole, women of all age groups studied prefer an effective temperature for comfort, 1.0 deg higher than men. All men and women over 40 years of age prefer a temperature 1 deg ET higher than that desired by persons below this age. The persons serving in all of these studies were representative of office workers dressed for air conditioned spaces in the summer season, and engaged in the customary office activity.

FIG. 11. RELATION BETWEEN EFFECTIVE TEMPERATURE AND PERCENTAGE OBSERVATIONS INDICATING COMFORT

On the basis of present knowledge, for different geographical regions and age groups, the most popular temperature varies from a low of 66 ET in winter to a high of 73 ET in summer. The spread for summer comfort is 69 to 73 ET.

A spread of 3 deg in the optimum effective temperature for summer cooling is ascribed to geographical location. However, variations in sensation of comfort among individuals may be greater for any given location than variations due to a difference in geographical location. The available information indicates that changes in weather conditions over a period of a few days do not alter the optimum indoor temperature.

Sudden chilling of persons entering a cooled and air conditioned space during the summer months, may at times be important. It is due to the rapid evaporation of perspiration which accumulated on the skin and in the clothing during previous subjection to hot and humid outside conditions and increased heat loss by radiation. While studies<sup>23</sup> have shown that for healthy individuals this chilling is not harmful, under some condi-

tions it may be unpleasant or even harmful. People entering and remaining in cooled spaces for short periods, 15 min or less, may be satisfied with less cooling. For long occupancy very little deviation from the optimum effective temperature is indicated.

Upon leaving an air-cooled space and re-entering a hot atmosphere, sudden warming occurs. Experiments at the A.S.H.A.E. Research Laboratory<sup>26</sup> and elsewhere<sup>25</sup> indicated no demonstrable harm to a healthy individual. Adaptation occurred as soon as normal perspiration was established. Mild exercise shortened the adaptation time.

A great number of persons seem to be fairly content in summer with a higher plane of indoor temperature. Studies by the University of Illinois<sup>27</sup> in cooperation with the A.S.H.A.E. Committee on Research indicate that effective temperatures as high as 74.5 ET are acceptable in the living quarters of a residence, and while this condition is not representative of optimum comfort, it provides sufficient relief in hot weather to be acceptable to the majority of users, in the interest of economy. Individual minority differences can be counteracted by clothing.

Satisfactory comfort conditions for persons at work<sup>28</sup> vary, depending upon the rate of work and the amount of clothing worn. In general, the greater the degree of activity, the lower the effective temperature necessary for comfort. Clothing has been evaluated for its overall insulation effects by a physical unit, the *clo* which equals 0.116 C deg per (kilogram calorie) (square meter) (hour).<sup>29</sup> Yaglou<sup>30</sup> criticizes the concept of overall insulation, and points out that different parts of the body require different amounts of insulation. The literature on effects of clothing is difficult to coordinate at the present time, as much of it is still in military service reports which are yet to be published and amplified.

For prematurely born infants, the optimum temperature varies from 100 to 75 F, depending upon the stage of development. The optimum relative humidity for these infants is placed at 65 percent.<sup>31</sup> No data are yet available on the optimum air conditions for full term infants and young children up to school age. Satisfactory air conditions for these age groups are assumed to vary from 75 to 68 F with natural indoor humidities. For children (having high metabolism) at school, in winter clothes, 70 F has been considered correct, with 55 F recommended for gymnasiums.

## CHAPTER 7

## AIR CONDITIONING IN THE PREVENTION AND TREATMENT OF DISEASE

Sanitary Ventilation, Control of Airborne Infection, Value of Air Cooling Under Tropical Conditions, Treatment of Disease, Operating Rooms, Nurseries for Premature Infants, Fever Therapy, Cold Therapy, Allergic Disorders, Oxygen Therapy, General Hospital Air Conditioning

THE Second World War caused an increase of interest in the preventive aspects of air conditioning. It re-emphasized the importance of the control of airborne infection and demonstrated the value of air cooling under tropical conditions for the prevention of heat rash, for promoting proper rest and sleep, and in the convalescence of patients.

The problem of air conditioning or air purification in shelters, hospitals, or any buildings, following an atomic explosion has the attention of engineers, military personnel, public health authorities, private physicians, and the general public. The type and structure of shelters are important. In strategic areas likely to be bombed, they should be windowless, underground, strong enough to resist blast and have sufficient cover to protect against initial radiation. Suitable ventilation is a necessity, and could be provided by the use of pressurized installation in which any air taken from the outside is forced through a ventilator. Air conditioning and heating or cooling systems could then be kept in continuous operation for improving inside air conditions and controlling room temperature. Heat transmission through the walls, carbon dioxide accumulation, and the total number of people using the shelter, are factors in determining the necessity for using outside air. Such a shelter should be closed to outside air during the period immediately following a blast.

A surface or subsurface burst of an atomic bomb would result in a wide dispersion of airborne radioactive particles.<sup>1</sup> Windows of buildings within a three-mile radius from the point of detonation of a 20 KT bomb would be broken, and consequently, any protection however slight, obtainable through the use of conventional air-conditioning systems would not be accomplished. Beyond the three-mile radius many structures may be found with windows undamaged and otherwise capable of providing some degree of protection from airborne radioactive particles by the utilization of an air-conditioning system. However, conventional air-conditioning systems should not be relied upon for such protection in urban structures which may be utilized in the accomplishment of specific missions following an atomic detonation. There are special techniques and devices available which will provide this protection.

The smog incident in Donora, Pa., has focused the attention of health authorities and engineers on the problem of air contamination by toxic gases. The exact way in which such substances affect the human being is unknown.<sup>2</sup> There has been a great deal of speculation, but in reality there is little specific information concerning this problem. It is believed that in such cases the combination of contaminants, rather than any single substance, produces the toxic effects. It is known that low atmospheric pressure, with accumulation of toxic substances in increasingly higher

concentration, produced the condition in Donora. The U. S. Public Health team, in their investigation, found that this same city had experienced several previous incidences of lesser severity during the preceding 30 years. This was shown by much higher mortality rates during certain periods. A high percentage of the population of this city suffered to some extent during the recent *smog*. Older individuals were more seriously affected with cardio-respiratory symptoms.

Study of such a situation is rather difficult, as explained in the aforementioned report. The medical profession has much to learn about the effects of these substances on human beings, and until more precise knowledge is obtained, it is difficult to know when precise controls are really needed. Further research is urgently needed.<sup>8</sup>

### SANITARY VENTILATION

During the last 15 years great popular interest has been aroused in the spread of respiratory infection indoors, and control by ventilation or its sanitary equivalent by air disinfection. In Europe three important documents have appeared recently in English, Swedish, and French literature.<sup>4,5,6</sup> In the United States where the study began, the vast literature has been consolidated, and definitions, formulations, and factors of sanitary ventilation codified in a volume now being edited for publication.

The Council of Physical Medicine of the *American Medical Association* approved the radiant disinfection of air in 1943, and two sub-committees of the Committee on Research and Standards of the *American Public Health Association* have reported favorably upon the control of airborne infection by sanitary ventilation and on air sanitation respectively.<sup>7,8,9,10</sup> The work of a Technical Advisory Committee on Air Sterilization of the A.S.H.V.E. has from time to time since 1944 reported progress in *THE JOURNAL*, and has recommended a set of definitions, formulations and factors for joint adoption by the *American Public Health Association* and the Society.

But this important new field of sanitary ventilation is just emerging from the research to the development stage. When consolidation and codification of present data have been completed, a more comprehensive treatment in *THE GUIDE* may be possible. The following section on Control of Airborne Infection gives some idea of the scope of the subject.

### CONTROL OF AIRBORNE INFECTION

The majority of airborne diseases are spread indoors where people gather. Any program of air sanitation is influenced by a number of factors. In the winter months, the closing of doors, windows and other means of access to the outside air to conserve warmth, as well as the crowding of persons indoors, provides conditions conducive to a high incidence of contagion. This seasonal phenomenon, illustrated in Fig. 1 which represents a study made by the U. S. Public Health Service, will concern the ventilating engineer insofar as air quality (determined by temperature, humidity, air replenishment and type of air movement and by freedom from contamination) is a major intrinsic factor. Apart from the seasonal picture of airborne contagion, are such extrinsic factors as rate of turnover of personnel, and the marked susceptibility of the recruit in comparison with permanent personnel<sup>11</sup> as shown in Fig. 2 by studies of military personnel housed in barracks. These extraneous variables and the factor of contact infection (direct spray) tend to complicate any evaluation of the effectiveness of air sanitation for elimination of micro-organisms in droplet-nuclei and droplet-dust. Thus, control measures may eliminate consistently 90 percent

of airborne organisms in laboratory tests, but cannot effect a decrease in actual incidence of infection exceeding 30 percent. Thirty percent may be the maximal reduction in infection possible by air treatment methods. The distinction should be clearly drawn, therefore, between the effectiveness of a procedure in laboratory tests and its effectiveness and applicability in actually reducing the incidence of airborne disease. On the other hand, recent studies suggest that inhalation of dust-borne bacteria is more important than direct inhalation of infectious droplets or droplet nuclei in the spread of respiratory tract infections.<sup>12</sup>

The following sequence of events has been postulated as occurring in a large proportion of intra-ward infections: (a) ejection of relatively large protected infective particles from patients; (b) rapid venting or settling of these particles so that those remaining airborne are in low con-

Occurrence of diseases causing disability for 8 consecutive days or longer in a group of 100,000 wage earners (10 percent women) in different industries.  
\* Graph obtained from Dean K. Brundage, U. S. Public Health Service.

FIG. 1. STUDY OF AVERAGE MONTHLY FREQUENCY (1921-1926 INCLUSIVE) OF SPECIFIED RESPIRATORY DISEASES\*

centration; (c) survival of infective particles to permit the accumulation of high concentrations on surfaces; (d) repeated reintroduction of infective particles into the air under the stimulus of ward activities or by air currents of the order of 50 fpm over the floor; and (e) extension of infective areas by air turbulence throughout the ward or hospital. The most important link in this probable infection chain has been demonstrated to be the reintroduction of particles into the air.<sup>13</sup>

Intensive studies on air disinfection have indicated two distinct control measures: (a) suppression of dust and lint, and (b) disinfection of droplet-nuclei. A third measure, control of relative humidity, is important. It has been shown that the viability of certain organisms sprayed into the atmosphere from a liquid suspension is dependent on relative humidity. The mortality rate of the organisms is very high at a relative humidity of 50 percent,<sup>14</sup> and decreases at humidities above and below this figure. It

has also been reported that the influenza virus loses much of its virulence when the relative humidity is 50 percent.<sup>15</sup>

Well controlled, large scale tests of the various methods of air sterilization conducted in barracks<sup>16, 17</sup> have confirmed the importance of dust control in minimizing the spread of airborne disease, a consideration which has guided the practices of ventilating engineers for a number of years. The importance of the dust factor has been emphasized by many engineers, and has been convincingly demonstrated by subsequent bacteriologic studies aboard ships.

Treatment of floors and bedclothes with oil emulsions has proved effective in reducing bacterial dispersion by as much as 90 percent in Army barracks and station hospitals.<sup>17</sup> The incidence of acute respiratory infections was from 10 to 30 percent lower in barracks with oiled floors and bedclothes than it was in control barracks which received no special treatment. More recent studies, however, have yielded inconsistent results.

FIG. 2. MONTHLY INCIDENCE OF ACUTE RESPIRATORY ILLNESS AMONG NAVAL RECRUITS AND SHIP'S COMPANY (PERMANENT PERSONNEL)<sup>1</sup>

An emulsifying mixture, *Fixanol C* containing cetyl pyridinium bromide, when incorporated in the oil-in-water emulsion imparted a bactericidal action to the emulsion. Blankets treated with this substance and oil became bactericidal and retained this property for as long as three months. The possibility of hypersensitivity of an occasional individual to bromide drugs should be borne in mind when exposing large groups to treated garments or blankets.<sup>12</sup>

No simple method for disinfecting droplet-nuclei has yet been devised. Under favorable laboratory conditions, propylene glycol in concentrations of 0.07 to 0.14 milligrams per liter, and triethylene glycol in a concentration of 0.0045 milligrams per liter were highly germicidal for most airborne bacteria in clean air when the relative humidity was between 40 and 60 percent.<sup>18, 19, 20</sup> A humidity of 50 percent, without the use of glycol vapor, has been reported as destructive to some bacteria. However, maximum rates of bactericidal action of triethylene glycol vapor will be secured at humidities between 20 to 50 percent.<sup>21</sup>

In a recent report on the effect of triethylene glycol vapor in air disinfection, it is pointed out that the rate of ventilation, as determined by the number of air changes per hour, is important and that continuous vaporization is needed to maintain effective concentrations of glycol vapor.<sup>21</sup>

In the absence of an apparatus to measure the concentration of vapor in the room, a slight fog is an indication of adequate concentration. Absence of such a fog indicates a non-bactericidal concentration. The report stated: "However, under experimental conditions we have observed no apparent decomposition of triethylene glycol when temperatures up to 290 F were maintained at the site of vaporization, provided the vaporizing unit was designed so that heat was applied to liquid glycol only at the point of vapor formation. On the other hand, decomposition was frequently observed when the vaporizing temperature was raised above 290 F, or when liquid glycol was kept above 120 F for long periods of time. The precise nature of the decomposition products is as yet unknown, but they may well be irritant or toxic and their formation should be avoided. For this reason, it is felt that a limit of 290 F should be applied to the temperature employed in vaporization, and furthermore, that liquid glycol should not be heated above 120 F for long periods of time."

It was also recommended that a given vaporizer be capable of various outputs as measured by grams of liquid glycol vaporized per hour; for instance, from 0.5 g to at least 2.0 g per 1000 cu ft of volume treated, for small vaporizing units. Such high rates secure bactericidal concentration in less than an hour. Each room should be furnished with a single small vaporizer, and one vaporizer should not be expected to handle a volume greater than 4000 cu ft. Apparatus for the production of glycol vapor, and an independent duct system for carrying this vapor and diluting air for large rooms or spaces, and unit type vaporizers for small spaces, have been described recently.<sup>22</sup> There is also available a device for the automatic regulation of glycol vapor in the air called the glycostat. This instrument has been calibrated to measure the degrees of saturation of the air with glycol vapor by direct reading of the variations in the intensity of light reflected from the glycol condensing surface of the wheel of the instrument.<sup>23</sup>

Under practical conditions, particularly in the presence of dust in the air, glycol effectiveness is much reduced. The use of other chemical aerosols that have been tried is limited by their toxicity, odor, or destructiveness to fabrics and metals. A recently reported controlled experiment in the offices of the Metropolitan Life Insurance Company showed that under ordinary working conditions triethylene glycol vapor failed to reduce the number of airborne bacteria and the incidence rate of minor respiratory infections.<sup>24</sup>

Ultraviolet radiation of floors and upper air has been studied extensively at the Naval Training Center, Sampson, N. Y. In barracks housing naval recruits, hospital admissions for respiratory infections (mostly *catarrhal fever*) were 25 percent lower in a group of men exposed to ultraviolet radiation—2537 Angstrom Units, 1 to 7 ergs per (cm<sup>2</sup>) (sec) at bed level—than they were in adjacent control barracks without ultraviolet radiation.<sup>25</sup>

A controlled study over a six-year period on the evaluation of ultraviolet radiation of sleeping quarters as a supplement of accepted methods of respiratory disease control was recently reported.<sup>26</sup> The amount of radiation over the last two years of the period was believed to be about five times that recommended commercially. No significant effect in the incidence of disease could be detected in about 400 inmates during the six-year period. This conclusion may not be applicable to present ultraviolet equipment installed in accordance with manufacturers' recommendations. The data imply that air layers were not sufficiently mixed. However, more efficient mixing would have been obtained at the expense of increased

circulation of dust and lint. Sources of ultraviolet radiation should be so situated as to protect the eyes of the occupants of the room from direct or reflected rays. A combination of ultraviolet radiation and dust control measures is believed to be more effective than either one of the two used alone, but the proof for this has yet to come.

There is no doubt that these methods will reduce the number of bacteria in the air of an enclosed space, but there is still considerable question as to whether they are practical measures for reducing the total number of respiratory infections among personnel, since exposure by contact is an important factor. Bourdillon and his group concluded that there is justification for attempting to reduce the load of air-borne microorganisms by the methods now at our disposal.<sup>4</sup> They have explored the properties of a number of compounds, and their conclusions are in agreement with those of American investigators.

The present status is admirably reviewed by the Committee on Sanitary Engineering of the *National Research Council*,<sup>27</sup> and by a subcommittee of the *American Public Health Association*.<sup>9</sup> Both committees feel that the problem of air disinfection is still in the experimental stage. Knowledge concerning the effectiveness of glycol vapors has not kept pace with the development of vaporizing devices, and there is real danger that commercial exploitation of the various devices may discredit the method and discourage careful research in this important field.<sup>28</sup> More experimentation is needed for arriving at a definite conclusion concerning its use in industry and public buildings.

#### VALUE OF AIR COOLING UNDER TROPICAL CONDITIONS

The commissioning of a class of naval hospital ships with all wards, laboratories and living spaces air cooled is a notable achievement to provide better treatment of patients, especially those suffering from extensive burns, by control of environmental factors. Although statistics are not at hand to indicate the deaths or retarded recoveries of patients due to lack of air cooling in ships operating in tropical waters, it is generally agreed among competent observers that high temperature and humidity are major factors in prolonging disability and increasing mortality of the sick and injured. Physiologic data obtained on healthy men, moreover, show the large loss of body fluids and the stress on the cardiovascular system in terms of increased pulse rate when these men are continuously subjected to high temperatures. Even at rest about 50 cc of fluid per hour are lost as sweat<sup>29</sup> through intact skin. In burn patients the difficulty, encountered in temperate climates, of maintaining fluid and electrolyte balance is tremendously augmented by the additional evaporative fluid loss in hot environments.

Patients who have such varied conditions as heart disease, thyrotoxicosis, shock from any cause, severe hemorrhage, or those who have had an anesthetic, will invariably store heat when subjected to a hot, humid environment. The gradient between the body surface temperature and the environmental temperature is such that loss by radiation is slight. The heat loss by evaporation in a warm, humid environment is low whether the patient does or does not perspire. The heat regulatory center may be temporarily deranged following an anesthetic, brain injury, or after an overdose of barbiturate. Loss of fluids and electrolytes is another influencing factor. Cooling the body is the answer to this problem, and this can best be done in a cool room of low relative humidity where conditions for heat loss are ideal. This measure is also valuable in controlling temperature height of patients with various acute febrile diseases.<sup>30</sup>

Frequently from 50 to 75 percent of personnel aboard naval vessels operating in tropical waters are afflicted with heat rash to a degree that interferes with rest and sleep. In carefully controlled experiments<sup>29</sup> it was possible to produce a fulminating type of rash in all men living continuously at an effective temperature of 85 (90 F dry-bulb and 83 F wet-bulb). In the control group, 12 out of 24 hr were spent in a relatively cool atmosphere of 75 ET (80 F dry-bulb, and 70 F wet-bulb). These men either remained free from heat rash, or occasionally developed a mild form. Thus, intermittent cooling to a degree which prevented sweating in men at rest eliminated a serious handicap to good performance of duty.

In both laboratory tests and aboard hospital ships a relatively cool living environment of 76 to 78 ET provided an atmosphere conducive to rest and sleep without excessive sweating. Berthing spaces tended to have extremely low odor levels. Motivation, initiative and alertness, in contrast to the usual irritability and lack of incentive incident to residence in tropical climate, were maintained.<sup>31</sup>

Little has been done, however, to obtain practical methods for application of air conditioning under heavy heat loads and on the enormous scale that would be needed to modify life in the tropics. It is not improbable that cooled houses in a tropical climate, if used consistently for one generation, would modify the whole character of a population. The obvious advantages of part time cooling on personnel to promote rest and sleep in tropical areas would provide a prophylactic measure of great potential importance.

#### TREATMENT OF DISEASE

In the past few years considerable progress has been made in using air conditioning as an adjunct in the treatment of various diseases. Among the important applications are those in operating rooms, nurseries for premature infants, maternity and delivery rooms, children's wards, clinics for arthritic patients, heat therapy, cold therapy, oxygen therapy, X-ray rooms, the control of allergic disorders, and for the physiological effects in industry.

Normal individuals may be subjected to considerable strain in adjusting to hot, humid conditions. Heat loss by radiation is reduced, as is loss by evaporation of sweat. Individuals with certain disease processes are at a still greater disadvantage since they may also have difficulty in the transport of heat from the interior to the surface of the body via the circulation.

Patients with thyrotoxicosis tolerate hot, humid conditions or *heat waves* very poorly. Their metabolism is high, and therefore their heat production is excessive. They may be unable to eliminate heat from the body surface as rapidly as it is produced and transported to the skin. They develop hyperthermia or fever, and a tachycardia or rapid heart rate. The demand on the circulation for transport of heat from the interior of the body to the skin surface is increased. The increased body temperature leads to increased cell metabolism, and in turn to still greater heat production. This vicious cycle may threaten life if the cardio-vascular or transport mechanism breaks down. A cool, dry environment favors the loss of heat by radiation and evaporation from the skin, and may save the life of the patient with thyrotoxicosis.

Cardiac patients may be unable to maintain the circulation necessary to insure normal heat loss. Recently the importance of air conditioning hospital wards and rooms of cardiac patients, particularly those with congestive heart failure, has been stressed as a therapeutic measure.<sup>32</sup> It is more important in tropical or subtropical climates. Individuals with head

injuries, those subjected to brain operations, and those with barbiturate poisoning may have hyperthermia, especially in a hot environment, due to a disturbance in the heat regulatory center of the brain. Obviously, one of the most important factors in recovery is an environment in which the patient can lose heat by radiation and evaporation, namely, a cool room with dehumidified air.

The patient in shock, or the patient who has had a severe hemorrhage, may have an inadequate volume of circulating blood and be unable to maintain an adequate skin circulation. This may result in heat storage or fever. Patients with extensive skin burns may be unable to lose heat adequately from the limited uninvolved skin surface, and thus develop a fever. They need adequate fluid replacement, saline solution, plasma or blood to expand the circulating blood volume and thereby improve peripheral circulation. A cool environment is valuable in aiding heat loss after adequate skin circulation is established.

A hot, dry environment (89.6 F and 35 percent relative humidity) has been used over an extended period for the treatment of patients with rheumatoid arthritis, with reported improvement.<sup>33</sup>

### OPERATING ROOMS

The widest application of air conditioning in hospitals is in operating rooms. Complete air conditioning of operating wards is important because winter humidification helps reduce the danger of anesthetic gases; summer cooling with some dehumidification tends to eliminate excessive fatigue and to protect the patient and operating personnel; and finally, filtering aids the removal of allergens from the operating room air.

#### Reducing Explosion Hazard

Explosion hazards in operating rooms increased with the introduction of anesthetic gases and apparatus. Ether administered by the old drop method gives rise to an explosive mixture, but in practice this method is still regarded as comparatively safe. When ether is mixed with pure oxygen, or nitrous oxide in certain concentrations, the explosion hazard may be as great as with ethylene-oxygen, or cyclopropane-oxygen mixtures.

Of the anesthetic gases nitrous oxide alone does not explode but supports combustion. Ether, vinyl ether, ethylene, and cyclopropane are as potentially dangerous as gasoline or illuminating gas in the home.<sup>34</sup> Chloroform does not explode violently in contact with flame, but decomposes to liberate phosgene. All of the anesthetic gases and vapors, except ethylene, are heavier than air. Although the incidence of injury or death from explosion is negligible compared with other hazards in the operating room, the dramatic features surrounding an explosion justify continued investigation to eliminate the hazard.

During the course of ethylene anesthesia, the mixture, usually 80 percent ethylene and 20 percent oxygen, is so rich that the danger of explosion is slight in the immediate vicinity of the face mask, but leakage of ethylene into the air may accumulate to any lower concentration, and thus introduce a serious hazard. The most dangerous period is at the end of the operation when the patient's lungs and the anesthesia apparatus are customarily washed out with oxygen with or without the addition of carbon dioxide. Even when this procedure is omitted, it is difficult in practice to avoid dilution of the anesthetic gas with air during the normal course of breathing following the administration. In either case the mixture would pass through the explosion range and extraordinary precaution is necessary for the safety of the patient and operating personnel.

In a study<sup>35</sup> of 230 anesthetic explosions and fires, 70 percent of the explosions and 60 percent of the deaths were caused by igniting agents other than static sparks. The *National Fire Protection Association*<sup>36</sup> made certain recommendations for safe practice based on available information in Pamphlet No. 56, Recommended Safe Practice for Hospital Operating Rooms (July 1952). These recommendations outline in some detail ways and means for eliminating or correcting hazardous conditions which experience and investigation have shown to contribute to the hazards in question. They are divided into three parts: Part I, General, deals with the nature of the hazards, Part II, Construction and Equipment, deals with physical standards for features incorporated into the construction and equipment of the surgical suite, and Part III, Administration, contains precautions to be observed by hospital personnel. The requirements and recommendations are interdependent and each will be ineffective unless coordinated with the other. To approach complete success in the prevention of anesthetic explosions, all persons—the surgical staff, the nursing staff, the maintenance staff and administrative personnel—must be educated and periodically reminded of the explosive nature of combustible anesthetic agents.

Experience has shown that neither high humidity nor intercoupling devices have eliminated the danger from static electric discharge. The removal of gas concentrations from the operating table area, by means of specially devised exhaust ventilation, should be thoroughly tested. Portable duct systems as installed aboard ship should be acceptable. Serious explosions can occur in a closed system, but proper precautions will reduce this hazard to a minimum.

A comprehensive study of the explosion problem and of the general causes and prevention of operating room hazards, by the *University of Pittsburgh*, the *ASHAE Research Laboratory*, and the *U. S. Bureau of Mines* has led to a fruitful attempt to eliminate the explosive range of cyclopropane, one of the best but most difficult gases to handle. The use of helium as a diluent in the total gaseous mixture controls the oxygen concentration by displacement and, because of its flame quenching properties, it is the ideal gas for this purpose. In addition, a gaseous mixture containing helium is more difficult to ignite by electric discharges, and this quality also increases the safety factor of anesthetic administration.

#### Operating Room Conditions

Little is known about optimum air conditions for maintaining normal body temperatures during anesthesia and the immediate post-operative period. An anesthetized patient displays dilation of blood vessels in the skin resulting in profuse sweating and (it has been believed) inability to regulate body temperature. From this it was concluded that all anesthetized patients suffered considerable heat loss, although there may be little more than 0.8 F variation in the rectal temperature during the course of the operation.<sup>37</sup> The severe physiological effects, such as excessive sweating and rapid pulse, of high operating room temperatures on attendants and patients during the hot months signify the need for proper cooling. Statements of surgeons who operate in both air conditioned and non-air conditioned rooms strongly indicate that the recuperative power of the patient is greater when operated upon in air conditioned rooms.<sup>37</sup>

Although the comfortable air conditions for the operators are not identical with those for the patient, it is usually not difficult to compromise within a range of 55 to 60 percent relative humidity and 72 to 80 F temperature.

The work just cited reported that 68 to 70 F effective temperature not only furnished comfort for the operating room workers, but apparently prevented exhaustion of patients as evidenced by rapid convalescence in the recovery ward. Additional heat may be furnished to patients locally or by suitable covering, according to body temperature in individual cases.

In the control of airborne infection in the operating room, the prevention of dispersal of infectious materials into the air, control of dust, and proper ventilation supersede attempts to remove or kill pathogenic organisms. The bacterial content of conditioned operating rooms is generally lower than that of non-conditioned rooms.

Bacterial counts aboard an air-conditioned submarine were found to be exceptionally low and not cumulative with time, although all of the air was recirculated for more than 12 hours<sup>38</sup> without replenishment. The removal of bacteria by the process of air cooling and condensation of moisture out of air, merits further study.<sup>39</sup>

The degree of air contamination can be reduced by proper ventilation if velocity of air over the floor does not exceed 50 fpm. Research is in progress on the use of filtered air flowing through a system of mechanical cleaners which protect the patient against infection from attendants, and from bacteria-containing air in the corridor or ward.<sup>40</sup>

Operations are frequently postponed on allergic patients during asthmatic manifestations through fear of complications. The removal of airborne allergens, therefore, is in some cases an important function of the air conditioning system in preparing patients for operation.

Central system air conditioning plants and unit air conditioners producing between 8 and 12 air changes per hour of adequately filtered and properly conditioned air are generally acceptable to the medical profession for operating rooms. Opinions vary considerably on the use of all outside air *versus* recirculation for operating rooms. There is a current trend among eminent authorities on anesthesiology to recommend that a minimum of 50 percent outside air be introduced to the operating room, with a maximum of 50 percent recirculated filtered room air. A separate exhaust fan system is usually necessary to confine and remove the gases and odors. Double windows are desirable and often necessary to prevent condensation and frosting on the glass in cold weather, and to minimize drafts. The air flow of 8 to 12 air changes in operating rooms should: (1) reduce the concentration of the anesthetic to well below the pharmacologic threshold in the vicinity of the operating personnel; (2) remove the great amounts of heat and sometimes moisture, from sterilizing equipment if inside the operating room, from the powerful surgical lights, from solar heat, and from the bodies of the operatives; and (3) provide extra capacity for quickly preparing the room for emergency operations. Much can be gained by thermal insulation of sterilizing equipment, and by thorough exhaust ventilation of sterilizing rooms adjoining the operating rooms. An air conditioned recovery ward in connection with the air conditioned operating room, is of great value in stabilizing peripheral circulation, and in reducing excessive loss of fluids on hot humid days.

### NURSERIES FOR PREMATURE INFANTS

One of the most important requirements in the care of premature infants is the stabilization of body temperature. This is necessary because the infant's heat regulatory system is not fully developed, with the resultant tendency for environmental temperature to influence body temperature.

The younger the premature infant, the greater is the tendency. As the infant's metabolism is low, heat production is not adequate to maintain a normal body temperature in a cool environment. The resistance to infection is low, and the mortality rate is high. In general, the younger the age of the premature infant, the higher the mortality rate.

Nurseries constructed for metabolic research should be air conditioned so that conditions are reproducible. Results of such studies may be invalid if environmental conditions are not identical, since fluid and electrolyte loss may vary greatly with change in environmental conditions.

### Air Conditioning Requirements

The optimum air conditions for growth and development of premature infants were determined by extensive research<sup>41</sup> at the Children's Hospital, Boston, Mass., using four valid criteria, namely, stability of body temperature, gain in weight, incidence of digestive syndromes, and mortality. Individual temperature requirements varied widely (from 72 to 100 F) according to the constitutional state of the infants and body weights. The optimum relative humidity was about 65 percent, and the air movement less than 20 fpm.

A single nursery conditioned to 77 F and 65 percent relative humidity was found to fulfill satisfactorily the requirements of the majority of premature infants. Additional heat for weak (or debilitated) infants may be furnished in the cribs or by means of electric incubators placed inside the conditioned nursery, and the temperature adjusted according to individual requirements. In this way multiplicity of chambers and of air conditioning apparatus is obviated; the infants in the heated beds derive the benefit of breathing cool humid air, and the nurses and doctors need not expose themselves to extreme conditions.

**Importance of Humidity:** Although external heat is an important factor in the maintenance of normal body temperature, humidity appears to be of equal or greater importance. When the premature nurseries at the Children's Hospital were kept at relative humidity between 25 and 50 percent for two weeks or longer, the body temperature became unstable, gain in weight diminished, the incidence of gastro-intestinal disturbances increased, and the mortality rose. On the other hand, continuous exposure to air conditions with 55 to 65 percent relative humidity gave satisfactory results over a period of years. The initial physiologic loss of body weight (loss occurring within first four days of life) was found to vary inversely with the humidity. In the old nurseries with natural humidity it averaged 12.4 percent of the birth weight; in the conditioned nurseries it was 8.9 percent with 25 to 49 percent relative humidity, and 6.0 percent with 50 to 75 percent relative humidity. The number of days required to regain the birth weight was correspondingly maximum in the old nursery, and minimum in the conditioned nurseries under high humidity.

Maximum gains in body weight occurred in the conditioned nurseries under high humidity (55 to 65 percent) in infants weighing less than 5 lb. The gains were less under low humidity (25 to 50 percent) in the same nurseries, and in the old nurseries prior to use of air conditioning apparatus.

The incidence and severity of digestive syndromes, with diarrhea, persistent vomiting, diminishing gain or loss of body weight, and other symptoms, were generally from two to three times as high under low as under high humidity.

Summarizing, the best chances for life in premature infants are created by maintaining a relative humidity of 65 percent in the nursery, and by

providing a uniform environmental temperature just sufficiently high to keep the body temperature within normal limits. Medical and nursing care are, of course, factors of equal and sometimes of greater importance.

### Air Conditioning Equipment

Many of the installations now in use are of the central system type providing for filtration, for humidification and heating in cold weather, and for cooling and dehumidification in hot weather. A ventilation rate between 8 and 12 air changes per hour is desirable to remove odors and maintain uniformity of temperatures in extremes of weather. Recirculation should not be used in these wards owing to odors and the possibility of infection. There should be a frequent change in spray water.

### Control of Airborne Infection

The protection of the premature and older infant against infection is of the utmost importance. It was found in one installation equipped with air conditioning, germicidal lights and mechanical barriers that air conditioning alone did not prevent the spread of respiratory cross-infections.<sup>42</sup> Bacterial ultraviolet barriers, air conditioning and mechanical barriers are efficient. However, infections are brought in by, and often spread by, ward personnel in spite of these measures.

## FEVER THERAPY

Artificial production of high fever in man can be considered an imitation of nature's way of overcoming invading pathogenic organisms. The action may be direct and specific by destruction of the invading organism within the safe limit of human temperatures, or indirect in the case of heat resistant organisms, by general mobilization of the defensive mechanisms of the body.

Although the action may be direct and specific by destruction of the invading organisms within the safe human limits, fever therapy exerts much of its benefit through the improvement of the mechanism of bodily defense. A serious challenge to the theory on which fever therapy is based comes from the demonstration that high fever causes a reduction in the concentration of circulating antibodies in experimental animals.

Patients for fever therapy should be carefully selected. The most serious complications which may arise are heat stroke, heat exhaustion and circulatory collapse. The chief minor complications are heat cramps, fever blisters and mild dehydration.

The limits of induced systemic fever are usually between 104 and 107 F (rectal), and the duration from 3 to 8 hours at a time. The total period of fever treatment varies with the type of the organism involved.

The diseases which respond favorably to artificial fever therapy are gonorrhea and its complications (which include arthritis, pelvic infections in women, and involvement of the eye), syphilis and chorea.

The most striking results are seen in gonorrhea and syphilis, since the causative organisms can be destroyed at temperatures compatible with human life. However, the use of fever therapy has decreased since penicillin has been found so effective in the treatment of gonorrhea and syphilis. Mild fever, up to 101 F for one hour, has recently been used in the treatment of rheumatoid arthritis. This degree of fever is not bactericidal, but is believed to stimulate the body defense mechanism.

### Equipment for Production of Fever

Artificial fever can be induced by injections of various crystalloid or colloid substances, bacterial products of typhoid and malarial organisms, or by physical methods using hot baths, radiant heat cabinets, hot humidified air cabinets, or by short wave diathermy in combination with a cabinet.

The relative advantages of various methods have been evaluated clinically.<sup>43</sup> Among the devices for the production of fever by physical means, the one most widely used is the hot humid air or *air conditioned* cabinet. This apparatus was developed at the *Kettering Institute for Medical Research* at Miami Valley Hospital in Dayton, Ohio.

In the earlier studies of the Society, temperatures were elevated more easily using saturated atmospheres. A fever therapy apparatus<sup>44</sup> using these same principles has proved efficient as a means of inducing and maintaining fever in a body, with small likelihood of burns because of the comparatively low dry-bulb temperatures.

When heat is necessary in treating legs or arms, such media as short or long wave diathermy, micro-waves, infrared, water baths, etc., have been used extensively. A recent development, a saturated atmosphere heating unit, similar to one previously described has proven satisfactory, because heat may be administered over longer periods which render deep heating possible without fear of burns or shocks. Local heating has been somewhat satisfactory in relieving the painful symptoms of peripheral vascular disease.

This procedure, however, is not without danger. Elevation of tissue temperature increases cell metabolism and the need for oxygen. The inadequate blood supply and oxygen deficiency may lead to tissue death or gangrene. Application of heat to the trunk or abdomen, with consequent reflex dilatation of the vessels of the extremities, eliminates this danger of local heat application.

Short wave diathermy within the cabinet during the induction phase has been used. When the desired body temperature has been reached by electrical induction, the atmosphere of the enclosure is kept at saturation to prevent heat loss, thus maintaining the patient's temperature at the desired point. The two underlying principles in the production of fever by the hot, humid air cabinet are: (1) the transfer of heat by conduction from the circulating hot air to the body, and (2) prevention of heat loss. The latter is more important. In an atmosphere of high humidity, the heat loss by evaporation is markedly decreased.

## COLD THERAPY

Cold as an anesthetic agent was advocated by Allen several years ago.<sup>45</sup> Freezing of the tissue must be avoided. For certain patients, in whom amputation of an extremity is indicated, the application of a tourniquet with cooling of the affected extremity down to near freezing (5 C or 40 F) is of value. The patient, following this procedure can be prepared for surgery without the handicap of absorption of septic products and severe pain. This procedure has proven especially valuable in the neglected diabetic patient with an infected gangrenous extremity. Time for treatment of coma and hydration of the patient is gained. However, if amputation of an extremity is not indicated, the application of a tourniquet and pack-

ing in ice are dangerous procedures, since loss of the limb usually results. An extremity with inadequate blood supply can be readily cooled without the use of a tourniquet, but such an extremity is also usually eventually lost. Theoretically, cooling is said to reduce the metabolism of the tissue with suspension of the vital processes. It also reduces the blood flow to practically zero, and few extremities with inadequate blood supply remain viable or recover.

Packing in ice, or use of low temperatures, is contra-indicated in the treatment of patients with frostbite, immersion foot or trench foot. The affected extremities should be exposed to the air in a cool room and not rubbed with snow or packed in ice. The lowering of temperature by packing the body in ice for treatment of cancer has not proven successful.

The methods used for refrigeration, depending upon available facilities, are as follows:<sup>45</sup>

- (1) Cracked or shaved ice which is simple and has the advantage of not freezing tissues. However, it is cumbersome and sloppy to handle and is unsuited to prolonged treatments.
- (2) Use of ice in a pail for immersion of local parts.
- (3) Special boxes for holding ice with padded or curtained openings for the limb.
- (4) Bare ice bags and cloth bags for iced wet dressings for prolonged treatments and convenience.
- (5) A double chambered cabinet using dry ice has been constructed.
- (6) Electrical refrigerating apparatus, consisting of a compact noiseless unit that pumps fluid to various types of applications, is available. The applicators may be in the form of blankets containing rubber tubes suitable for covering the entire body, or all or part of a limb. Special applicators are available for insertion into various body cavities, and for inducing dental anesthesia.
- (7) An air chamber at regulated temperature for treatments of frostbite and immersion foot, and amputation stumps.

The electrical apparatus is costly, but has the advantages of thermostatic regulation, light weight, freedom of movement, and permits prolonged treatments with heat, as well as cold over the range of temperatures therapeutically desirable.

### ALLERGIC DISORDERS

Hay fever, asthma, eczema and contact dermatitis are classified as allergic disorders. The allergic individual responds to contact with a variety of substances, which are innocuous to a non-allergic person, with severe manifestations of hypersensitivity.

These substances are known as allergens and consist of airborne irritants such as dusts, molds, feathers, pollens, animal dander and others; of food protein such as milk, wheat, eggs, etc., or of simple chemicals brought in contact with the skin. They may enter the body by various routes of which inhalation is the most common type. Ingestion of offending food substances is not infrequent.

The offending substance reacts with the sensitized cells of the mucous membranes or skin. During this reaction, histamine or a histamine-like substance is released and causes (a) increased capillary permeability, (b) secretion of mucus and (c) muscular contraction. In the eyes and nose this produces itching, redness and lacrimation or rhinorrhea, in short, the symptoms of hay fever. In the lungs it causes, in addition to the secretory

response, a contraction of the smooth muscles of the bronchi resulting in bronchial asthma.

It is commonly known that non-specific environmental factors such as dust, irritating gases, change of temperature and humidity may precipitate asthmatic attacks in allergic subjects, even in the absence of exposure to specific allergens. It is assumed that the presence of frequent allergic bronchial constriction renders the smooth muscles of the bronchi so sensitive to various non-specific stimuli that the threshold of their response to such irritation is considerably lower than that of a non-allergic individual.

### Air Conditioning Apparatus

Of all the measures to relieve a specifically sensitive individual, elimination of exposure to the responsible allergen is the most efficient, though not always a practical, form of treatment. In recent years considerable effort has been made to accomplish such elimination by removal of respiratory allergens from enclosures by filtration or other air conditioning processes.

Paper or cloth filters, mounted in inexpensive window or floor units, prove quite satisfactory in many cases, but since dust and smoke frequently cause asthmatic attacks, it is desirable that an air filter, to be of full value in the treatment of asthma, should remove all possible dusts and pollens regardless of size or amount. Electrostatic air cleaners are more efficient than most commonly used types for capturing very fine dust.

Although the chief remedial factor in the treatment by conditioned air is the filtration of pollen, a certain amount of cooling and dehumidification appears to be desirable. A comfortable temperature between 70 and 75 F, and a relative humidity well below 50 percent proved satisfactory.<sup>46</sup> Direct drafts, overcooling or overheating are apt to initiate or aggravate the symptoms.

### Limitations of Air Conditioning Methods

The results obtained with air filtration, or other air conditioning processes, in the control of allergic conditions, are fairly comparable to those obtained by desensitization treatment, so long as the patients remain in the pollen-free atmosphere. For all practical purposes filtration gives only temporary relief. In mild cases sleeping in an air conditioned space may make it possible for the individual to pass more comfortable nights. With rare exceptions, the symptoms recur on exposure to pollen-laden air. Moreover, the usefulness of air conditioning methods is limited, because all cases are not caused by airborne substances. Cases of bacterial asthma do not respond to treatment with filtered air.

Despite these limitations, air conditioning methods possess definite advantages in the simplicity of treatment, convenience, and under certain conditions, almost immediate relief.<sup>47</sup> Pollen cases are usually relieved of most of their symptoms within 1 to 3 hr after exposure to properly filtered air. A pollen-free atmosphere is especially valuable when desensitization has given little or no relief, and when desensitization is not advisable owing to intercurrent illness.

### OXYGEN THERAPY

Oxygen therapy is used to prevent or relieve anoxia. Some of the more important clinical conditions in which oxygen treatment is beneficial include pneumonia, severe anemia, cardiac decompensation, pulmonary ate-

lectasis, asphyxia and asthma. The effectiveness of oxygen therapy is dependent on the concentration of the oxygen in the inspired air, or the partial pressure of oxygen in the pulmonary alveoli.

Oxygen is usually administered by nasal catheter, face mask or tent.<sup>48</sup> The necessity of air conditioning in oxygen therapy arises from the fact that oxygen is too expensive a gas to waste in the ventilation of oxygen tents and oxygen chambers. Air conditioning is applied to the oxygen tent or chamber through reconditioning of the atmosphere in a closed circuit. Excessive heat, moisture and carbon dioxide are removed.

### Oxygen Tents

In oxygen tents, the air enriched with oxygen is usually circulated by means of a small motor blower which sends the air over soda lime to remove carbon dioxide, and then over ice to remove excess heat and moisture. The concentration of oxygen in the tent is regulated by means of a pressure reducing valve and flow meter. In an inadequately cooled tent, high temperatures and humidities are inevitable, increasing the discomfort of the patient and imposing an added strain on an already overburdened heart. Oxygen therapy under such conditions may do more harm than good. An ice melting rate of approximately 10 lb per hour gives satisfactory results in patients with fever in a medium size oxygen tent.

Oxygen tents are confining to the patient. They may terrify the restless and delirious patient. Medical and nursing care is complicated, as the tent must be opened or removed with attendant loss of oxygen. Oxygen concentrations of 50 percent or more are difficult to maintain, and it is a problem to keep the temperature and humidity low enough in hot weather. However, with attention to details, the patient can be made quite comfortable. In fact, during hot, humid weather an oxygen tent may be very valuable in controlling a patient's temperature, since the upper part of the body within the cooled tent loses heat rapidly.

### Oxygen Chambers

The conventional oxygen chamber is an air-tight sheet metal enclosure of fire-proof construction, large enough to accommodate one or two patients. Trap doors or curtains are provided for the personnel, food and service, to avoid loss of oxygen. Glass windows in the ceiling and walls admit light from outside the chamber. The air conditioning system may be of the gravity type, or of the fan type using mechanical refrigeration or air drying agents.

The temperature and humidity requirement in oxygen therapy depends primarily upon the physical condition of the patient, and secondarily upon the type of disease. In pneumonias<sup>49</sup> prescribed conditions should be a temperature of 60 to 75 F, humidity 50 to 55 percent, moderate air movement, oxygen concentration of 50 percent, and carbon dioxide of less than one percent.

### Oxygen in Aviation

An important application of the principle of oxygen therapy is in aviation. At the present time all high altitude military airplanes in this country are provided with gaseous oxygen equipment, and military personnel are required to utilize oxygen at all times while in flight above 15,000 ft, or between 12,000 to 15,000 ft for longer than two hours, or between 10,000

to 12,000 ft for longer than six hours. The use of oxygen in commercial aviation will depend on the height and duration of the flights, as well as the state of health of the passengers. The necessity for portable, comfortable equipment, the possible fire hazards due to smoking, and the use of oxygen on sleeper planes are some of the difficulties facing civil airline operators. The pressure cabin airplane is a solution to the problem.

### GENERAL HOSPITAL AIR CONDITIONING

Complete conditioning of a large hospital involves a capital investment and running expenses which may not be justified. In clean and quiet districts, the requirements of almost all general and private wards during the cool season of the year can be satisfactorily fulfilled by the use of conventional heating equipment, in conjunction with window air supply and gravity or mechanical exhaust. Insulation against heat and sound is much more important than humidification in winter; it will also help in keeping the building cool in warm weather. Excessive outside noise and dust may require the use of silencers and air filters in the openings.

Cooling and dehumidification in warm weather are important. In new hospitals particularly, the desirability of cooling certain sections of the building should be given serious consideration. Financial reasons may preclude the cooling of the entire building, but the needs of the average hospital can be met by the use of built-in room coolers and a few portable units which can be wheeled from ward to ward when needed.

In the North, and certain sections of the Pacific Coast, cooling is needed but a few days during summer, while in the South, it can be used to advantage from May to October, and in tropical climates almost continuously throughout the year.

F. L. Grocott of the Anglo-Iranian Oil Co. states that in Iran, the medical staff after 10 years' experience with air conditioning, demand a uniform environment of 75 F and 50 percent relative humidity (70 ET) under all summer outside conditions for general wards and treatment rooms, and 70 F with 30 to 50 percent relative humidity (65-66 ET) for winter conditions. In the operating rooms, 70 F with 50 percent relative humidity (66 ET) is demanded all the year 'round, although the annual external range is 40 F to 120 F. No ill effects have been noted in the medical personnel, though they are exposed to changes from external to internal conditions many times daily. Temperature shock in either direction seems to create discomfort for a short interval, but if the individual is in good health, no injury results.<sup>50</sup>

Aside from comfort and recuperative power of the patients, cooling is of great assistance in the treatment of fevers in the new-born and in post-operative cases, in enteric disorders, fevers, heat stroke, heart failure, thyroid crisis, and in a variety of other ailments which often accompany summer heat waves.

### Problem of Odors

The evacuation of battle casualties in aircraft and their subsequent hospitalization have stimulated efforts to minimize odors arising from draining wounds, old odorous casts, and gangrenous wounds. For aircraft, chemical sprays and vapors, perfumes, oxidizing gases and simple exhaust methods are unsatisfactory. An ideal deodorant would purify the air by means of odor adsorption so that subsequently the air can be recirculated.

Based upon the effectiveness of activated carbon commercially and industrially to adsorb odors, individual adsorption units have been used successfully. In hospital wards the question of superiority of adsorption methods for elimination of odors over other methods remains to be answered. The present status of the problem is that the commercial aspect is highly controversial.<sup>51</sup>

## CHAPTER 8

## AIR CONTAMINANTS

Classification of Air Contaminants; Sizes of Airborne Particles; Air Pollution by Smoke, Ash and Cinders; Smoke Abatement and Air Pollution Control; Odor Nuisance; Industrial Air Contaminants; Flammable Gases and Vapors; Combustible Dusts; Atmospheric Pollen; Airborne Bacteria; Radioactive Air Contaminants

THE normal constituents of the earth's atmosphere are oxygen, nitrogen, carbon dioxide, water vapor, argon, small or negligible amounts of other inert gases, hydrogen, variable traces of ozone, and small quantities of microscopic and submicroscopic solid matter, sometimes called *permanent atmospheric impurities*. From the viewpoint of the air conditioning engineer, all other airborne substances may be termed *contaminants*. This term is applied preferably, however, to undesirable or chance impurities, since the occasion may arise for adding to the air controlled amounts of solid or gaseous diluents for the prevention of explosions; germicidal vapors or mists (aerosols) for bacteria control; masking substances for odor control; or a substitute for one of the normal gases, as, for example, when helium is used to replace nitrogen in atmospheres for compressed air workers or divers.

Control of the chemical quality of air is one of the functions of complete air conditioning, and some knowledge of the composition, concentration and properties of air contaminants under various circumstances is therefore essential.

Air contaminants arise from the normal processes of wear, erosion, wind-storm, sea-spray evaporation, thermal disintegration, earthquake, volcanic eruption, combustion, manufacturing, transportation, agriculture, and the biochemical or biological processes of life. They are classified at various times as organic and inorganic, visible or invisible, microscopic or macroscopic, particulate or gaseous, toxic or harmless, beneficial or destructive. The following classification is based chiefly upon the origin or method of formation of air contaminants.

## CLASSIFICATION OF AIR CONTAMINANTS

Dust, Fumes, and Smokes are solid particulate air contaminants.

Dusts are solid particles projected into the air by natural forces, such as wind, volcanic eruption or earthquake, and by mechanical processes, such as crushing, grinding, milling, drilling, demolition, shovelling, conveying, screening, bagging and sweeping. Some of these forces produce dust from larger masses, while others simply disperse materials that are already pulverized. Generally, particles are not called dust unless they are smaller than about 100 microns. Dusts may be of mineral type, such as rock, ore, metal, sand; vegetable, such as grain, flour, wood, cotton, pollen; or animal, such as wool, hair, silk, feathers, leather.

Fumes are solid particles commonly formed by the condensation of vapors from normally solid materials such as molten metals. Metallic fumes generally occur as the oxides in air because of the highly reactive nature of finely divided matter. Fumes may also be formed by sublimation, distillation, calcination, or chemical reaction, whenever such processes create airborne particles predominately below the 1 micron size. Fumes permitted to age tend to flocculate into clumps or aggregates of larger size, thereby facilitating removal from air.

Smokes are the extremely small solid particles produced by incomplete combustion

of organic substances such as tobacco, wood, coal, oil, tar and other carbonaceous materials. The term *smoke* is commonly applied to the mixture of solid, liquid and gaseous products of combustion, although the technical literature prefers to distinguish between such components as soot or carbon particles, fly-ash, cinders, tarry matter, unburned gases, and gaseous combustion products. The finest particulate constituents are much less than 1 micron in size, often in the range of 0.1 to 0.3 micron.

Mists and Fogs are liquid particulate air contaminants.

Mists are very small airborne droplets of materials that are ordinarily liquid at normal temperatures and pressures. They may be formed by atomizing, spraying, splashing, mixing, violent chemical reaction, electrolytic evolution of gas from a liquid, or escape of a dissolved gas upon release of pressure. Very small droplets expelled or atomized into the air by sneezing constitute mists containing microorganisms that become air contaminants.

Fogs are limited by some classifications to airborne droplets formed by condensation from the vapor state. This arbitrary distinction between mist and fog is of minor importance, as both terms are used to indicate the particulate state of airborne liquids (occasionally termed *aerosols*). Fog nozzles are so named because of their ability to produce extra fine droplets as compared to the mist from ordinary spray devices. The highly volatile nature of some liquids quickly reduces their airborne droplets from the mist to the fog range, and eventually to the vapor phase until the air becomes saturated with that liquid. Many droplets in fogs or clouds are microscopic and submicroscopic in size, and may be conceived as the transition state between the larger mists and the vapors.

Vapors and Gases are non-particulate air contaminants.

Vapors are the gaseous phase of substances that are either liquid or solid in their commonly known state, examples being gasoline, kerosene, benzene, carbon tetrachloride, mercury, iodine, camphor. Vapors may be changed to the solid or liquid form by increasing the pressure, decreasing the temperature or applying both processes simultaneously. They are removed from the air by condensation with less difficulty than are the gases.

Gases are normally formless fluids which tend to occupy a space or enclosure completely and uniformly at ordinary temperatures and pressures. The following substances qualify as gases: oxygen, nitrogen, carbon dioxide, carbon monoxide, hydrogen, ammonia, sulfur dioxide. Gases, likewise, may be solidified or liquefied by the proper control of temperature and pressure.

The preceding classification is not suitable for the airborne living organisms, which range in size from the submicroscopic viruses to the largest pollen grains, not considering the smallest insect life. Bacteria range from about 0.2 to 5 microns in size, fungus spores from 1 to 10 microns, and pollen from 5 to 150 microns.

#### SIZES OF AIRBORNE PARTICLES

Fig. 1 is a graphic tabulation of the properties of airborne solids and liquids arranged according to size on the micron scale. There are 25,400 microns in 1 inch.

Particles larger than 10 microns are unlikely to remain suspended in air currents of moderate strength, but settle out by gravity at speeds dependent upon the shape, size and specific gravity of the particle, wind velocity, orientation of the collecting surface, and topography. These larger particles are of major interest to the engineer in the solution of nuisance problems, but it is usually the smaller particles, or those below 10 microns, that remain in the air long enough to be of hygienic as well as economic significance.

Industrial dust particles are predominantly of the order of 1 micron in size. Tremendous numbers are also present in the submicroscopic range below 0.5 micron, but those below 0.1 micron are not believed at present

to be of practical importance, possibly due to their exceedingly small mass in comparison with the balance of airborne matter. In fact, particles this small may become the *permanent* atmospheric impurities that have little, if any, opportunity of settling because of the continual motion imparted to them by air currents and the molecular activity of gases (Brownian Movement).

FIG. 1. SIZES AND CHARACTERISTICS OF AIRBORNE PARTICULATE MATTER

The survey<sup>1</sup> of atmospheric pollution in 14 American cities conducted from 1931 to 1933 indicated the average size of outdoor dust particles to be 0.5 micron, as collected by the Owens jet dust counter and measured under the microscope. Inability of the *light field* microscope to reveal

particles in the 0.1 micron vicinity may have influenced the determination of average particle size.

The lower limit of particle size visible to the naked eye cannot be stated definitely. It depends not only upon the individual eye, but also upon the shape and color of the particle, intensity and quality of the light, and nature of the background or opportunity for contrast. Under ideal conditions a particle of 10-micron size might be recognized, while under less favorable conditions it may be impossible to distinguish a particle smaller than 50 microns. The lower limit of visibility probably ranges from 10 to 50 microns.

Dusts, powders and granular materials are frequently classified by reference to the size of screens used for separation. Particles above 40 microns are said to be the *screen sizes* and those below, the *sub-screen* or microscopic sizes. Approximate or theoretical sizes of particles corresponding to the mesh scale of the U. S. Standard Sieve Series are given in Table 1.

Microscopic examination of screened dust indicates that the average diameter of a sample of irregular particles may be substantially larger

TABLE 1. RELATION OF SCREEN MESH TO PARTICLE SIZE

| U. S. Standard Sieve Mesh...     | 400 | 325 | 200 | 140 | 100 | 60  | 35  | 18   |
|----------------------------------|-----|-----|-----|-----|-----|-----|-----|------|
| Nominal Sieve Opening in Microns | 37  | 44  | 74  | 105 | 149 | 250 | 500 | 1000 |

than the openings of the screen through which it has passed, if the particle shapes deviate considerably from the spherical form.<sup>2</sup> The smallest dimension of many such particles will correspond with the maximum permissible distance between the wires of commercial screens made to ASTM Standard Specifications. Screening does not give sharp separation into size groups, and accordingly, such a classification is statistical rather than absolute.

### AIR POLLUTION BY SMOKE, ASH AND CINDERS

Total airborne solids settling in urban areas are usually reported as *soot fall* in tons per (square mile) (month). Such data published for the cities in this country range from 20 to 200 tons per (square mile) (month). To the air conditioning engineer this information may indicate the effectiveness of smoke abatement or fuel combustion control methods in his locality, but it does not provide a suitable index of the suspended dust that air cleaners in a ventilating system are expected to capture.<sup>3, 4, 5</sup> Gravimetric or weight data of the type given in Table 2 are preferable. In some cases airborne particle counts may be necessary, as for pollen, bacteria, spores, and insoluble dusts causing illness or lung disease.

Dust concentrations by weight cannot be converted readily to concentrations by particle count because of the variability of particle size, shape and specific gravity, and the inherent characteristics of dust counting and weighing procedures. One milligram of dust per cubic meter of air may represent dust counts from 1 million to 100 million particles per cubic foot of air (lightfield microscope technic) according to the size distribution of

the airborne dust sample. Information of this type for a specified application is best obtained by simultaneous sampling for both counting and weighing and noting carefully at the time all factors that might affect the reproducibility of the count-weight ratio.

### Smoke Abatement and Air Pollution Control

Successful abatement of atmospheric pollution caused by smoke requires the combined efforts of the combustion engineer, industrial executive, public health officer, city planning commission and the community at large. Electrification of industry and railroads, increases in the use of domestic oil and gas furnaces, and segregation of industrial districts are gradually providing effective aid in the solution of this problem. In the large cities where nuisance from smoke, fly-ash and cinders is more serious, limited areas obtain some relief by the use of district heating. (See Chapters 14, 15 and 16 for further discussion on fuel burning technic.)

TABLE 2. DUST CONCENTRATION RANGES

| LOCATION                             | GRAINS PER 1000 Cu Ft* | MILLIGRAMS PER CUBIC METER |
|--------------------------------------|------------------------|----------------------------|
| Rural and suburban districts         | 0.02-0.2               | 0.05-0.5                   |
| Metropolitan district                | 0.04-0.4               | 0.1-1.0                    |
| Industrial districts                 | 0.1-2.0                | 0.2-5.0                    |
| Ordinary factories or workrooms      | 0.2-4.0                | 0.5-10                     |
| Excessively dusty factories or mines | 4-400                  | 10-1000                    |
| Minimum explosive concentrations     | 4000-200,000           | 10,000-500,000             |

\* 1 grain per 1000 cu ft = 2.3 milligrams per cubic meter.

1 oz per cubic foot = 1 gram per liter = 1000 grams per cubic meter

Many present ordinances limit the number of minutes in any one hour that smoke of a specified density (determined by comparison with a Ringelmann Chart which is described in Chapter 52) may be discharged.

There is now considerable interest and activity in the control of air pollution factors in addition to smoke. Difficulty in the establishment of acceptable criteria for certain corrosive and irritant gases, such as fluorides and the oxides of sulphur and nitrogen discharged with the gases of combustion, and the frequently complicated technical and economic problems encountered in control, have delayed the drafting and enforcement of legislative measures. Recent reports of an increased incidence of diseases, such as pneumonia and lung cancer, in areas high in certain air contaminants, require further critical investigation before acceptance. The values finally adopted will undoubtedly be lower than the M.A.C. (Maximum Allowable Concentration) limits for use in industry, because the exposure is continuous compared with the 8-hour day, 5 or 6-day week upon which M.A.C. values are based, and because the exposed population contains individuals with greater variation in age and health status.

In foggy weather, or with an *inversion* of atmospheric conditions, accumulation of gaseous contaminants may cause irritation of eyes, nose, and respiratory passages, and possibly cause even more serious physiological effects. The Meuse Valley fog disaster (Belgium 1930) and the Donora smog (Pennsylvania 1948) are classic examples in the history of gaseous air pollution. In both instances it is believed that irritant gases, princi-

pally from industrial plants, accumulating during periods of exceptionally prolonged meteorological *inversion* and fog, contributed to the illness of many persons, and to the death of some who were especially susceptible.

### Absorption of Solar Radiation

Absorption of solar ultraviolet light by smoke and soot is recognized as a health problem in many industrial cities. Measurements of solar radiation in Baltimore<sup>6</sup> by actinic methods demonstrated that ultraviolet light intensity in the country was 50 percent greater than in the city. In New York City<sup>7</sup> a loss as great as 50 per cent in visible light was found by photoelectric measurements.

### ODOR NUISANCE

A problem companionate with smoke abatement is the control of odor nuisance in the neighborhood of industrial plants discharging noxious or offensive air contaminants. Community planning and zoning will avoid much of the difficulty in the future, but meanwhile many industrial cities must resort to corrective measures by requiring installation of air cleaning devices, alteration of manufacturing processes, or termination of the offensive operation in residential or commercial districts.

Control of outdoor odor nuisance is especially troublesome because of the extremely minute quantities of contaminant that are capable of offending through a wide area. New industrial chemicals with strange or unfamiliar odors tend to receive more attention from the neighborhood than the customary odors generated by well known processes and raw materials. Methods of odor control currently in use include charcoal adsorption, scrubbing towers and air washers, chlorination, condensation, masking, passage of the odorous air through combustion chambers, dispersion through a tall stack, and best of all, substitution of less offensive materials whenever possible.<sup>8, 9, 10, 11</sup>

Control of air quality within buildings ventilated for human occupancy is discussed in Chapter 6. Tobacco smoke odors, cooking odors and body odors are air contaminants of the nuisance type which now command a decisive position in the standards of air quality for indoor comfort. However, the engineer will find, at times, that odors originating *outside* buildings in industrial or business districts may determine the kind and capacity of equipment he must provide for a high quality air supply installation.

### INDUSTRIAL AIR CONTAMINANTS

Many industrial processes are sources of contaminants. Their control is an important function of the ventilating or air conditioning engineer, because the atmosphere within buildings is the medium whereby such finely divided matter is dispersed and transported from the source to remote locations where it may cause property damage, nuisance, fire, explosion, disease and even death.

Tables 3, 4 and 5 give maximum allowable concentration values for many industrial air contaminants. Some of these values have been proposed by ASA Sectional Committee Z37 on Allowable Concentrations of Toxic Dusts and Gases, and others by the Committee on Threshold Limits of the American Conference of Governmental Industrial Hygienists. The

values have been adopted by the *American Conference of Governmental Industrial Hygienists* and by many of the official industrial hygiene agencies.

It must be emphasized that these limits in the great majority of instances are only *suggested maximum working levels* since they are estimates, based in many cases upon incomplete environmental and medical studies. Where there is agreement between the ASA Standard Z37 and A.C.G.I.H. values, reliability of the ASA Standard is increased. The values are not fixed, but are subject to revision, upward or downward, with the development of new information. There is by no means complete agreement regarding these values among responsible industrial hygienists.

In applying these guide limits, the following factors must be considered:

1. The duration of exposure is 8 hr a day for 5 or 6 days a week.
2. The measurements are indicative of the concentration in the breathing zone of the exposed person.
3. The M.A.C. is usually accepted as the average exposure value when the upper limits do not greatly exceed the M.A.C. value. For example, it cannot be assumed that if 100 ppm is considered *safe* for 8-hour exposure, that 800 ppm for one hour will be permissible.
4. Two substances with similar M.A.C. values may be quite different as to physiological effects at other concentrations. In one instance the selection of a limit may be predicated upon a discomfort factor, with a wide margin of safety before systemic effects would be encountered, while in another case the value represents an appreciable fraction of the concentration which may be associated with severe and irreversible injury.
5. These values are *upper* limits; it is desirable to operate well below the levels if the engineering and economic factors permit. The prudent engineer will incorporate a reasonable margin of safety in his estimates of ventilation capacity.

In Table 3, Column 1 lists the ASA Sectional Committee Z37 M.A.C. values; Column 2, those of the A.C.G.I.H. Committee on Threshold Limits. Column 3 gives the value in grams per cubic meter or ounces per 1000 cu ft for the corresponding A.C.G.I.H. limits; Column 4 shows the liquid ounces of chemical, if liquid at 20 C (68 F), which, if equally dispersed in 1000 cu ft, would give the corresponding M.A.C.

In Table 4, Columns 1 and 2 are respectively the M.A.C. values from the ASA and A.C.G.I.H. Committees.

In Table 5, the M.A.C. values for industrial dusts as given were obtained from data of the A.C.G.I.H. Committee on Threshold Limits.

A.C.G.I.H. limits for either gamma or Roentgen radiations are 0.3 roentgens per week.

Information on the properties and effects, with respect to health, of specific industrial air contaminants is available in publications listed at the end of this chapter.

### FLAMMABLE GASES AND VAPORS

Adequate ventilation is a primary requirement for minimizing the hazard of fire or explosion due to gases and vapors. The need for good ventilation is not removed by the use of other precautions, such as the elimination of known ignition sources, segregation of hazardous operations, adoption of safe building construction, and installation of automatic alarms. Some safety engineers regard over-ventilation of an operation employing flammable liquids as a legitimate operating charge for the privilege or necessity of using a dangerous process. However, it is not possible to

TABLE 3. MAXIMUM ALLOWABLE CONCENTRATION OF GASES AND VAPORS

\* A.C.G.I.H. = American Conference of Governmental Industrial Hygienists.

<sup>b</sup> Liquid ounces (at 20 C) of chemical in 1000 cu ft.<sup>c</sup> From 1953 list.

apply a reasonable safety factor to the ventilation estimate without consideration of the concentrations of gases or vapors that approach the danger point. Safety engineers prefer to limit the concentration to  $\frac{1}{4}$  or  $\frac{1}{5}$  of the lower explosive limit, and this fact should be given full weight in determining the capacity and design of ventilating equipment. Rarely should consideration be given to operation above the upper explosive limit in the open areas of buildings or rooms—even though unoccupied—because the danger of temporary drop of gas concentration to a point within the explosive range is too great.

Ability of a flammable liquid to form explosive mixtures is determined largely by its vapor pressure, volatility, or rate of evaporation. *Flash*

TABLE 4. LIMITS FOR TOXIC DUSTS, FUMES AND MISTS

point is a convenient method of expressing this property in terms of the temperature scale. It may be defined as the temperature to which a combustible liquid must be heated to produce a flash when a small flame is passed across the surface of the liquid. The higher the flash point, the more safely can the liquid be handled. Liquids with flash points under 70 F should be regarded as highly flammable.

Upper and lower limits of flammability of gases and vapors, and the flash points of the corresponding liquids are given in Table 6.

Methods for estimating the flammable limits of mixtures of gases or vapors must be applied with caution; the reader is referred to other publications for this information.<sup>12, 13</sup>

Design of equipment for the control of combustible anesthetics is outlined in Chapter 7. Construction of equipment for handling air contain-

ing flammable substances, or operating in atmospheres so contaminated, is discussed in Chapter 46.

It is customary to report the concentrations of flammable gases or vapors in percent by volume, or *volume percent*. Comparison with concentrations on the *part per million* scale used in chemical, medical or industrial hygiene literature is readily made by the conversion: 1 percent = 10,000 ppm (parts of contaminant per million parts of air, by volume, or in other words, cubic feet of contaminant per million cubic feet of air). It will be noted in Table 6 that nearly all of the substances listed have lower explosive limits above 1.0 percent, while the *maximum allowable concentrations* for gases and vapors in Table 3 are below 1000 ppm or 0.1 percent in most cases. Therefore, control of toxic or injurious vapors to levels below their maximum allowable concentrations for health usually requires much more effective ventilation than for the prevention of a fire hazard.

### COMBUSTIBLE DUSTS

A dust explosion is essentially a sudden pressure rise caused by the very rapid burning of airborne dust. The primary explosion often originates

TABLE 5. LIMITS FOR MINERAL DUSTS

| SUBSTANCE                                       | THRESHOLD LIMIT VALUES<br>A.C.G.I.H. 1954<br>mppcf* |
|-------------------------------------------------|-----------------------------------------------------|
| Aluminum                                        | 50                                                  |
| Asbestos                                        | 5                                                   |

| Total dust (below 5% free SiO <sub>2</sub> )    | 50                                                  |

\* mppcf—million particles per cubic foot of air, standard light field count.

from a small amount of dust in suspension exposed to a source of ignition and the pressure and vibration it creates may be sufficient to dislodge large accumulations of dust on horizontal ledges or surfaces of the building and equipment, thereby creating a secondary explosion of great force. Thus the air conditioning engineer is involved for two reasons: (1) to obtain a movement of dust-laden air into exhaust hoods or openings, and through ventilating or pneumatic conveying ducts, in a manner that will prevent accumulation of highly flammable dust at points where it could ignite inside the equipment; and (2) to so design *process ventilation* as to prevent the escape of dust which might settle on horizontal surfaces and become a potential source of disaster at some distance from the dusty operation. (See Chapter 46).

Intensity of a dust explosion depends upon: chemical and thermal properties of the dust; particle size and shape; concentration in air; proportion of inert dust in the air; moisture content and composition of the air; size and temperature of the ignition source; and degree of dispersion of the dust cloud. Investigations on the explosibility of dusts require determination of the maximum pressure developed during explosion of a known air concentration, as well as determination of the rate of pressure rise. In-

investigators frequently experience difficulty in obtaining dust suspensions of uniform dispersion, and this should be kept in mind when comparing results from several sources.<sup>14</sup>

Minimum explosive concentrations of airborne dusts already tested range from 0.01 to 0.5 oz per cubic foot, or 10 to 500 grams per cubic meter of air. Maximum pressures generated have been reported as high as 500 psi, although they are more likely to be of the order of 50 psi. Investigations on the flammable characteristics of dusts are currently made at 0.1 and 0.5 oz. per cubic foot.<sup>15-21</sup>

### ATMOSPHERIC POLLEN

Properties of pollen grains discharged by weeds, grasses and trees and responsible for hay fever, are of special interest to designers of air cleaning equipment (see Allergic Disorders in Chapter 7, and Air Cleaning, Chapter 34). Whole grains and fragments transported by the air range chiefly between 10 and 50 microns in size, but some have been measured as small as 5 microns, and others over 100 microns in diameter. Ragweed pollen grains are fairly uniform in size within the range of 15 to 25 microns. Pollen grains can be removed from the air more readily than the particles of dust prevalent in outdoor air or produced by dusty processes, since the latter predominate in the range of 0.1 to 10 microns in size.

Most grains are quite hygroscopic and therefore vary in weight with the humidity. Illustrations and data on individual pollen grains are available in the botanical literature.<sup>22, 23, 24</sup> Geographical distribution of plants known to produce hay fever is also recorded.<sup>25, 26</sup>

The quantity of pollen grains in the air is generally estimated by exposing an adhesive-coated glass plate outdoors for 24 hr, and then counting calibrated areas under the microscope. Methods are available for determining the number of grains in a measured volume of air,<sup>25, 27, 28</sup> but their greater accuracy has not caused them to replace the more simple *gravity slide method* used for most pollen counts. Counting technics vary somewhat, but the daily pollen counts reported in local newspapers during the

hay fever season usually represent the number of grains found on 1.8 sq cm of a 24-hr gravity slide.

Hay fever sufferers may notice the first symptoms when the pollen count is 10 to 25, and in some localities the maximum figures for the seasonal peak may approach 1000 for a 24-hr period, depending upon the sampling and reporting methods of the laboratory. Translation of gravity counts by special formulas to a volumetric basis, or the number of grains per cubic yard or per cubic foot of air, is unreliable because of the complexity of the modifying factors. When such information is important, it is best obtained directly by a volumetric instrument. The number of pollen grains per cubic yard of air evidently varies from 2 to 20 times the number found on 1 sq cm of a 24-hr gravity slide, depending on grain diameter, shape, specific gravity, wind velocity, humidity and physical placement of the collecting plate.<sup>29, 30, 31</sup>

### AIRBORNE BACTERIA

Study of the occurrence and significance of micro-organisms in the atmospheres of the indoor world is absorbing the energies of a substantial number of physicians, bacteriologists, aerobiologists, physicists, public health workers, engineers and hospital personnel. Some data are available on the types and quantities of bacteria found in a variety of spaces, but it is not possible at present to use this information as a conclusive index of the potential health hazard of a given environment. The reported number of airborne organisms may vary from 1 to 1000 per cubic foot of air, influenced somewhat by the method of testing.<sup>32</sup> Many are attached to the dust particles present in the air.

Where it seems advisable or desirable to control the bacterial content of rooms, public conveyances or buildings, highly effective methods are available (see Chapter 7), and their extended use may do much to assist the workers in this field in accumulating the necessary mass of evidence that will decide the practical value of air sterilization for the control of communicable disease. It is now well established that ultraviolet radiation is feasible for the protection or preservation of pharmaceuticals, cosmetics, and food products.

### RADIOACTIVE AIR CONTAMINANTS<sup>33</sup>

Radioactive air contaminants are physically similar to ordinary industrial and chemical plant contaminants. They differ from ordinary contaminants, however, in that they may be highly toxic when ingested and may present a direct radiation hazard when accumulated in appreciable quantities. Another factor which must be considered in the filtration of these materials is the possibility of their being concentrated in plant and animal life in the area of contamination. Concentrations resulting from absorptions by plants and subsequent feeding of animals in the magnitude of several thousand times, is not unusual. Tolerances for radioactive contaminants have been established and are under continuing study and review. Guidance in regard to tolerance levels for discharge of contaminated air in different types of localities can best be had from the classified literature which is available through proper clearance procedures.

### CHAPTER 9

## HEAT TRANSMISSION COEFFICIENTS OF BUILDING MATERIALS

Heat Transfer Symbols; Calculating Overall Coefficients; Conductivity of Homogeneous Materials; Soil Conductivity and Specific Heat; Surface Conductance; Air Space Conductance; Practical Coefficients and Their Use; Insulating Materials; Computed Coefficients of Walls, Roofs, Ceilings and Floors; Combined Ceiling and Roof Coefficients; Glass Coefficients; Calculating Surface Temperatures

THE design of air conditioning or heating systems for buildings requires a knowledge of the thermal properties of the walls enclosing the space. (The term *walls* in this case, includes windows, doors, ceilings, floors, roofs and skylights). The rate of heat flow through the walls under steady-state conditions at design temperatures is usually the basis for calculating the heat required. For a given wall under standard conditions the rate is a specific value designated as *U*, the overall coefficient of heat transmission or thermal transmittance. It may be determined by test in a guarded hot box apparatus, or it may be computed from known values of the thermal conductance of the various components. Because testing of all combinations of building materials is impracticable, the procedure and necessary data for calculation of the value of *U* are given in this chapter, together with tables of computed values for the more common constructions.

### HEAT TRANSFER SYMBOLS

*U* = overall coefficient of heat transmission or thermal transmittance (air to air); the time rate of heat flow expressed in Btu per (hour) (square foot) (Fahrenheit degree temperature difference between air on the inside and air on the outside of a wall, floor, roof or ceiling). The term is applied to the usual combinations of materials, and also to single materials, such as window glass, and includes the surface conductance on both sides.

*k* = thermal conductivity; the time rate of heat flow through a homogeneous material under steady conditions per unit temperature gradient through unit area perpendicular to the temperature gradient. Its value is expressed in Btu per (hour) (square foot) (Fahrenheit degree per inch of thickness). Materials are considered homogeneous when the value of *k* is not affected by variation in thickness or size of sample within the range normally used in construction.

*C* = thermal conductance; the time rate of heat flow through a unit area of a material from one of its surfaces to the other per unit temperature difference between the two surfaces. Its value is expressed in Btu per (hour) (square foot) (Fahrenheit degree). The term is applied to specific materials as used, either homogeneous or heterogeneous, for the thickness stated, not per inch of thickness.

*f* = film or surface conductance; the time rate of heat flow between a unit area of a surface and the surrounding air. Its value is expressed in Btu per (hour) (square foot of surface) (Fahrenheit degree temperature difference). Subscripts *i* and *o* are used to differentiate between inside and outside surface conductances, respectively.

*a* = thermal conductance of an air space; the time rate of heat flow through a unit area of an air space per unit temperature difference between the boundary surfaces. Its value is expressed in Btu per (hour) (square foot of area) (Fahrenheit degree). The conductance of an air space is dependent on the temperature difference, the height, the depth, the position and the character of the boundary surfaces. The relationships are not linear, and accurate values must be obtained by test and not by computation.

$e$  = emissivity; the ratio of the total radiant flux emitted by a surface to that emitted by an ideal black body at the same temperature.

$E$  = effective emissivity; the combined effect of the surface emissivities  $e$  of the boundary surfaces of an air space; the boundaries assumed to be parallel and of large dimensions as compared to the distance between them.

$r$  = surface reflectivity; the ratio of the radiant flux reflected by an opaque surface to that falling upon it.

$R$  = thermal resistance. Its value is obtained from the reciprocal of heat transfer as expressed by  $U$ ,  $k$ ,  $C$ ,  $f$  or  $a$ . It is expressed in (hours) (square feet) (Fahrenheit degrees) per (Btu). For example, a wall with a  $U$  value of 0.25 would have a resistance value of  $R = 1/0.25 = 4.0$ . Therefore, 4 hours would be required for the transfer of one Btu for each square foot of area and each degree of temperature differential.

### CALCULATING OVERALL COEFFICIENTS

From Chapter 5, Equation 7, the total resistance to heat flow through a wall is equal numerically to the sum of the resistances in series.

$$R_T = R_1 + R_2 + R_3 + R_4 + \dots + R_n \quad (1)$$

where  $R_1$ ,  $R_2$ , etc., are the individual resistances of the wall components.

$R_T$  = total resistance.

FIG. 1. TYPICAL VARIATION OF THERMAL CONDUCTIVITY WITH DENSITY—FOR FIBROUS MATERIAL

For a wall of a single homogeneous material of conductivity  $k$  and thickness  $x$ , with surface coefficients  $f_i$  and  $f_o$ ,

$$R_T = \frac{1}{f_i} + \frac{x}{k} + \frac{1}{f_o} \quad (2)$$

Then by definition,

$$U = 1/R_T$$

For a wall with air space construction and consisting of two homogeneous materials of conductivities  $k_1$  and  $k_2$ , thicknesses  $x_1$  and  $x_2$ , respectively, and separated by an air space of conductance  $a$ ,

$$R_T = \frac{1}{f_i} + \frac{x_1}{k_1} + \frac{1}{a} + \frac{x_2}{k_2} + \frac{1}{f_o} \quad (3)$$

and

$$U = 1/R_T$$

In the case of types of building materials having non-uniform or irregular sections such as hollow clay tile or concrete blocks, it is necessary to use the conductance  $C$  of the section unit as manufactured instead of a conductivity  $k$ . The resistance of the section  $1/C$  is therefore substituted for  $x/k$  in Equations 2 and 3.

### CONDUCTIVITIES AND CONDUCTANCES

The method of calculating the overall coefficient of heat transmission for a given construction is comparatively simple, but accurate values of conductivities and conductances must be used to obtain satisfactory results. In addition, there are sometimes parallel heat flow paths of different resistances in the same wall, and these may necessitate modification of the formula. In such cases calculated results should be checked by test.

The determination of the fundamental conductivities and conductances requires considerable skill and experience to obtain accurate results. It is recommended that thermal conductivities of homogeneous materials be determined by means of the Guarded Hot Plate.<sup>1</sup> For determination of conductances, a Guarded Hot Box method<sup>2</sup> is generally used.

Tables 1 and 2 give conductivities and conductances selected by the ASHAE Technical Advisory Committee on Insulation from available information. The values selected were those which in the judgment of the committee were good design values for surfaces, spaces, etc., and for the types of products marketed today.

FIG. 2. TYPICAL VARIATION OF THERMAL CONDUCTIVITY WITH MEAN TEMPERATURE

### Conductivity of Homogeneous Materials

*Thermal conductivity* is a property of a homogeneous material and of types of building materials such as lumber, brick, and stone, which may be considered homogeneous. Most insulating materials, except reflective types, are of a porous nature and consist of combinations of solid matter with small voids. The thermal conductivity of these materials will vary with density, mean temperature, size of voids, fibers, or particles, degree and extent of bond between particles, moisture present, and the arrangement of fibers or particles within the material.

The effect of density upon conductivity (at constant mean temperature) is illustrated for two fibrous materials in Fig. 1. Typical variation of conductivity with mean temperature is shown in Fig. 2.

### Thermal Conductivity of Soil

The following statements are based largely on results of a study<sup>3</sup> made in the *Engineering Experiment Station, University of Minnesota*, and published in *Bulletin No. 28*. Tests were made on nineteen different soils which represented a wide textural variety, including gravel, sand, sandy loam, silt loam and clay, as well as some crushed rocks and a fibrous peat. Moisture contents in tests varied from air-dried values to those greater than the optimum moisture content; densities varied from a loosely-poured

\* Conductances are for surfaces of the stated emissivity facing surroundings having an emissivity equal to 0.9 and at the same temperature as the ambient air. Values are based on a surface-air temperature difference of 10 F and for surface temperature of 70 F. (See Table 2 for surface conductances for moving air.)

Notes: <sup>a</sup> Spaces of uniform thickness, bounded by moderately smooth surfaces.

<sup>b</sup> Where a range of thickness is given, the given conductance is the average over the range; extreme values within the range differ therefrom by less than 10 percent.

<sup>c</sup> Interpolation, and moderate extrapolation, of conductance values are permissible for other values of mean temperature, temperature difference and effective emissivity E.

<sup>d</sup> Effective emissivity of space, E, is given by  $\frac{1}{E} = \frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1$  where  $\epsilon_1$  and  $\epsilon_2$  are the emissivities of the surfaces of the air space. (See Section C. below).

<sup>f</sup> The conductances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

\* Based on National Bureau of Standards data presented in Housing Research Paper No. 32, *Housing and Home Finance Agency*, 1954 (U. S. Government Printing Office, Washington, D. C.)

<sup>a</sup> Representative values for dry materials at 75 F mean temperature, selected by the A.S.H.A.E. Technical Advisory Committee on Insulation. They are intended as design (not specification) values for materials of building construction in normal use. For conductivity of a particular product, the user may obtain the value supplied by the manufacturer or secure the results of unbiased tests.

<sup>b</sup> Air space resistance values shown here are based on a temperature difference of 20 F deg and a mean temperature of 50 F for spaces faced both sides with ordinary non-reflective materials ( $e = 0.90$  and  $E = 0.82$ ).

<sup>c</sup> Surface resistance values shown here are for ordinary non-reflective materials ( $e = 0.90$ ).

<sup>d</sup> See also Insulating Materials, Board.

<sup>e</sup> Includes paper backing and facing if any. In cases where the insulation forms a boundary (highly reflective or otherwise) of an air space, refer to Table 1, Sections B and C, to obtain the insulating value of the air space for the appropriate effective emissivity and temperature conditions of the space.

<sup>f</sup> Insulating values of acoustical tile vary depending on density of the board and on the type, size and depth of the perforations. An average conductivity  $k$  value is 0.42.

<sup>g</sup> The U. S. Department of Commerce, Simplified Practice Recommendation for Thermal Conductance Factors for Preformed Above-Deck Roof Insulation, No. R 257-55, recognizes the specification of roof insulation on the basis of the  $C$  values shown. Roof insulation is made in thicknesses to meet these values. Therefore, thickness supplied by different manufacturers may vary depending on the conductivity  $k$  value of the particular material.

<sup>h</sup> Not oven dried—conductivity  $k$  prior to drying, approximately 1 to 3 years.

condition to the maximum density obtainable by heavy ramming. The general findings of the investigation are as follows:

**Effect of Temperature.** Soils were tested at several mean temperatures. The degree of influence of temperature depends upon whether it is above or below freezing. For increases of moisture content exceeding about 6 to 12 percent, the conductivity of frozen soil becomes progressively greater than that of the unfrozen soil.

**Effect of Density.** Density affects the thermal conductivity of a soil in about the same manner for all soils, at any moisture content, and for either the frozen or unfrozen condition. On the average, each one pound per cubic foot increase in dry density increases the thermal conductivity by about 3 percent.

**Effect of Moisture.** An increase in moisture content, up to the point of saturation,

causes an increase in thermal conductivity. The rate of increase in typical soils was as follows: average conductivities, in Btu per (square foot) (hour) (Fahrenheit degree per inch), of four sands at a density of 110 lb per cu ft were: 6.8 at 2.5 percent moisture, 8.9 at 5 percent moisture, 11.2 at 10 percent moisture. Five soils of a fine texture at a density of 100 lb per cu ft, gave average conductivities of 6.7 at 10 percent moisture, and 9.5 at 20 percent. Thus, the doubling of moisture content within the ranges cited increases the conductivity by approximately 30 or 40 percent. At higher moisture contents the percentage increase would be less.

**Effect of Soil Characteristics.** The thermal conductivity of the soil, at a given density and moisture content, varies in general with the texture of a soil, being relatively high for coarse-textured soils and relatively low for fine-textured soils. The mineral composition of the soils also affects the conductivity. Quartz tends to give high values, whereas minerals such as plagioclase-feldspar and pyroxene, which are constituents of basic rocks tend to give low values of thermal conductivity. These points are illustrated by the values in Table 3 which lists seventeen soils in approximate order of their magnitude of thermal conductivity from greatest to least for

— (inches per inch).

<sup>a</sup>  $k$  = Btu per (square foot) (hour) (Fahrenheit degree per inch).

seven different density-moisture content conditions. Some of the values in this table have been determined by extrapolation and are consequently approximate. Blank spaces in the table indicate that the density or moisture content, or both, are such that no tests were possible for that condition or that no tests were sufficiently close to permit a reasonable extrapolation of the data. Granular soils, particularly those with high quartz contents, head the tabulation or have the greatest conductivity at a given condition. Sandy loam soils are midway in the table and fine grained soils such as clay and silt loam are last.

**Estimating Thermal Conductivity.** The four diagrams of Fig. 3 are presented to aid in the estimate of the thermal conductivity of any soil. Two of the charts are for sands or sandy soils, and two for silt and clay soils. One of the diagrams for each type of soils is for the frozen, and the other for the unfrozen condition. It is expected that these charts will give conductivity values with a precision of 25 percent. The effect of such factors as density, moisture content, freezing, or texture may be easily approximated by use of these graphs.

### Specific Heat of Soils

Tests to determine specific heat were run on twelve soils. On five of the soils, tests were made at three or four mean temperatures varying

from about 10 to 140 F. The specific heat values of all twelve soils varied by only a small amount (about 0.01), and averaged 0.19 at 140 F. The specific heat values of the soils decreased with a decrease in temperature. The average value at zero F would be about 0.16. Values at temperatures between zero and 140 F can be estimated by considering a straight-line relationship between the two values given.

### Surface Conductance

The surface conductance of a wall is the combined heat transfer to or from the wall by radiation, convection and conduction. Each of the three portions making up the total may vary, independently of the others, thus

FIG. 3. DETERMINING THERMAL CONDUCTIVITY OF SOILS FROM DENSITY AND MOISTURE CONTENT

affecting the total conductance. The heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emissivity), the temperature difference between them, and the solid angle through which they see each other. The heat transfer by convection and conduction is controlled by the roughness of the surface, by air movement, and temperature difference between the air and the surface.

The importance of the effect of temperature of surrounding surfaces on the surface conductance, due to the effect on radiation, is illustrated in Table 4, which applies to a vertical surface at 80 F, with ambient air at 70 F and with radiation exchange corresponding to an effective emissivity of 0.83.

In many cases, because the heat resistance of the internal parts of the wall is high compared with the surface resistance, the surface factors are of minor importance. In other cases, e.g., single glass windows, the surface resistances constitute almost the entire resistance and are therefore very important. An analysis of various factors affecting surface conductance

and the difference between surface and air temperatures will be found in Reference 5. (See also Chapter 24.)

The convection part of the surface conductance is affected markedly by air movement. This is illustrated by Fig. 4, which shows the results of tests<sup>6</sup> made on 12 in. square samples of different materials at a mean temperature of 20 F, and for wind velocities up to 40 mph. These conductances include the radiation portion of the coefficient which, for the conditions of the tests, was about 0.7 Btu per (hr) (sq ft) (F deg). More recent tests<sup>7</sup> on smooth surfaces show that surface length also affects significantly the convection part of conductance; the average value decreases as the surface length increases. Moreover, observations<sup>8</sup> of the magnitude of low temperature radiant energy received from outdoor surroundings show that only under certain conditions may the out-of-doors be treated as a black body radiating at air temperature.

Because of these factors, the selection of surface conductance coefficients for a practical building becomes a matter of judgment. In calculating the overall heat transmission coefficients for the walls, etc., of Tables 7, 8, 9, 15, 16, 17, 18, 19, and 21, 1.65 has been selected as an average inside surface conductance, and 6.0 as an average outside surface conductance for a 15 mph

TABLE 4. VARIATION IN SURFACE CONDUCTANCE COEFFICIENT FOR VERTICAL SURFACES WITH DIFFERENT TEMPERATURES OF SURROUNDING SURFACE

| SURROUNDING SURFACE TEMPERATURE    | 75 F | 70 F | 60 F | 60 F | 50 F |
|------------------------------------|------|------|------|------|------|
| Convection—Btu per (hr) (sq ft)... | 6.6  | 6.6  | 6.6  | 6.6  | 6.6  |
| Radiation—Btu per (hr) (sq ft).... | 4.4  | 8.6  | 9.6  | 17.0 | 24.9 |
| Total—Btu per (hr) (sq ft).....    | 11.0 | 15.2 | 16.2 | 23.6 | 31.5 |

wind. Both values combine the effects of convection and radiation, and are applicable to ordinary building materials. They should not be used for low emissivity surfaces such as bright metal. Values of  $U$  for windows in Table 20 have been computed from somewhat different data, as described in a later section, in order to give proper weight to actual surface conductance.

In special cases, where surface conductances become important factors in the overall rates of heat transfer, more selective coefficients may be required. Principles and data given in Chapter 5, Heat Transfer, may be applied in such cases.

#### Air Space Conductance

The transfer of heat across an air space involves the boundary surfaces as well as the intervening air, and depends markedly on the orientation of the air space and the direction of heat flow. The coefficients given for air space conductance represent the total conductance from one surface bounding the air space to the other. The total conductance is the sum of a component due to radiation and a component due to convection and conduction combined. These components may vary independently of each other.

The radiation portion of the coefficient is affected by the temperature of the two boundary surfaces, and by their respective surface emissivities<sup>9</sup>, the combined effect of which is expressed by means of the effective emissivity  $E$  of the air space. The radiation component is not affected by the thickness of the space or by its orientation or direction of heat flow. The

#### Heat Transmission Coefficients of Building Materials

heat transfer by convection and conduction combined, however, is markedly affected by the orientation of the air space and the direction of heat flow, is significantly affected by the temperature difference across the space and in some cases by the thickness of the space, and is affected to only a small extent by the mean temperature of its surfaces. For air spaces usually employed in building construction, the radiation and convection-conduction components may vary independently of each other.

Table 1, Section B, gives the thermal conductances and resistances of air spaces of uniform thickness and moderately smooth surfaces, based on

FIG. 4. CURVES SHOWING RELATION BETWEEN SURFACE CONDUCTANCES FOR DIFFERENT SURFACES AT 20 F MEAN TEMPERATURE

experimental measurements conducted at the National Bureau of Standards.<sup>9</sup> Although the conductances of air spaces vary to some extent with thickness in the range over  $\frac{3}{4}$  in., average values are tabulated for the range from  $\frac{3}{4}$  in. to 4 in., for all except horizontal spaces with heat flow downward. The error involved by averaging is less than 10 percent in the extreme case and less than 5 percent in most. For more exact values Reference 9 may be consulted.

For narrow air spaces, which may be defined as those for which the product of the cube of the thickness of the space in inches times the temperature difference (Fahrenheit degrees) across the space is less than 3 for heat flow horizontally or downward, or less than 1 for heat flow upward, the conductance is the sum of the radiative heat transfer coefficient and that for conduction alone through air, since convection is practically suppressed. The radiation component can be computed by means of Equation 4 and Table 4 of Chapter 5; the conduction component can be

TABLE 5. CONDUCTIVITIES ( $k$ ), CONDUCTANCES ( $C$ ), AND RESISTANCES ( $R$ ) USED IN CALCULATING HEAT TRANSMISSION COEFFICIENTS ( $U$ ) IN TABLES 7 TO 19\*

These constants are expressed in Btu per (hour) (square foot) (Fahrenheit degree temperature difference). Conductivities ( $k$ ) are per inch thickness and conductances ( $C$ ) are for thickness or construction stated, not per inch thickness

Conductivities (k) are for construction stated, not per inch thickness

\* The values in this table do not agree exactly with those given in Table 2 which was revised in this issue, but the differences are not significant for design use. Tables 5 and 7 through 19 are in the process of revision so that they will correspond to Table 2.

† For practical accuracy these values can be used as an average for vertical and horizontal surfaces. Where accuracy is desired refer to Table 2. These values for Tables 5 and 7 through 19 are in the process of revision.

computed using the conductivity of air at the appropriate mean temperature (see Table 1, Chapter 5).

The effects of different mean temperatures, temperature differences, and effective emissivities are indicated in Table 1, Section B. As indicated, use may be made of interpolation and moderate extrapolation of conductance values in the table to obtain conductances for conditions moderately different from those given. Interpolation of resistance values is not recommended, especially in relation to emissivity values.

Table 1, Section C gives values for the surface reflectivities and emissivities of materials used as boundaries of air spaces in building construction, for total radiation at ordinary building temperatures. Effective emissivities for various combinations of these materials, for use in conjunction with Section B of Table 1, are given in the last two columns of Section C.

When considering heat transfer across air spaces in building construction, the emissivities of the boundary surfaces should be known. The possibility of change in emissivity of highly reflective surfaces due to exposure to conditions promoting chemical action, deposition of dust, soiling of the surface

or the application of coatings, even though transparent to the eye, must be considered in selecting a material for use.<sup>10</sup> Surface emissivity values should be obtained by tests.

### PRACTICAL COEFFICIENTS AND THEIR USE

For practical purposes it is necessary to compute average coefficients that may be applied to various materials and types of construction. Table 2, as revised in this issue, gives representative values for dry materials at 70 F mean temperature, as selected by the ASHAE Technical Advisory Committee on Insulation. Since there may be some variation in the materials and in test conditions, these selected values may not be in exact agreement with published data of all manufacturers. The exact value for the conductivity or conductance of a certain manufacturer's material can only be secured from unbiased tests or guaranteed by the manufacturer.

#### Caution

The conductivity or conductance values given in Tables 1 and 2 are taken from values obtained in most cases by the guarded hot plate method ASTM Standard C-177-45 which states,

"Because of the requirements prescribed in this method as to conditions under which conductivity tests shall be made, it should be recognized that the conductivity coefficients obtained will not necessarily be the values pertaining under all service conditions. As an example, the method provides that the conductivity coefficient shall be obtained by test on dry specimens, while in service such a condition will seldom be realized."

The user should realize that the average conductivity and conductance values given in Tables 2 or 5 do not necessarily apply to all products of the same general description. In using these values, judgment should be exercised with regard to the extent to which the product (either as received or as applied) will comply with the tabulated values. Exact conductivities or conductances for specific materials should be obtained from the manufacturer. Table 5 has been retained in this edition because it is the basis for computation of the  $U$ -values shown in Tables 7 to 18.

Because  $U$  values for heat flow upward, such as for ceilings in winter, may differ greatly from  $U$  values for heat flow downward, such as for ceilings in summer, a serious error may be made in calculating heat losses or gains if the appropriate  $U$  value is not used. (See Chapter 13 for recommended temperature gradients for cooling loads.)

Due to the inconsistency of actual building construction, because of the human element, many designers do not use overall coefficients of transmission lower than 0.10 for walls and particularly roofs, except where the construction is installed under continuous supervision. It should also be noted that these coefficients do not include any factor of safety and that when no supervision is used, some designers incorporate a 10 percent factor of safety.

Attention is called to the necessity of applying the insulating material in accordance with the manufacturer's specification. The engineer must evaluate carefully the economic considerations involved in the selection of an insulating material as adapted to various building constructions. Lack of proper evaluation, or improper installation may lead to unsatisfactory results. Special attention must be given to vapor barriers as outlined in Chapter 10. Moisture from condensation or other sources materially reduces the heat-flow resistance of insulation.

### Insulating Materials

In order to determine the benefit derived from the addition of insulating materials to a given construction, the overall coefficient of heat transmission,  $U_i$  of the insulated construction may be compared with the corresponding coefficient  $U$  without insulation. Table 6 (Part A to Part D) may be used for determining the coefficients of transmission of constructions with any combination of fibrous, bulk, or mass insulation and air spaces of various effective emissivities.

### INSULATED CONSTRUCTIONS—HOW TO USE TABLE 6

In Tables 7 to 17,  $U$  values are given for many common types of building wall, floor, and ceiling constructions. For such of these constructions as contain an air space, the tabulated  $U$  value is based on the assumption that the air space is empty, and that its surfaces are of ordinary building materials of low thermal reflectivity, such as wood, masonry, plaster or paper. Considerable benefit in reducing the heat transmission coefficient of a construction can be effected by the application of thermal insulating materials in the air space.

Table 6 provides a means of determining, without calculations, the  $U$  value of the between-framing area of such constructions with the added insulation installed in the air space. Column 1 of Table 6 refers to the  $U$  values of uninsulated constructions as taken from Tables 7 to 17. Columns 2 to 14 of the table give corresponding coefficients  $U_i$  for the constructions with various insulating applications in the between-framing air space, as indicated by the column headings. Table 6 is in four parts, corresponding to the type of building element and the direction of heat flow. Each part is based on temperature conditions considered generally appropriate for the case.

Any and all  $U$  values are based on a series of assumptions as to nominal characteristics. Common variations in conditions, materials, workmanship, etc. can introduce much greater variations in  $U$  values than the variations resulting from the assumed mean temperatures and temperature differences described. From this it is also clear that the use of more than two significant figures in stating a  $U$  value is assuming more precision than can possibly exist. Three significant figures are used in Table 6 merely as a means of reducing cumulative errors when the table is used several times to obtain a single result. It should not be assumed that the figures are accurate, over-all, to three significant figures. Also a result taken from Table 6 should always be rounded off to two significant figures.

#### To use Table 6:

1. Find in Column 1 of the appropriate table the value for  $U$  obtained from Tables 7 to 17.
2. If there is a column which exactly corresponds to the condition for which you desire the  $U$  value, read the answer in this column, opposite the Column 1 value. Interpolate if necessary.
3. If there is no column which fully corresponds to the condition for which you desire the  $U$  value, then obtain the answer by means of two or more steps—each time using the value obtained in one step to reenter the same table through Column 1. In this way  $U$  values may be obtained for combinations of insulation in the framing space.

#### Special Uses of Table 6

Values of  $U_i$  for insulating applications or combinations other than those indicated by the headings of Columns 2 to 14 of Table 6 can be ascertained

TABLE 6. DETERMINATION OF  $U$  VALUE RESULTING FROM ADDITION OF INSULATION OR AIR SPACES TO UNINSULATED BUILDING SECTIONS\*  
PART A. WALLS\*

\* For constructions with air spaces as insulation, coefficients are based on National Bureau of Standards data in Housing Research Paper No. 32 (U. S. Government Printing Office, Washington, D. C.).

<sup>a</sup> Based on an indoor-outdoor temperature difference of 70 F deg, and a mean temperature of 50 F. Values are applicable conservatively to winter and summer conditions.

<sup>b</sup>  $U$  value taken from Tables 7 to 17, based on one non-reflective air space between framing members.

<sup>c</sup> Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).

<sup>d</sup> Spaces of uniform thickness not less than 3/4 in.

<sup>e</sup> For values of effective emissivity  $E$  of air space, see Table 1, Section C.

<sup>f</sup> Certain  $U$  values in Column 6 differ from Column 1 because they are adjusted to the specific temperature drop across the air space in question as affected by the  $U$  value of the construction.

TABLE 6. DETERMINATION OF  $U$  VALUE RESULTING FROM ADDITION OF INSULATION OR AIR SPACES TO UNINSULATED BUILDING SECTIONS\* (Continued)  
PART B. FLOORS—HEAT FLOW DOWN

\* For constructions with air spaces as insulation, coefficients are based on National Bureau of Standards data in Housing Research Paper No. 32 (U. S. Government Printing Office, Washington, D. C.).

<sup>a</sup> Based on a temperature difference of 50 F deg from air to air, and a mean temperature of 50 F.

<sup>b</sup>  $U$  value taken from Tables 12 and 13, in which it is assumed that the air space between joists or above the suspended ceiling is non-reflective ( $E = 0.92$ ).

<sup>c</sup> Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).

<sup>d</sup> Spaces of uniform thickness not less than 3/4 in.

<sup>e</sup> For values of effective emissivity  $E$  of air space, see Table 1, Section C.

TABLE 6. DETERMINATION OF U VALUE RESULTING FROM ADDITION OF INSULATION OR AIR SPACES TO UNINSULATED BUILDING SECTIONS\* (Continued)

\* For construction with air spaces as insulation, coefficients are based on National Bureau of Standards data in Housing Research Paper No. 32 (U. S. Government Printing Office, Wash., D. C.).

<sup>1</sup> Based on a temperature difference of 75 deg F from air to air, and a mean temperature of 40 F.

<sup>2</sup> U value taken from Tables 12, 13 and 15-16, in which it is assumed that the air space between joists or above the suspended ceiling is non-reflective (E = 0.82).

<sup>3</sup> Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).

<sup>4</sup> Spaces of uniform thickness not less than 1/4 in.

<sup>5</sup> For values of effective emissivity E of air space, see Table 1, Section C.

<sup>6</sup> Certain U values in Column 6 differ from Column 1 because they are adjusted to the specific temperature drop across the air space in question as affected by the U value of the insulation.

TABLE 6. DETERMINATION OF U VALUE RESULTING FROM ADDITION OF INSULATION OR AIR SPACES TO UNINSULATED BUILDING SECTIONS\* (Continued)

PART D. CEILINGS—HEAT FLOW DOWN† (SUMMER CONDITION)

| 0.12                                                | 0.098                                            | 0.083 | 0.064 | 0.051 | 0.051 | 0.120                                                                | 0.093 | 0.063 | 0.108 | 0.072                                                                 | 0.086 | 0.098 | 0.059 | 0.036                                                                   |    |  |  |
| 0.10                                                | 0.085                                            | 0.073 | 0.058 | 0.047 | 0.047 | 0.099                                                                | 0.080 | 0.056 | 0.091 | 0.064                                                                 | 0.086 | 0.084 | 0.054 | 0.033                                                                   |    |  |  |
| 0.08                                                | 0.070                                            | 0.062 | 0.050 | 0.042 | 0.042 | 0.079                                                                | 0.068 | 0.048 | 0.074 | 0.054                                                                 | 0.084 | 0.070 | 0.046 | 0.030                                                                   |    |  |  |

For construction with air spaces as insulation, see Fig. 1.

\* For construction with air spaces as insulation, coefficients are based on National Bureau of Standards data in Housing Research Paper No. 32 (U. S. Government Printing Office, Wash., D. C.).

<sup>1</sup> Based on a temperature difference of 35 F deg from air to air, and a mean temperature of 100 F.

<sup>2</sup> U value taken from Tables 7 to 17, in which it is assumed that the air space between joists or above the suspended ceiling is non-reflective (E = 0.82).

<sup>3</sup> Thermal conductivity of fibrous or bulk insulation taken as 0.27 Btu per (hr) (sq ft) (F deg per in.).

<sup>4</sup> Spaces of uniform thickness not less than 1/4 in.

<sup>5</sup> For values of effective emissivity E of air space, see Table 1, Section C.

if the table is used appropriately. For instance, going horizontally in the table from Column 2 to Column 3 is equivalent to adding  $\frac{1}{2}$  in. of fibrous insulation to the construction; similarly, going from Column 2 to Column 4 adds  $1\frac{1}{2}$  in. of fibrous insulation to the construction. In the same way, going horizontally from Column 8 to Column 11 is equivalent to adding to a construction the insulating value of one additional highly reflective ( $E = 0.05$ ) air space, and going from Column 6 to Column 12 in effect adds two non-reflective ( $E = 0.82$ ) air spaces to the construction, etc.

### CORRECTION FOR FRAMING

Correction for parallel heat flow through framing and insulated areas may be made by use of Fig. 5. Correction for the effect of framing should

FIG. 5. CORRECTION FOR EFFECT OF FRAMING IN INSULATED BUILDING SECTIONS

$U_{av}$  = average  $U$  value for building section.  
 $U_i$  =  $U$  value for area between framing members.  
 $U_s$  =  $U$  value for area backed by framing members.  
 $S$  = Percentage of area backed by framing members.

be applied after final  $U_i$  and  $U_s$  values have been obtained for a given construction. In many cases this correction may be omitted.

**Example 1:** Consider a frame wall with 2-in. blanket insulation which has a  $U_i$  value of 0.08. By calculation it is found that heat loss from the area backed by framing members ( $U_s$ ) is 0.13.  $U_s/U_i$  is 1.63. From Fig. 5 if 15 per cent of wall area is backed by framing, the value  $U_{av}/U_i = 1.1$ .  $U_{av}$  is therefore  $1.1 \times 0.08 = 0.088$ .

### Computed Heat Transmission Coefficients

Computed overall heat transmission coefficients of many common types of building construction are given in Tables 7 to 21. In the analysis of any wall construction for the purpose of calculating the overall coefficient of heat transmission  $U$ , it is first necessary to determine the paths of heat flow, that is, whether they are parallel or series, or a combination of both. This is in accordance with the basic laws of heat transfer which state that in parallel flow the conductances are additive, while in series flow the resistances are additive. Likewise, in order to determine the total resistance for the wall, the conductance must be known.

The importance of this analysis cannot be over-emphasized. This is especially true in wall constructions in which there are parallel paths of heat flow, and one path has a high heat transfer, while others have a low heat transfer. The method of making this calculation can best be shown by *Example 2* and Fig. 6. As this wall was tested by the hot box method

at the University of Minnesota, a direct comparison can be made between calculated and tested values.

**Example 2:** Calculate the coefficient of heat transmission  $U$  for a wall shown in Fig. 6. Wall construction consists of two 4-in. concrete walls separated by a  $2\frac{1}{2}$ -in. space filled with insulation;  $\frac{1}{4}$ -in. diameter metal tie rods are imbedded a distance of 1 in. in each 4-in. concrete wall, and spaced 9 in. vertically and 12 in. horizontally. Values of  $k$  are: insulation 0.30, concrete 12.00, tie rods 400.00.

**Solution:** In Fig. 6 the following paths of heat flow from plane A to plane F will be noted:

1. From A to B: One path through 3 in. of concrete.
2. From B to C: Two paths, (a) through 1 in. of tie rod, and (b) through 1 in. of concrete.

FIG. 6. SECTION OF CONCRETE WALL HAVING STEEL TIE RODS AND INSULATION

3. From C to D: Two paths, (a) through  $2\frac{1}{2}$  in. of tie rod, and (b) through  $2\frac{1}{2}$  in. of insulation.
4. From D to E: Two paths, (a) through 1 in. of tie rod, and (b) through 1 in. of concrete.
5. From E to F: One path through 3 in. of concrete.

It will be noted that items 2 and 4 are paths of similar flow, and could be treated as one. If equilibrium or steady state heat transfer is assumed, there will exist a temperature difference between the metal tie rod and the concrete, and also between the metal tie rod and the insulating material. The rate of heat transfer between these materials is dependent upon their conductivity values and the temperature difference. As the conductivity of the metal tie rods is considerably higher than that of the concrete or insulating material, it cannot be assumed that the same rate of heat transfer takes place for all parallel paths. Likewise, an appreciable error would be made by assuming that no heat transfer takes place between the metal tie rod and the surrounding materials. Although the pattern of the isotherms is unknown, the following method of calculation does partially take into account the heat flow between the metal tie rods and its bounding materials.

**Parallel Flow.** The conductances through the areas of parallel heat flow may be determined as follows:

1. The area of each  $\frac{1}{4}$ -in. diameter tie rod is 0.00034 sq ft, and as the tie rods are spaced 9 in. vertically, and 12 in. horizontally, there will be  $0.00034 \times \frac{4}{3} = 0.00045$  sq ft of tie rod to each square foot of wall area. Then from plane B to plane C, the conductance  $C_1$  is

$$C_1 = \frac{0.00045}{1.0} \times \frac{400}{1.0} + \frac{0.99955}{1.0} \times \frac{12}{1.0} = 0.180 + 11.994 = 12.174$$

2. For tie rod and insulation from plane C to plane D the conductance  $C_2$  is

$$C_2 = \frac{0.00045}{1.0} \times \frac{400}{2.5} + \frac{0.99952}{1.0} \times \frac{0.30}{2.5} = 0.072 + 0.120 = 0.192$$

3. For tie rod and concrete from plane D to plane E the conductance  $C_3$  is

$$C_3 = \frac{0.00045}{1.0} \times \frac{400}{1.0} + \frac{0.99952}{1.0} \times \frac{12}{1.0} = 0.180 + 11.994 = 12.174$$

*Series Flow.* After the conductance values have been determined, the total resistance and  $U$  value can be determined as follows:

$$R_T = \frac{1}{f_i} + \frac{x_1}{k_1} + \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \frac{x_2}{k_2} + \frac{1}{f_o}$$

$$R_T = \frac{1}{1.65} + \frac{3.0}{12.0} + \frac{1}{12.174} + \frac{1}{0.192} + \frac{1}{12.174} + \frac{3.0}{12.0} + \frac{1}{6.0}$$

$$R_T = 0.606 + 0.250 + 0.0822 + 5.208 + 0.0822 + 0.250 + 0.167 = 6.727$$

$$U = \frac{1}{R_T} = \frac{1}{6.727} = 0.149 \text{ Btu per (hr) (sq ft) (F deg).}$$

The Hot Box test value, from *University of Minnesota*, for this wall, corrected for a 15 mph wind velocity, was  $U = 0.150$  Btu per (hr) (sq ft) (F deg). The error between the calculated and test values would be

$$\frac{0.150 - 0.149}{0.150} \times 100 = 1 \text{ percent.}$$

If the effect of the tie rods were omitted from the calculations, the overall  $U$  value would be 0.103. Although the percentage of area occupied by

the tie rods per square foot of wall area is  $\frac{0.00045}{1.0} \times 100 = 0.045$  percent, the error between the calculated and test values would be

$$\frac{0.150 - 0.103}{0.150} \times 100 = 31 \text{ percent.}$$

### Values Used in Calculation of $U$ Value Tables

In making the calculations for values of  $U$  shown in Tables 7 to 19, the following conditions have been assumed:

- Equilibrium or steady-state heat transfer, eliminating effects of heat capacity.
- Surrounding surfaces at ambient air temperatures.
- Exterior wind velocity of 15 mph for winter and 7.5 mph for summer.
- Surface emissivity of ordinary building materials = 0.83.
- Spaces between framing or furring not insulated. (See Table 6 for method of correcting for added insulation.)
- Air spaces are  $\frac{3}{4}$  in. or more in width.
- Variations of conductivity with mean temperature neglected.
- Corrections for framing to be made on basis of parallel heat flow through  $2 \times 4$  in. (nominal) studs, 16 in. on centers, the framing covering 15 per cent of wall area, as indicated in Fig. 5.
- Thermal resistance for gypsum board and insulating board apply equally to plain material and to those which may be decorated at the factory or on the job.

Actual thicknesses of lumber assumed to be as follows:

| Nominal                    | Actual             | Nominal                         | Actual             |
|----------------------------|--------------------|---------------------------------|--------------------|
| 1 in. (S-2-S)              | $\frac{3}{4}$ in.  | 3 in. (S-2-S)                   | $2\frac{3}{4}$ in. |
| $1\frac{1}{2}$ in. (S-2-S) | $1\frac{1}{8}$ in. | 4 in. (S-2-S)                   | $3\frac{3}{4}$ in. |
| 2 in. (S-2-S)              | $1\frac{1}{2}$ in. | Finish flooring, (maple or oak) | $\frac{1}{4}$ in.  |
| $2\frac{1}{2}$ in. (S-2-S) | $2\frac{1}{4}$ in. |                                 |                    |

Coefficients for frame construction are corrected for the effect of framing where such correction would increase the coefficients, but not where the correction would decrease the coefficients.<sup>11</sup>

It should be noted that the effects of poor workmanship in construction and installation have an increasingly greater percentage effect on heat transmission as the coefficient becomes numerically smaller. Failure to meet design estimates may be caused by lack of proper attention to exact compliance with specifications. A factor of safety may be employed as a precaution when it is judged desirable.

### Roof Coefficients

Computations for wood shingle roofs applied over wood stripping are based on 1 by 4 in. wood strips, spaced 2 in. apart. Values for roofs containing Spanish and French clay roofing tile are assumed the same as for slate roofs. Values for pitched roofs in Table 17 apply where the roof is over a heated attic or top floor, so that the heat passes directly through the roof structure, including any interior finish material.

### Combined Ceiling and Roof Coefficients

If the attic space between the ceiling and roof is unheated and not ventilated, the combined coefficient from room air below the ceiling to exterior air can be calculated from the following formula:

$$R_T = \frac{1}{U_{ce}} + \frac{1}{nU_r} \quad (4)$$

and

$$U = 1/R_T \quad (5)$$

where  $U$  = combined coefficient to be used with ceiling area.

$R_T$  = total resistance of ceiling and roof.

$U_{ce}$  = coefficient of transmission of ceiling.

$U_r$  = coefficient of transmission of roof.

$n$  = ratio of roof area to ceiling area.

It should be noted that the overall coefficient  $U$  should be multiplied by the ceiling area to determine heat loss, and not by the roof area. Values of  $U_r$  and  $U_{ce}$  should be calculated using a value of 2.2 (the reciprocal of one-half the air space resistance) rather than 1.65 for the conductances of surfaces facing the attic, since the attic is equivalent to an air space.

If the attic contains windows, dormers and vertical wall spaces, and if their area is small compared to that of the roof, they may be considered part of the roof area. For accuracy, the sum of the coefficients of each individual section, multiplied by its percentage of the total area, should be used as  $U_r$ . Where attic wall areas are large, it is preferable to estimate the attic temperature as illustrated in Chapter 12, and calculate the heat loss through the ceiling by multiplying the value of  $U_{ce}$  for the ceiling by the difference in temperature above and below the ceiling.

TABLE 7. COEFFICIENTS OF TRANSMISSION (*U*) OF FRAME WALLS\*

These coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

NO INSULATION BETWEEN STUDS\* (SEE TABLE 6)

| EXTERIOR FINISH                                                                                                  | INTERIOR FINISH                                        | TYPE OF SHEATHING      |                         |                                  |                                  | WALL NUMBER |

(See text p. 186.) \* See Table 5, Note a.

<sup>a</sup> Coefficients not weighted; effect of studding neglected.

<sup>b</sup> Plaster assumed 3/4 in. thick.

<sup>c</sup> Plaster assumed 1/2 in. thick.

<sup>d</sup> Furring strips (1 in. nominal thickness) between wood shingles and all sheathings except wood.

<sup>e</sup> Small air space and mortar between building paper and brick veneer neglected.

<sup>f</sup> Nominal thickness, 1 in.

TABLE 8. COEFFICIENTS OF TRANSMISSION (*U*) OF MASONRY WALLS\*

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

| TYPE OF MASONRY                                                                                                                | THICKNESS OF MASONRY INCHES         | INTERIOR FINISH<br>(PLUS INSULATION WHERE INDICATED) |                            |                                     |                                                      |                                                     |                                                                   |                                                               |                                                             |                                                                         | WALL NUMBER |

(See text p. 186.) \* See Table 5 Note a.

<sup>a</sup> Based on 4 in. hard brick and remainder common brick.

<sup>b</sup> The 8 in. and 10 in. tile figures are based on two cells in the direction of heat flow. The 12 in. tile is based on three cells in the direction of heat flow. The 16 in. tile consists of one 10 in. and one 6 in. tile, each having two cells in the direction of heat flow.

<sup>c</sup> Limestone or sandstone.

<sup>d</sup> These figures may be used with sufficient accuracy for concrete walls with stucco exterior finish.

<sup>e</sup> Expanded slag, burned clay or pumice.

<sup>f</sup> Thickness of plaster assumed 1/2 in.

<sup>g</sup> Thickness of plaster assumed 1/2 in.

<sup>h</sup> Based on 2 in. furring strips; one air space.

TABLE 9. COEFFICIENTS OF TRANSMISSION (*U*) OF BRICK AND STONE VENEER MASONRY WALLS\*

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

(See text p. 186). \* See Table 5, Note a.

<sup>a</sup> Coefficients not weighted; effect of studding neglected.<sup>b</sup> Plaster assumed ½ in. thick.<sup>c</sup> Plaster assumed ¾ in. thick.<sup>d</sup> For partitions with other insulations between studs refer to Table 6, using values in Column B of above table, in left-hand column of Table 6. Example: What is the coefficient of transmission (*U*) of a partition consisting of gypsum lath and plaster on both sides of studs with 2 in. blanket between studs? Solution: According to above table, this partition with no insulation between studs (No. 4B) has a coefficient of 0.34. Referring to Table 6, it will be found that a wall having a coefficient of 0.34 with no insulation between studs, will have a coefficient of 0.10 (approx.) with 2 in. of blanket insulation between studs (No. 56B).TABLE 11. COEFFICIENTS OF TRANSMISSION (*U*) OF MASONRY PARTITIONS\*

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on still air (no wind) conditions on both sides.

(See text p. 186). \* See Table 5, Note a.

<sup>a</sup> 2 in. solid plaster partition, *U* = 0.53.<sup>b</sup> Expanded slag, burned clay or pumice.

TABLE 12. COEFFICIENTS OF TRANSMISSION ( $U$ ) OF FRAME CONSTRUCTION CEILINGS AND FLOORS\*

TABLE 12. COEFFICIENTS OF TRANSMISSION (U) OF FRAME CONSTRUCTION CEILINGS AND FLOORS  
Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference between the air on the two sides) and are based on still air (no wind) conditions on both sides.

|                                               |                                                                 |                                              |        |                                           |       |                                       |       |                                        |       |       |       |  |

(See text p. 189). \* See Table 5, Note a.

a Coefficient corrected for framing on basis of 15 percent area, 2 in. x 4 in. (nominal) framing, 16 in. on centers.

b 1/2 in. yellow pine or fir.

c 1/2 in. pine or fir sub-flooring plus 1/2 in. hardwood finish flooring.

d Plaster assumed 1/2 in. thick.

e Plaster assumed 1/2 in. thick.

f Based on insulation in contact with ceiling, and consequently no air space between.

g For coefficients for constructions in Columns M and N (except No. 1) with insulation between joists, refer to Table 6. Example: The coefficient for No. 3-N of Table 12 is 0.24. With 2 in. blanket insulation between joists, the coefficient will be 0.083. (See Table 6). Column D of Table 6 applicable only for 3/4 in. joists.

h For 1/2 in. insulating board sheathing applied to the under side of the joists, the coefficient for single wood floor (Column M) is 0.18 and for double wood floor (Column N) is 0.10.

i For coefficients with insulation between joists, see Table 6.

TABLE 13. COEFFICIENTS OF TRANSMISSION ( $U$ ) OF CONCRETE CONSTRUCTION FLOORS AND CEILINGS\*

Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on still air (no wind) conditions on both sides.

\* Thickness of tile assumed to be 1 in. \* See Table 5, Note a.

b Conductivity of asphalt tile assumed to be 3.1.

c Thickness of wood assumed to be 1/2 in.; thickness of mastic, 1/2 in. (k = 4.5). Col. D may also be used for concrete covered with carpet.

d Based on 1/2 in. yellow pine or fir sub-flooring and 1/2 in. hardwood finish flooring with an air space between sub-floor and concrete.

e Thickness of plaster assumed to be 1/2 in.

f Thickness of plaster assumed to be 1/2 in.

g For other thickness of concrete, interpolate.

TABLE 14. COEFFICIENTS OF TRANSMISSION ( $U$ ) OF CONCRETE BASEMENT FLOORS ON GROUND WITH VARIOUS TYPES OF FINISH FLOORING

$U = 0.10$  Btu per (hr) (sq ft) (Fahrenheit degree temperature difference between the ground and the air over the floor).

\* Since authentic data are not available, this coefficient is sometimes used for concrete floors on ground. For more recent procedures refer to National Bureau of Standards Report BMS-103, 11, 12.

### Basement Floor, Basement Wall and Concrete Slab Floor Coefficients

The heat transfer through basement walls and floors to the ground is dependent on the temperature difference between the air within and that of the ground, on the material constituting the wall or floor, and on the conductivity of the surrounding earth. The conductivity of the earth will vary with local conditions, and is usually unknown. Tests<sup>12</sup> at the A.S.H.A.E. Research Laboratory indicate a heat flow of approximately 2.0 Btu per (hr) (sq ft) through an uninsulated concrete basement floor, with a temperature difference of 20 deg between ground temperature and the air temperature 6 in. above the floor. Based on this result a coefficient of 0.10 Btu per (hr) (sq ft) (Fahrenheit degree difference) is recommended for calculation where it is desirable to allow for the small basement floor heat loss, e.g., for heated basements.

For basement walls the same coefficient may be used, but due to closer proximity to the surface of the ground, the temperature difference for win-

TABLE 15. COEFFICIENTS OF TRANSMISSION (*U*) OF FLAT ROOFS COVERED WITH BUILT-UP ROOFING. NO CEILING—UNDER SIDE OF ROOF EXPOSED\*

(See Table 16 for Flat Roofs with Ceilings)

These coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

| TYPE OF ROOF DECK                                                                   | THICK-<br>NESS OF<br>ROOF<br>DECK<br>(INCHES) | NO IN-<br>SULA-<br>TION | INSULATION ON TOP OF DECK<br>(COVERED WITH BUILT-UP ROOFING) |       |           |       |       |                                |       |       | NUM-<br>BER |

\* See Table 5, Note a.

\* Coefficient of transmission of bare corrugated iron (no roofing) is 1.50 Btu per (hr) (sq ft of projected area) (F deg difference in temperature) based on an outside wind velocity of 15 mph.

<sup>b</sup> 67 1/2 percent gypsum, 12 1/2 percent wood fiber. Thickness indicated includes 1/2 in. gypsum board.<sup>c</sup> Nominal thicknesses specified—actual thicknesses used in calculations.TABLE 16. COEFFICIENTS OF TRANSMISSION (*U*) OF FLAT ROOFS COVERED WITH BUILT-UP ROOFING. WITH LATH AND PLASTER CEILINGS\*

(See Table 15 for Flat Roofs with No Ceilings)

These coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

\* See Table 5, Note a.

\* Calculations based on metal lath and plaster ceilings, but coefficients may be used with sufficient accuracy for gypsum lath or wood lath and plaster ceilings. It is assumed that there is an air space between the under side of the roof deck and the upper side of the ceiling.

<sup>b</sup> 67 1/2 percent gypsum, 12 1/2 percent wood fiber. Thickness indicated includes 1/2 in. gypsum board.<sup>c</sup> Nominal thicknesses specified—actual thicknesses used in calculations.

TABLE 17. COEFFICIENTS OF TRANSMISSION ( $U$ ) OF PITCHED ROOFS\*  
Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

Coefficients are expressed in *Btu per (hour) (square foot)*, and are based on an outside wind velocity of 15 mph.  
the air on the two sides), and are based on an outside wind velocity of 15 mph.

TYPE OF CEILING  
(APPLIED DIRECTLY TO ROOF RAFTERS)

No Ceiling Applied to Rafters.

(See text on p. 189) \* See Table 5, Note a.  
<sup>a</sup> Coefficients corrected for framing on basis of 15 percent area, 2 in. x 4 in. (nominal), 16 in. on centers.  
<sup>b</sup> Figures in Columns I, J, K and L may be used with sufficient accuracy for rigid asbestos shingles on wood sheathing. Layer of slater's felt neglected.

<sup>c</sup> Sheathing and wood strips assumed 2 1/2 in. thick.

<sup>d</sup> Plaster assumed 3/4 in. thick.

<sup>e</sup> Plaster assumed 1/2 in. thick.

<sup>f</sup> No air space included in I-A, I-E or I-I; all other coefficients based on one air space.

TABLE 18. COMBINED COEFFICIENTS OF TRANSMISSION ( $U$ ) OF UNVENTED PITCHED ROOFS\* AND HORIZONTAL CEILINGS—BASED ON CEILING AREA\*\*

Coefficients are expressed in Btu per (hour) (square foot of ceiling area) (Fahrenheit degree difference in temperature between the air on the two sides), and are based on an outside wind velocity of 15 mph.

(See text on p. 189.) \* See Table 5, Note a.

<sup>a</sup> Calculations based on 1/2 pitch roof ( $n = 1.2$ ) using the following formula:

$$U = \frac{U_r \times U_{ce}}{U_r + \frac{U_{ce}}{n}}$$

$U$  = combined coefficient to be used with ceiling area.

$U_r$  = coefficient of transmission of the roof.

$U_{ce}$  = coefficient of transmission of the ceiling.

$n$  = the ratio of the area of the roof to the area of the ceiling.

<sup>b</sup> Use ceiling area (not roof area) with these coefficients.

<sup>c</sup> Coefficients in Columns D, E and F may be used with sufficient accuracy for tile, slate and rigid asbestos shingles on wood sheathing.

<sup>d</sup> Based on 1 x 4 in. strips spaced 2 in. apart.

<sup>e</sup> Sheathing assumed 2 1/2 in. thick.

<sup>f</sup> Values of  $U_{ce}$  to be used in this column may be selected from Table 12.

ter design conditions will be greater than for the floor. The test results indicate a unit area heat loss, at mid-height of the basement wall approximately twice that of the same floor area.

For concrete slab floors laid in contact with the ground at grade level, recent tests<sup>13</sup> indicate that for small floor areas (equal to that of a house 25 feet square) the heat loss may be calculated as proportional to the length of exposed edge rather than total area. This amounts to 0.81 Btu per (hr) (linear foot of exposed edge) (Fahrenheit degree difference between

TABLE 19. COEFFICIENTS OF TRANSMISSION ( $U$ ) OF SOLID WOOD DOORS\*  
Coefficients are expressed in Btu per (hour) (square foot) (Fahrenheit degree difference in temperature between the air on the two sides), and are based upon an outside wind velocity of 15 mph.

<sup>c</sup> Unit type double glazing (two lights or panes in same opening).

<sup>d</sup> Use with  $U$  values for two sheets with 1 in. air space.

<sup>e</sup> Based on area of exposed portion of sash; does not include frame or portions of sash concealed by frame.

<sup>f</sup> For metal storm sash or metal sash with attached storm pane.

the inside air temperature and the average outside air temperature). It should be noted that this may be appreciably reduced by insulating under the ground slab, and also along the edges between the floor and the abutting walls. See also sections on Basement Temperatures and Heat Loss, and on Floor Heat Loss in Basementless Houses, in Chapter 12. In most calculations if the perimeter loss is calculated accurately, no other floor loss need be considered.

### Glass Coefficients

The  $U$  values for glass sheets and hollow glass block, given in Sections A, B and C of Table 20, have been computed by methods and data given in an A.S.H.V.E. Research Paper.<sup>8</sup> It is assumed that the surface conductance for convection loss to the air is 4.0 Btu per (hr) (sq ft) (F deg). It is also assumed that the glass loses heat by radiation to the ground and to the clear sky, which together have an effective radiating temperature below the air temperature. It is therefore necessary to determine, by trial and error, the temperature of the outdoor glass surface such that the sum of the radiation and convection losses equals the heat conducted through the glass section, and equals the heat delivered to the glass from the heated space. This heat flow, divided by the air-to-air temperature difference, results in a  $U$  value which is used in the usual manner. The equivalent surface conductance for radiation and convection combined, based on air-to-surface temperature difference, therefore varies from about 5.5 for single glass to about 6.6 for double glass for exactly the same environmental design conditions.

It is assumed that the room air temperature equals the average temperature of the room surfaces seen by the glass. Special consideration should be given to those cases where the glass sees interior surfaces at temperatures differing greatly from the room air temperature, i.e., such cases as in sun rooms, greenhouses, and some panel heated rooms, or where there is an unusual amount of air motion in the vicinity of the glass. Although based on zero outdoor air, the values change only slightly with different design temperatures, being about 5 percent greater for a 30 F outdoor design temperature.

In computing the Table 20 values, consideration of the dependence of the indoor surface conductances upon temperature and direction of heat flow leads to surface conductances averaging about 1.50 for block and vertical glass, and about 1.80 for horizontal glass, as compared to the value of 1.65 used in computing  $U$  values given in other tables in this chapter. These values should therefore be used in estimating the temperature at which condensation on glass surfaces will occur.

The application factors given in Section D of Table 20 are based upon hot box tests summarized in a research bulletin,<sup>14</sup> and are approximate only. In practice, some variation in heat flow through windows having the same ratio of glass to sash area, may be expected because of difference in construction details and in air space edge effects. The high conductance of aluminum and steel sash must be taken into consideration where excessive amounts of metal sash and frames are involved. This is particularly important when they are in close proximity to radiation heat sources and are consequently subjected to high differential temperatures.

### Wind Velocity Correction for $U$ Values

Tables 7 to 9, and 15 to 19, present values of  $U$  for walls and other surfaces based on an outside wind velocity of 15 mph. Table 21 shows comparative values of  $U$  for other wind velocities.

**Example 3:** Find the coefficient of transmission  $U$  of a frame wall consisting of stucco,  $\frac{25}{32}$ -in. insulation board sheathing, 2 x 4-in. studs, gypsum lath and plaster, and with 2-in. blanket insulation between studs, for 25 mph wind velocity.

**Solution:** From Table 7, Wall No. 20, with no insulation between studs has a value of  $U = 0.19$ . From Table 6, Col. 4, this wall with 2-in. insulation added has a value of  $U = 0.084$ . Entering Table 21 in the 15 mph column, interpolate between 0.080 and 0.090 in 15 mph column and proceed horizontally to the 25 mph column where the  $U$  value is found by interpolation to be 0.085.

TABLE 21. CONVERSION TABLE FOR WALL COEFFICIENT  $U$  FOR VARIOUS WIND VELOCITIES

<sup>a</sup>  $U$  in first column is from previous tables or as calculated for 15 mph wind velocity.

### CALCULATING SURFACE TEMPERATURES

In many heating and cooling load calculations it is necessary to determine the inside surface temperature or the temperature of the surfaces within the structure. As the resistance of any path of heat flow is expressed in Fahrenheit degrees per (Btu) (hour) (square foot), the resistances through any two paths of heat flow would be proportional to the temperature drop through these paths, and can be expressed as follows:

$$\frac{R_1}{R_2} = \frac{(t_i - t_x)}{(t_i - t_o)} \quad (6)$$

where

$R_1$  = the resistance from the inside air to any point in the structure at which the temperature is to be determined.

$R_2$  = the overall resistance of the wall from inside air to outside air.

$t_i$  = inside air temperature.

$t_x$  = temperature to be determined.

$t_o$  = outside air temperature.

**Example 4:** Determine the inside surface temperature for a wall having an overall coefficient of heat transmission  $U = 0.25$ , inside air temperature 70 F, outside air temperature -20 F.

**Solution:**

$$R_1 = 1/f_i = 1/1.65 = 0.606$$

$$R_2 = 1/U = 1/0.25 = 4.00$$

Then, by Equation 6

$$\frac{0.606}{4.00} = \frac{70 - t_x}{70 - (-20)}$$

$$t_x = 56.4 \text{ F}$$

The same procedure can be used for determining the temperature at any point within the structure.

A chart for determining inside wall surface temperature is given in Fig. 12 of Chapter 24, Panel Heating.

## CHAPTER 10

## MOISTURE IN BUILDING CONSTRUCTION

Properties of Water in Air; Water in Building Materials; Movement of Moisture in Materials; Vapor Transmission; Permeance and Testing; Visible Condensation; Concealed Condensation in Heated Buildings; Control of Concealed Condensation; Condensation in Cooled Structures

THE behavior of moisture is too often overlooked or given scant attention in the design and construction of buildings. It is present as a vapor in all air and as adsorbed moisture in most building materials. It may be present also at times in the free liquid state or as ice, in the solid state, within the range of temperatures encountered in many buildings. Problems involving moisture may arise from changes in moisture content, from the presence of excessive moisture, or from effects associated with its changes in state.

Of particular interest here is the change from the vapor to the liquid or solid state, known as condensation. This may be associated with a reduction of temperature with time, or may occur as a result of migration of water vapor to regions of lower temperature. Moisture problems involving condensation are therefore most likely to occur in buildings in any climate in which there is a source of water vapor at temperatures above normal, or in cooled structures, and in buildings in cold climates.

Moisture problems in residences occur in winter and become increasingly important as homes are built smaller and tighter. Water vapor originates from such necessary living requirements as cooking, laundering, bathing, and the breathing and perspiration of people. In a typical family of four, the average daily production of water vapor from these sources may be as much as 25 lb, and may be much greater where such appliances as humidifiers, automatic washers, and dryers are used.<sup>1</sup> Another large source of water vapor is sometimes the bare earth in a crawl space or basement. All this water vapor must escape from the dwelling.

## PROPERTIES OF WATER VAPOR IN AIR

Water vapor in air is a gas which occupies all the space, along with the air present. In many ways, the water vapor can act independently of the air, since in general its properties do not depend on the presence of the air. It exerts its own vapor pressure, and can move about through air in a space, or move through materials under differences in its own vapor pressure, independently of the air. However, when the air is moved suddenly or is heated or cooled, the water vapor present is similarly affected, so that it is usually necessary to consider it as a part of an air-vapor mixture.

The properties of mixtures of air and water vapor are relatively well known and are dealt with fully in Chapter 3, Thermodynamics. Changes in these properties with heating and cooling can be followed readily with the aid of a psychrometric chart, shown in outline in Fig. 1. The satura-

tion line represents the limiting concentrations of water vapor which can exist as vapor at various temperatures.

A common condition inside buildings, 70 F. and 40 percent relative humidity, is represented by point A. This is a condition of partial saturation; i.e., less than 100 percent relative humidity. The vapor pressure of the water present in the air, although not shown on the chart, can be calculated readily from the vapor pressure at saturation and the relative humidity, since relative humidity is very nearly equal to the ratio of the actual vapor pressure to the saturation pressure at the existing temperature.

The increasing relative humidity accompanying cooling from the condition represented by A on the chart to point B can readily be followed. At B, however, at 44.6 F., the relative humidity becomes 100 percent, and the air-vapor mixture is said to be saturated. The temperature at which this particular air-vapor mixture, upon cooling, becomes saturated is its

FIG. 1. TWO TYPICAL HEATING AND COOLING PROCESSES IN AIR WITHIN BUILDINGS SHOWN ON A.S.H.V.E. PSYCHROMETRIC CHART

dew-point temperature. Upon further cooling, to 35 F., the original amount of water vapor can no longer be retained and is reduced, in this case, to the condition represented by C, from 0.0633 lb per lb dry air to 0.0427 lb per lb dry air. The process ABC is typical of that which an air-vapor mixture experiences when it comes in contact with a cool window surface. Cooling from B to C results in visible condensation on the glass surface. If the point C were below 32 F., the condensation would be in the form of frost.

Once the temperature drops below the dew point, or frost point if below 32 F., the vapor pressure at the condensing surface is also reduced, thereby establishing a gradient of vapor pressure from the room air to the window surface. This gradient will operate, in conjunction with the convective action within the room, to move water vapor continuously to the window surface to be condensed, so long as the concentration of water vapor in the room is maintained.

A common winter process is that shown by DE, showing air at 20 F., saturated, being heated to 70 F. with a resulting large decrease in relative humidity. This explains, in part, the greatly reduced relative humidities

experienced in houses in extreme cold weather, when cold outside air enters the house and is heated.

### WATER IN BUILDING MATERIALS

The surfaces of most common materials have an affinity for water molecules. Molecular forces of attraction will hold water molecules to the surface, but decrease very rapidly with increase in distance of molecular proportions. The film thickness and therefore the amount of water held in equilibrium with the surrounding atmosphere is roughly proportional to relative humidity. Surface films of water molecules, at low humidities, may be only one molecule thick; at moderate humidities poly-molecular films may be established, while at humidities very close to 100 percent, the films become so thick, relatively, that small pores may become filled and larger capillaries may be partially filled. At saturation conditions all voids in the material may be completely filled.

Some materials such as silica gel, alumina and most natural fibrous materials present very large effective surfaces to the water molecules, so that the amount of water held on the effective surface in these materials may be relatively large, even at moderate humidities. These are said to be hygroscopic. Other materials, such as most metals, not penetrated by the water molecules, present relatively small surfaces and so may take only minute quantities of water, except when wetted directly by liquid.

Substances having a great affinity for water, and their use as dehumidifying agents, are described in Chapter 38. Data on the moisture contents of various common materials in equilibrium with the atmosphere at various relative humidities are given in Table 2 of Chapter 45, and equilibrium moisture content is further discussed in Chapter 47 on Industrial Drying Systems.

Significant dimensional changes take place in many materials used in buildings, with change in moisture content. Those which take place in wood, of the order of 0.1, 2, and 4 percent in the longitudinal, radial and tangential directions, respectively, on a change from air dry at 12 to 15 percent moisture content to oven dry are perhaps the best known. Most wood-fiber products, including papers, will exhibit moisture expansion consistent with the basic wood properties to a degree dependent on the fiber orientation and arrangement. Data on wood are available in publications on wood technology. Almost all plant and animal fibers experience appreciable moisture changes with changing relative humidity and undergo substantial dimensional changes of the same order as those in wood. Less generally recognized are the dimensional changes which can occur in masonry materials as a result of changes in moisture content.

Water is either an essential or a contributory factor in almost all cases of breakdown of building materials resulting from chemical changes such as the rusting of steel, physical changes such as the spalling of masonry by frost action, or biological processes such as the rotting of wood. The control of water in building constructions may be necessary to ensure adequate service from the materials involved.

Condensation of water vapor, although not the only means by which wetting may be brought about, is nevertheless a most insidious one particularly in respect of freeze-thaw breakdown, since from its nature it is most likely to occur at points of low temperature at which there may later be risk of freezing while the material remains in a saturated condition.

Moisture in building materials may have a marked effect upon the transmission of heat through them. It has been commonly assumed that moisture when present in a material will remain more or less stationary and will increase the conductivity largely by adding to the path available for heat flow. On this basis, the effect of moisture on heat flow can be accounted for quite simply by the use of suitable coefficients of conductivity in the usual heat-flow equations. The data presented in Chapter 9 on moist soils are of this type.

Evidence to date indicates, however, that in porous materials partially saturated with water there is likely to be a migration of moisture to the cold side under the influence of the temperature gradient. This can occur by a process of evaporation, vapor flow, and condensation within the material, a substantial amount of heat being transferred as latent heat of the vapor, particularly in the case of open fibrous materials. The transmission of heat through moist materials becomes complex whenever conditions are such as to produce any appreciable migration of the moisture, and, consequently, calculations by the usual heat-flow theory alone, are an approximation.

#### MOVEMENT OF MOISTURE IN MATERIALS

Moisture is caused to migrate in granular media or in porous solids by gradients in hydrostatic pressure, vapor pressure, capillary forces, concentration of salts, temperature, or electrical potential. Neither the various mechanisms nor the particular potentials involved are entirely unrelated. They are frequently combined in most complex ways not at all well understood. A temperature gradient in a moist material usually produces a vapor-pressure gradient with consequent vapor migration. Whether the temperature gradient is able to produce migration by other mechanisms is still being debated. There is a relationship between vapor pressure and capillary force, and with a condition of capillary-force gradient but uniform temperature, there will also be a vapor-pressure gradient. At high relative humidities small capillaries may be completely filled and larger capillaries partially filled, so that movement of liquid water may occur in combination with vapor movement. There is some evidence that under special conditions vapor movement and liquid movement through capillaries may occur simultaneously but in opposing directions.

#### VAPOR TRANSMISSION THROUGH MATERIALS

The equation presently used in calculating water-vapor transmission through materials is based on a form of Fick's Law, and is as follows:

$$w = -\mu \frac{dp}{dx} \quad (1)$$

where

- $w$  = weight of vapor transmitted through a unit area in unit time.
- $p$  = vapor pressure.
- $x$  = distance along the flow path.

and hence:

- $\frac{dp}{dx}$  = vapor pressure gradient.
- $\mu$  = permeability.

#### Moisture in Building Construction

The close parallel with Fourier's equation for heat flow will be noted. The actual transmission of vapor through a material is extremely complex, so that the coefficient,  $\mu$ , is not a simple one but is actually a function of relative humidity and temperature, and may vary along the flow path through the material in question.

Integrating Equation 1 from  $x = 0$  to  $x = l$  and from  $p_1$  to  $p_2$ , and rearranging, the following is obtained:

$$w = \frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2} \times \frac{(p_1 - p_2)}{l} \quad (2)$$

Let

$$\bar{\mu} = \frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2} \quad (3)$$

Then,

$$w = \bar{\mu} \frac{p_1 - p_2}{l} \quad (4)$$

where

$l$  = length of flow path (or thickness of material).

If Equation 1 had been integrated, assuming the coefficient  $\mu$  to be independent of vapor pressure (and temperature) along the flow path, Equation 4 would have been obtained, but with  $\bar{\mu}$  replaced by  $\mu$ . The coefficient  $\bar{\mu}$  is therefore an average permeability coefficient applicable to the varying conditions along the flow path of length  $l$ , while the coefficient  $\mu$  is the spot or differential permeability.

Equation 4 may be rewritten and units assigned:

$$W = \bar{\mu} A \theta \frac{\Delta p}{l} \quad (5)$$

where,

- $W$  = total weight of vapor transmitted, grains.
- $A$  = area of cross-section of the flow path, square feet.
- $\theta$  = time during which the transmission occurred, hours.
- $\Delta p$  = difference of vapor pressure between ends of the flow path, inches of mercury.
- $l$  = length of flow path, (or thickness of specimen), inches.

The basic units given are those now favored by the building industry. The permeability  $\mu$  or  $\bar{\mu}$  is therefore expressed in a unit of grains-inches per (square foot) (hour) (inch of mercury vapor pressure difference).

Whenever it is convenient to deal with a material of a stated or implied thickness other than the unit thickness to which  $\mu$  or  $\bar{\mu}$  refer, use may be made of the permeance coefficient  $M$ , where  $M = \mu/l$ . The designation perm for the unit of permeance is now widely used, and is a convenient substitute for the unit, 1 grain per (square foot) (hour) (inch of mercury vapor pressure difference).<sup>2</sup> The corresponding unit of permeability is perm-inch, since it is the permeance of unit thickness. The corresponding flow equation is:

$$W = M A \theta \Delta p \quad (6)$$

Resistance to vapor flow provided by a sheet or board is the reciprocal

of the permeance, and correspondingly, the over-all vapor resistance of an assembly (like a wall) of materials in series is the sum of the resistances of its component parts. The over-all permeance of the assembly may be found from the permeances of the individual components<sup>3, 4</sup> in a manner paralleling that used in calculating the over-all coefficient of thermal conductivity from the individual conductances:

$$M_t = \frac{1}{\left(\frac{1}{M_1} + \frac{1}{M_2} + \frac{1}{M_3} \cdots + \frac{1}{M_n}\right)} \quad (7)$$

This simple theory for vapor flow, as in the case of the corresponding

FIG. 2. TEMPERATURES AND VAPOR PRESSURES UNDER VAPOR FLOW CONDITIONS IN THE INSULATED FRAME WALL OF EXAMPLE 1.

simple heat-flow theory, assumes conditions of unidirectional, steady-state flow. Useful calculations can be made for an assembly or sub-assembly for which the inflow and outflow of vapor are equal (a condition at which no condensation occurs) if a permeance applicable to actual conditions can be assigned to each component part. Over-all permeances, vapor pressures and vapor flow can be calculated, and in conjunction with thermal calculations, relative humidities can be determined, and the imminence of condensation predicted. (See *Example 1*, and Fig. 2. See also Chapter 13, Cooling Load, for use of vapor-flow calculations.)

*Example 1:* A wood frame wall is exposed to inside conditions 70 F. and 50 percent relative humidity (0.37 in. Hg vapor pressure) and outside conditions 0 F. and 80 percent relative humidity (0.03 in. Hg vapor pressure). The wall consists of painted plaster on gypsum lath on the inside over 2 x 4 in. studs, mineral wool fill between

studs, 1 in. wood exterior sheathing, paper, and pine lap siding. Check for possible condensation.

To simplify the example, consider the paint, plaster and lath as a single element having a permeance  $M = 1.0$  perms and a thermal conductance  $C = 2.4$ , and the exterior sheathing, paper, siding and paint as another single element for which  $M = 2.0$  perms and  $C = 0.50$ . From Table 1 the value for the permeability of mineral wool fill may be found as  $\mu = 116$  perm-inches. The thermal conductivity for mineral wool,  $k = 0.27$ .

*Solution:* In this particular wall, insulated, and with moderate warm-side relative humidities, condensation is unlikely to occur until the sheathing is reached. To check directly for condensation on the warm side of the exterior sheathing (designated as plane X - X in Fig. 2 for convenient reference) proceed as follows:

Calculate according to the method of Chapter 9 the temperature at plane X - X. This is found to be 9 F. The saturation vapor pressure at this temperature is 0.06 in. Hg. If condensation is imminent or occurring at X - X, the vapor pressure there will be 0.06 in. Hg. Calculate the permeance for the portion of the wall from the warm side to X - X, and the vapor flow rate to X - X as follows:

$$\text{Permeance of wall to X - X} = \frac{1}{\frac{1}{1.0} + \frac{3.625}{116}} = 0.97 \text{ perms.}$$

$$\text{Vapor pressure drop to X - X} = 0.37 - 0.06 = 0.31 \text{ in. Hg.}$$

$$\text{Vapor flow to X - X} = 0.97 \times 0.31 = 0.30 \text{ grains per (sq ft) (hr).}$$

Calculate the vapor flow rate from X - X to outside as follows:

$$\text{Permeance of wall from X - X to outside} = 2.0 \text{ perms.}$$

$$\text{Vapor pressure drop from X - X to outside} = 0.06 - 0.03 = 0.03 \text{ in. Hg.}$$

$$\text{Vapor flow rate to outside} = 2.0 \times 0.03 = 0.06 \text{ grains per (sq ft) (hr).}$$

It is apparent that continuity of vapor flow is not possible, since at the highest vapor pressure at X - X permitted by the temperature, there is indicated a greater flow to plane X - X than from it to outside. Condensation is indicated at a rate of  $0.30 - 0.06 = 0.24$  grains per (sq ft) (hr).

Whether this condensation rate will be serious must still be decided, since it might readily be absorbed by the sheathing during the condensation period without excessive wetting. When the temperature at X - X is below freezing, as in this case, the condensation will be in the form of frost which may accumulate until released over a short period upon a rise in outside temperature.

Condensation will be reduced or avoided if the permeance of the warm side of the wall can be reduced so that the flow to X - X is limited to 0.06 grains per (sq ft) (hr). Permeance required for this is  $\frac{0.06}{0.37 - 0.06} = 0.19$  perms or less. A more resistant paint film on the plaster, reducing the paint-plaster-lath permeance to 0.19 perms would accomplish this.

When the critical plane for condensation is unknown, or for a more informative, graphical representation of the situation throughout the wall, temperatures and vapor pressures may be calculated and plotted as in Fig. 2. The vapor pressures throughout the wall, for continuity of flow, are calculated in a manner similar to the temperatures; the external vapor pressures are given, and the vapor pressure drops across each element are taken in proportion to resistance to vapor flow.

The curve for saturation vapor pressures at the various temperatures throughout the wall is also shown in Fig. 2 and is seen to fall below the curve for vapor pressures with continuity of flow, toward the outer portions of the wall. This indicates that with the given temperatures and vapor pressures, continuity of flow is not possible and that condensation will occur. Condensation on the sheathing is indicated as a definite possibility, and the new vapor pressure curve can be constructed for this condition, as shown. This new curve does not rise above the saturation-vapor-pres-

ure curve, thereby confirming that the critical plane for condensation was correctly assumed.

With the vapor pressures thus established, the relative humidities may be found, by reference to the saturation vapor pressures. The permeances originally assigned to the various elements may then be re-examined in the light of the service conditions of temperatures and relative humidities indicated, and the analysis repeated, if necessary, using more appropriate permeance values.

In a more detailed analysis, individual values might be assigned to the elements forming the outer portion of the wall, which is here dealt with as a composite, homogeneous element.

The transmission of water vapor as outlined is based on the assumption of a diffusion process. The possibility of vapor being transferred as part of a moving air stream has thus far been ignored, except in *Example 1* in which it is implied that the air circulation on either side of the wall will be sufficient to eliminate surface film resistances to vapor flow. Differences in total pressure of the air may result in a transfer of vapor with air, augmenting and at times over-riding the effects of the flow produced by vapor pressure gradients alone. This can be particularly important in the transfer of vapor through cracks and pinholes or through air-permeable building constructions.

This means of vapor transfer is similar to that of transfer of heat by air leakage in and through building constructions, requiring for purposes of calculation information on the nature and amount of the air leakage. It will seldom be important in constructions without air spaces and having parged or plastered surfaces. It may, however, be an important means of vapor transfer through constructions lacking in air tightness, and may contribute to condensation difficulties, since the mechanism of condensation is not dependent upon the way in which the vapor is transferred.

### PERMEANCE AND TESTING

The simplest method of finding the permeance of a specimen is to seal it over the top of a cup containing desiccant or water, placing it in a controlled atmosphere, and weighing it periodically. The steady rate of weight gain or loss is normally the water vapor transfer. When the cup contains a desiccant the procedure is called the *dry-cup method* and when the cup contains water, the *wet-cup method*. Usually the outside atmosphere is held at 50 percent relative humidity, thus providing, in either method, substantially the same difference of vapor pressure, but the results obtained by the two methods on the same specimens are likely to be much different, the wet cup method producing the higher values. The relationship between these values can best be understood by reference to Fig. 3, which shows a typical variation of spot permeability with relative humidity at one particular temperature (isothermal conditions) for a material such as wood. The vapor permeability is shown to vary only moderately at low humidities, but to increase at an increasing rate as higher humidities are reached. The dry-cup test of this material carried out with 0 percent relative humidity one side and 50 percent on the other, will experience throughout its thickness, because of the variation in relative humidity, a variation in spot permeability. The average permeability

$\bar{\mu}$ , is by definition (Equation 3), given by  $\frac{\int_{p_1}^{p_2} \mu dp}{p_1 - p_2}$ , and since at a fixed temperature there is a linear relationship between vapor pressure and relative humidity, this expression can be seen to correspond to the mean height of the area under the spot permeability curve, between the appro-

TABLE 1. PERMEANCE AND PERMEABILITY OF MATERIALS TO WATER VAPOR.

prate relative humidity limits. The average permeability as found for the dry-cup conditions should therefore have the value  $\bar{\mu}_1$ . Similarly for the wet-cup test between 50 percent and 100 percent relative humidity, the value should be  $\bar{\mu}_2$ . It is not uncommon for these values for wood and wood-fiber materials to be in the ratio of 1 to 3, or higher. (See Table 1.) The average permeability  $\bar{\mu}$  for any other relative humidities at a particular temperature is given by the mean height of the area under the curve of spot permeability for the material at that temperature, between

the appropriate limits of relative humidity. Only average permeabilities (or permeances) are measurable directly in practical tests. However, if several average permeabilities at different relative humidities are known, and can be plotted as for the wet-cup and dry-cup tests shown in Fig. 3, it is possible to construct, by trial and error, a spot permeability curve which will satisfy the condition that the average height of the curve between the appropriate limits for each test must equal the value found in each test. Separate curves are required for each temperature so that a large number of permeance cup tests would be required to cover a range of conditions of both temperature and humidity.

Experience to date shows that the effect of temperature is quite moderate and, for some purposes, differences in temperature at which tests are run

FIG. 3. RELATION BETWEEN DRY AND WET CUP TESTS AND THE SPOT PERMEABILITY FOR A MATERIAL SUCH AS WOOD

may be ignored. Corrections for temperature have been made with some success by the use of an equation based on activation energy<sup>5</sup> which states:

$$\mu = \mu_0 e^{-\frac{E}{RT}} \quad (8)$$

where, in appropriate units,

$\mu_0$  = permeability at  $T = \infty$

$R$  = gas constant

$E$  = activation energy

$e$  = Napierian base of logarithms = 2.718

$T$  = absolute temperature.

Through the use of this equation, spot permeability curves for a variety of temperatures can be constructed from a curve for one temperature, provided only that two tests at different temperatures can be run, from which  $E$ , the activation energy, can be evaluated. In this way it becomes pos-

sible to describe the permeability of a material reasonably completely from the results of as few as five single tests at carefully selected conditions.

No method has yet been found, other than by direct testing for a particular set of conditions, of predicting the effective permeabilities for conditions of temperature gradient along with a humidity (or vapor pressure) gradient, from data obtained under other conditions, even though this is the general situation in practice. A very considerable amount of information is available on the permeances and permeabilities of various materials, but these are frequently obtained at different conditions so that the results cannot be compared directly, nor do they often give a coverage of a range of conditions to permit construction of basic curves of spot permeability or permeance.

Since dry-cup and wet-cup tests are much easier to carry out than tests at intermediate humidities, many of the data available have been obtained in this way. In the absence of data obtained from tests duplicating the conditions of temperature and relative humidity in service the permeance of a piece of material may be judged adequately for many purposes if it is tested by both dry and wet methods. It is obvious that any statement of permeance of a specimen should include the conditions of test.

Method of test E96-53T of the *American Society for Testing Materials* describes procedures for testing for water vapor transmission of materials in sheet form under five different test conditions. These include the dry-cup and wet-cup methods, based on 50 percent relative humidity outside the cup, at either 73.4 or 90 F, and a fifth condition at an elevated temperature of 100 F, with relative humidities of 0 and 90 percent on either side of the sheet. Standard T448m-49 of the *Technical Association of the Pulp and Paper Industry* covers the determination of water vapor transmission of paper and paperboard, and calls for the dry-cup method at 73.4 F., based on 50 percent relative humidity outside the cup.

Unfortunately, there is no general agreement as yet to report results as coefficients of permeance, or of permeability where appropriate, as adopted in this chapter, or to use the same basic units. Test data are frequently reported in terms of weight transmitted per (unit area) (unit time). Such data may be called *water vapor transmission data* or WVT data and values are either high or low depending on the difference of vapor pressure chosen for the test. When this difference is known, WVT data can be converted to permeance, care being taken if conversion of the basic units (weight, area and time) is also required. The following formula applies:

$$\text{Permeance} = \frac{\text{WVT rating}}{\Delta p} \quad (9)$$

where,

WVT rating = weight of vapor transmitted, grains per (sq ft) (hour).

$\Delta p$  = vapor pressure difference in the test, in inches of mercury.

Permeance is expressed in perms.

Table 2 presents the conversion factors applicable to the commonly used units and test methods. Table 1 presents some data on typical building materials showing, in each case, the source and method and, where applicable, the thickness tested.

Water-proofed building papers are listed in *Federal Specifications UU-P-147*, May 24, 1948, according to water vapor resistance required as:

- Class A. For uses where a high degree of water vapor resistance is required.  
 Class B. For uses where a lower degree of water vapor resistance and of water resistance is required.  
 Class C. For uses where a moderate degree of water resistance is required.  
 Class D. For uses where low resistance to water vapor is required.

It may be noted that a paper may be *water-proof*, i.e. possess water resistance, and still have low water vapor resistance.

Detail requirements in these specifications are given as follows, the specified WVT Test being a dry method at 73 F:

Class A paper shall have a minimum tensile strength in each direction of either 35

\* Data obtained by one method cannot be reliably converted to another method.

To convert  $\frac{\text{grains}}{(24 \text{ hr}) (\text{sq m})}$  to perms multiply by 1.52.

lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 24 hr, and a maximum water vapor permeability (WVT) of 4 grams per (square meter) (24 hr) i.e. 0.576 perm.

Class B paper shall have a minimum tensile strength in each direction of either 35 lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 16 hr, and a maximum water vapor permeability (WVT) of 6 grams per (square meter) (24 hr) i.e. 0.864 perm.

Class C paper shall have a minimum tensile strength in each direction of either 35 lb per inch width, or 20 lb per inch width, as specified in the invitation for bids. Paper of both strengths shall have a minimum water resistance of 8 hr.

Class D paper shall have a minimum tensile strength in each direction of 20 lb per inch width. The paper shall have a minimum water resistance of 10 min., a minimum water vapor permeability (WVT) of 35 grams per (square meter) (24 hr) i.e. 5.04 perms.

## VISIBLE CONDENSATION

Just as moisture collects on the outer surface of a glass of cold water, so does it also condense on other cold materials. In winter, visible condensation may collect on cold closet walls and attic roofs and is commonly observed on frosted window panes. Although condensation, if liquid, may enter an unpainted surface as fast as it forms and thus be unseen, any condensation on a visible surface will for convenience here be called *visible condensation* to distinguish it from *concealed condensation*. Within residences and public buildings, visible condensation occurs in winter and may damage decorative finishes and window sash.

Interior visible condensation occurs when any surface is colder than the dew point of the near-by air. The temperature of any such surface—wall, roof, or glass—is dependent upon the air temperature inside and out-

FIG. 4. RELATIVE HUMIDITY AT WHICH VISIBLE CONDENSATION WILL APPEAR ON INSIDE SURFACE

side the building and the heat transfer coefficient  $U$  of the surface structure. Based on a value of 1.65 for the inside surface conductance, Fig. 4 shows the relative humidity in a room at 70 F when visible condensation will appear at various  $U$ -values. The curves for single and double glass at their usual  $U$ -values are included. It should be noted that  $U$ -values as commonly used are an average for a large area within which there may be spots, such as the studs in an insulated wall, where the transmittance is higher. The inside surface temperature of a wall will, in general, be lower at the bottom due to such things as stratification of inside air and the effects of air leakage and of convection in walls with air spaces. Since condensation seeks the coldest spot, values from Fig. 4 can be applied only with caution. As a result, the limit of relative humidity for a non-homogeneous wall is lower than might be inferred from its average  $U$ -value.

Normally, glass is the most likely spot in a heated room for appearance of condensation, but an uninsulated wall surface shielded from radiation by furniture, may be equally cold. In some cases where condensation is barely avoided, the surface, being but little warmer than the dew-point tempera-

ture, is exposed to moisture damage—such as swelling, mold or discoloration.

Visible condensation may occur also in summer. It is often seen on basement concrete walls and floors which are cooled by the earth and which being massive, tend to hold a constant temperature from day to day while the weather dew-point temperature rises. When no water vapor is released in the space, the dew point tends to equal that of the outside (though it is likely to lag when there is slight ventilation). At times the dew-point temperature rises above the temperature of walls and floors and condensation results. If the basement is decorated the trouble may be serious. As an operating problem, the solution may be to reduce ventilation at times of high weather dew point, to warm the walls, or to dehumidify

FIG. 5. RELATIVE HUMIDITY IN DWELLINGS

the space. Warming the walls, a slow process at best, is generally accomplished in favorable climates by excess ventilation. In a climate having low temperature at night, it may be feasible to ventilate only at night and thus reduce the moisture content of hygroscopic materials which will then act as a desiccant to retard the dew-point rise during the day. In basement walls and floors insulation should be applied in the concrete or on its outside. Insulation placed on the inside of such walls eliminates visible condensation but fosters concealed condensation. The control of the latter will be discussed. A practical and fully effective technique for such control has, however, not been developed. Usually, sub-surface dwellings should be designed for occupancy and should be dehumidified.

A similar situation is seen in dwellings with concrete floor slabs laid on the ground where such slabs are not a part of the heating system. In a northern climate where high dew-point temperatures occur in summer, condensation or very high relative humidity may damage rugs which are themselves contributors to the trouble since they reduce the floor slab temperature. Slab floors above grade are not so serious a problem as floor slabs on grade but their response to air temperature change is slow. Faster warming is accomplished by the removal of rugs and abundant ventilation at proper times. In their design, floor slabs should have as low specific heat and as high thermal resistance as is consistent with other requirements. Suitable insulation below the slab, especially well drained gravel, will help

somewhat. A top surface cover of insulating value that is unaffected by water on its lower side would be desirable in the less favorable northern climates.

The avoidance of interior visible condensation is partly a construction and partly an operating problem. It is accomplished by reducing the interior dew-point temperature or by raising the surface temperatures that are below the dew-point, or both. The dew-point temperature may be lowered by giving attention to the sources of the moisture, and in winter, may be controlled by ventilation, or possibly by some moisture absorption process. The temperatures of the inside room surfaces in winter may be increased by adding insulation to outside walls, by double glazing of windows, by circulating warm air over the surface, or perhaps by direct heating of the surface. The most expedient method of overcoming a surface condensation difficulty will depend upon special conditions surrounding the problem.

### CONCEALED CONDENSATION IN HEATED BUILDINGS

Water vapor produced in a building necessarily raises the vapor pressure above that outside thus providing the force that causes its diffusion into exterior walls. The amount of vapor pressure rise in the building depends on the amount of vapor produced and inversely on its chance to escape. The resulting balance may be expressed in terms of relative humidity if the inside temperature is 70 F. The relative humidity in heated buildings covers nearly all of the possible range. In zero weather it may be only 10 percent in an office, and 85 percent in an industrial plant where humidification is required for a process, or where vapor release is incidental to a process. In residences the relative humidity in cold winter weather ranges from 10 percent to 60 percent, the latter figure applying to a very small, crowded and unventilated dwelling. A 40 percent level is considered representative of a substantial number of modern tightly constructed small houses although the average house relative humidity is probably below 25 percent. Surveys in residences show that the relative humidity increases as would be expected in warmer weather. Fig. 5 represents the results of one such survey.<sup>5</sup>

When water vapor is allowed to enter a wall and condensation occurs on its outer cold elements, it appears as frost or liquid. If the weather temperature rises frequently, frost melts and becoming liquid, is likely to penetrate capillary materials like wood, or run down when the surface is non-absorbing or is already saturated with water. In weather that is continuously cold for a long period, the frost may build back into a cavity or fibrous insulation and, when it reaches a warmer plane, will run to lower, cooler levels where it forms a mass of ice. Water seepage to the weather side may occur harmlessly in masonry walls when the weather is above freezing but water seepage into the building must obviously be avoided. In typical frame construction with wood sheathing which has large water absorbing capacity, seepage is rare and occurs only after a long period of steady cold weather. More generally, moisture accumulates in wood sheathing and siding through the colder months and reaches a peak in late winter, after which the drying of spring and summer completes the annual cycle. The average winter temperature and its duration are factors in the condensation problem. In Fig. 6 the map of the United States is divided into condensation zones based on winter weather conditions. The solid lines separating the zones follow state lines, and are those recommended by the

*Housing and Home Finance Agency* for the guidance of owners, builders, and architects.<sup>14</sup> The dotted lines are the  $-20^{\circ}\text{F}$ ,  $0^{\circ}\text{F}$ , and  $+20^{\circ}\text{F}$  isotherms of winter design temperature taken from Fig. 1, Chapter 12. It will be noted that there is reasonably good correlation between the zones determined by the two sets of lines. Zone I roughly includes those areas where the design temperature is  $-20^{\circ}\text{F}$  or colder; zone II those for which the design temperature is zero to  $-20^{\circ}\text{F}$ , and zone III those at zero and warmer. Within each zone, similar degrees of condensation trouble are to be expected, and similar corrective measures apply.

In roofs, the condensation problem is much the same as in walls. The roof covering may be even more resistant to the escape of vapor than wall

FIG. 6. CONDENSATION ZONES IN THE UNITED STATES

(Zones Include Areas with Design Temperatures about as follows: Zone I,  $-20^{\circ}\text{F}$  and lower; Zone II,  $0^{\circ}\text{F}$  to  $-20^{\circ}\text{F}$ ; and Zone III, above  $0^{\circ}\text{F}$ . Note that cross hatched areas are outside of Zones I and III.)

coverings such as paint; and while paint is likely to be ruptured by excessive moisture, no such relief occurs in roofs. Thus roofs furnish conspicuous examples of rapid decay in lumber.

In crawl spaces over uncovered damp ground, a large water evaporation sometimes occurs and causes condensation on the outer ends of floor joists and other members that are below the floor line and near to the outside. Water vapor from the crawl space may also enter walls, be transported by rising air in a stack effect, and even reach the attic by this route when the wall structure permits. Ventilation, as discussed later in this chapter, is an important correction factor in these cases.

Insulation in a wall or roof reduces heat loss and lowers the temperature of the outer elements of the structure, thus increasing the possibility of condensation if the vapor path to the cold surface is not blocked. Since low vapor resistance is a characteristic of fibrous insulation, the needed vapor resistance must be provided by other means. It is to be noted that,

in typical residential conditions, condensation does not occur in fibrous insulation itself, except when frost has formed on sheathing and gradually built backward among the fibers. Wet insulation may result from this condition or from liquid condensation seeping down from a higher level.

### CONTROL OF CONCEALED CONDENSATION

An excessive accumulation of moisture in walls (or roofs) can be prevented by one or more of the following measures: (1) provide a vapor barrier to limit vapor entrance into the wall, (2) ventilate the building to reduce vapor pressure therein, (3) ventilate the wall cavity to remove vapor that has entered.

1. *Vapor Barrier.* A vapor barrier is the principal and most obvious correction, but each measure is more effective if aided by the effect of another. In habitations, some ventilation of the living space, either incidental or planned, is necessary. Also, a small amount of cavity ventilation is essential in cases where the vapor inflow is not completely stopped and the moisture storing capacity of the outer wall elements is slight. This applies to some prefabricated designs using metal siding.

Vapor barrier sheets are often built into the wall near the warm surface. In wood frame walls they may be applied to the inside surface of the studs. They are sometimes attached to the warm side of the insulating materials, or they may be applied on the cold side of plaster base materials. Special designs may be attached like wall paper to the inside of the wall, when satisfactory from the decorative view point. Sheet barriers often contain asphalt as the vapor resisting ingredient; metal foils, so placed that they are not too cold, may also be used.

The interior wall board or finish material may itself be vapor resistant, or a barrier coating may be applied to its concealed side when that side will not be too cold. The interior finished surface may be coated with a suitable paint having the required vapor resistance and also serving as the decorative finish, or it may be covered by another coat.

A paint coat on the interior finish, though of adequate resistance, is not likely to be so effective as a sheet barrier properly applied during the wall construction. This applies especially to houses of more than one story having cavities in ceilings which open into the outside walls. Such cavities allow vapor entering the ceiling to diffuse or be transported to the cold areas. Stoppage of this path is difficult, requiring normally the painting of the ceiling as well as the walls. Similar treatment may be required on internal partitions, or at least the first stud space adjacent to the cold wall.

The necessary barrier resistance depends on a number of factors. When the vapor flow occurs in annual cycles as in heated buildings, the requirement is not so exacting as it is for a cold storage room where there is no chance for drying out an accumulation of moisture. In a heated structure covered on the outside with materials highly resistant to water vapor such as paint or roll roofing, the winter season is a time of moisture accumulation in the cold outer elements and their safe moisture holding capacity is an important factor in determining the barrier requirement. A house without sheathing requires a better barrier; and a prefabricated design with only a sheet of metal outside of insulation requires very high barrier resistance. The interior vapor pressure and the length and severity of the winter are also important.

For typical frame dwellings with wood sheathing and siding in the northern United States, a barrier permeance of one perm or less has been found

satisfactory. There are cases, however, in residential construction where a one perm barrier would not be adequate and there are also many industrial applications in which a very much higher vapor resistance is required. In any event, the choice of an adequate barrier implies that its permeance be definitely established. The usually accepted test procedure for this purpose is a dry method at a temperature of 70 F to 80 F. If obtainable at reasonable cost (including good application), a barrier better than required should be chosen for any construction. Despite the theoretical possibility of safely discharging some vapor through a wall, a higher than minimum permeance is not preferred.

An exact statement showing which buildings require a vapor barrier is not readily formulated. However, in view of the distressing results its

FIG. 7. WATER VAPOR BALANCE IN A DWELLING  
(Vapor Barrier, 1 perm; Wall and Ceiling Area 2000 sq ft Insulated)

omission may bring, it is tentatively recommended that the walls of every well constructed modern dwelling include a vapor barrier when the construction includes any material that would be damaged by moisture or its freezing. This applies to all condensation zones in Fig. 6 when the  $U$  value for the wall is lower than 0.25 Btu per (sq ft) (hr) (F deg), and it applies in Zone I and Zone II to walls of higher transmittance.

In applying vapor resistance to a wall, there are certain fundamental principles which should be followed. First, the vapor barrier should be placed as near to the warm surface of the wall as practicable. Second, it should be continuous with no direct openings through the barrier. Good workmanship and application are very important. Workmanship that leaves two openings through the barrier, or around its margin, at different levels, connecting air spaces at only slightly different temperatures, leaves a path for thermosyphon air rotation which will transport large amounts of water vapor from the warmer space to the colder. If a membrane barrier is used back of the plaster or interior finish, its joints should be made over some solid framing member, and not between the studs or in similar places. Usually a two-inch lap over a framing member will make a sufficiently tight joint when the interior finish is applied. Such a lap, however, without backing would not be adequate. Barriers attached to the warm side of

insulation should form a continuous unbroken membrane over the entire insulated area. Edges should be lapped over framing members; ends of strips should be fastened by lapping over plates or headers. All openings for electrical fixtures and joints around window and door casings should be carefully sealed. Holes accidentally made in the barrier should be sealed.

2. *Ventilation of Living Space.* The second measure listed for the control of concealed condensation is ventilation of the house. This measure is obviously necessary as an accompaniment to a vapor barrier since, if the barrier blocks entrance into the walls, the water vapor must be removed

TABLE 3. RECOMMENDED GOOD PRACTICE<sup>a</sup>—LOFT AND ATTIC VENTILATION<sup>a</sup>

FLAT ROOF—SLOPE LESS THAN 3 INCHES IN 12 INCHES

Condensation Zone I<sup>b</sup>: Total net area of ventilation should be  $\frac{1}{2}$ sooth<sup>b</sup>, distributed uniformly at the eaves plus a vapor barrier in the top story ceiling. Free circulation must be provided through all spaces.  
Condensation Zone II and III: Same as for Zone I.

GABLE ROOF—SLOPE OVER 3 INCHES IN 12 INCHES

Condensation Zone I: Total net area of at least 2 louvers on opposite sides located near the ridge to be  $\frac{1}{2}$ sooth<sup>b</sup> plus a vapor barrier in the top story ceiling.  
Condensation Zone II: Same ventilation as for Zone I. A vapor barrier is not considered necessary.  
Condensation Zone III: Same as for Zone II.

HIP ROOF

Condensation Zone I: Total net area of ventilation should be  $\frac{1}{2}$ sooth<sup>b</sup> with  $\frac{1}{2}$ sooth<sup>b</sup> distributed uniformly at the eaves and  $\frac{1}{2}$ sooth<sup>b</sup> located at the ridge with all spaces interconnected. A vapor barrier should also be used in the top story ceiling.  
Condensation Zone II: Same ventilation as for Zone I. A vapor barrier is not considered necessary.  
Condensation Zone III: Same as for Zone II.

GABLE OR HIP ROOF—WITH OCCUPANCY CONTEMPLATED

Condensation Zone I: Total net area of ventilation should be  $\frac{1}{2}$ sooth<sup>b</sup> with  $\frac{1}{2}$ sooth<sup>b</sup> distributed uniformly at the eaves and  $\frac{1}{2}$ sooth<sup>b</sup> located at the ridge with all spaces interconnected. A vapor barrier should also be used on the warm side of the top full story ceiling, the dwarf walls, the sloping part of the roof, and the attic story ceiling.  
Condensation Zone II: Same as for Zone I.  
Condensation Zone III: Same as for Zone I except that a vapor barrier is not considered necessary if insulation is omitted.

<sup>a</sup> It is recognized that in many areas increased ventilation may be desirable for summer comfort. For winter comfort, insulation is recommended between a living space and a loft or attic ventilated at these rates.

<sup>b</sup> Refers to area enclosed within building lines at eave level.

<sup>c</sup> The zone numbers refer to Fig. 6.

by other means. No great volume of air change is necessary, however, and normal infiltration alone is frequently all that is required in winter weather.

The effectiveness of ventilation is shown in Fig. 7, which also shows the small amount of water vapor escaping into the barrier-equipped, well-insulated walls and ceilings (2000 sq ft) of a typical small dwelling, the floor being neglected. Evidently, ventilation of 2000 cu ft per hr will remove 21 lbs of vapor per day with the relative humidity at 40 percent, while at the same time 1.5 lbs escapes into the structure. The total vapor production (22.5 lb) is a typical amount. Double glass will be barely safe from visible condensation as will be seen in Fig. 4. By reference to Chapter 6, 2000 cu ft per hr appears to be near the minimum for odor control, and ventilation would have to be higher when cooking is done. By reference to Chapter 11, it appears that usual infiltration will normally supply the necessary air change, but that supplementary ventilation may be neces-

sary in kitchen and laundry for proper vapor control and for the reduction of peaks in relative humidity which would otherwise occur in those areas.

3. *Ventilation of Structure.* The third measure listed for the control of concealed condensation, ventilation of the structure itself, is effective in certain cases especially as a supplement to warm side vapor resistance which is considerable but not of itself fully adequate. Air from outside is used. The vents must be shielded from the entrance of rain and insects.

Attics and crawl spaces may be considered as parts of the structure, and for these portions ventilation is practically a necessity. Attic ventilation has long been an established practice but its effectiveness is likely to be diminished by the newer practice of adding insulation to ceilings. Insulation requires added ventilation which in turn necessitates adequate insulation. The recommended ventilation shown in Table 3 for dwellings<sup>14</sup> is based on such insulation. The *net area* refers to the total of all openings free from obstructions. The use of louvers and 8-mesh screen (usually recommended) requires a gross area 2.25 times that listed. In Zone I of Fig. 6 a ceiling vapor barrier is recommended for all constructions. It is also necessary that stray openings from walls into the attic, or around a loose fitting attic door be avoided. The *stack effect* allows a large inflow of warm air from the dwelling, transporting much vapor to a danger area. More desirable ventilation of the house can be arranged.

Crawl spaces under dwellings where the earth is damp and uncovered require a high rate of ventilation. At least four openings, one at each corner, as high as possible, should be provided.<sup>14</sup> Their total net area may be calculated by the formula:

$$a = \frac{2L}{100} + \frac{A}{300} \quad (10)$$

where:

$L$  = the perimeter of the crawl space, linear ft.

$A$  = the area of the crawl space, square feet.

$a$  = the total net area of all vents, (or the gross area if a 4-mesh screen is used), square feet.

This ventilation is usually sufficient but cools the first floor so much that insulation is needed. A better treatment is a cover on the damp ground. This cover may be a concrete slab, or merely heavy roll roofing laid on a graded surface with its edges lapped 2 in. (but not necessarily cemented). With this barrier, the vent area may be reduced to 10 percent of that calculated by Equation 10.

In building walls, cavity ventilation can be applied in a moderate climate as the sole vapor control system. In general, however, air passages in walls designed to remove an unrestricted vapor supply are unduly large and may waste considerable heat. On the other hand, a barrier as the only control measure would, in some cases, require so high a resistance as to be impractical. Ventilation of the structure in conjunction with a vapor barrier, is a procedure with important applications, but its general utility has not been fully investigated. Ventilation is most effective when each structural space has a clearly defined air passage with an inlet and outlet. In walls a small thermosyphon effect may be utilized by locating one vent at the bottom and one at the top of each space.

The best time to vapor-proof a building is during its construction. After a building is completed, ventilation of the occupied space is the most easily applied of the three basic control measures. Paint that is chosen for its low vapor permeance can be applied as a barrier on the interior with good results, care being taken that all areas, including parts of partitions and ceilings which offer an indirect vapor path to the cold wall, are covered. Ventilation of the wall cavity is effective in certain cases especially to supplement the foregoing measures. When such venting is required, each cavity space isolated by framing should be separately vented with an inlet and outlet judiciously placed, to accomplish proper air change.

### CONDENSATION IN COOLED STRUCTURES

Water vapor is sometimes an even greater problem in cooled structures than in those which are heated, but the basic facts of its migration and condensation on cold surfaces are the same. Refrigerators, cold pipes and cold vessels all require insulation and should be provided with a vapor barrier. The barrier, as always, should be placed on the warm side of the insulation and as close as possible to the warm surface of any enclosure. It resists the movement of water vapor toward the colder parts of the structure, and its job is even more exacting than that required in residential construction. In the case of an insulated cold pipe line, the process is likely to be uninterrupted for years and there is no chance for vapor that enters the insulation to dry out periodically. Also, no vapor can escape from the cold side, if this is a metal (vapor tight) pipe. For such an application vapor control requires insulating material that is itself very highly resistant to water vapor or a coating whose permeance is the minimum obtainable, not over 0.1 perm. Metal coverings are desirable but difficult to apply.

Similar considerations apply in the case of cold rooms whether constructed inside a heated building or as a separate building. In the latter case, cold rooms operating above freezing provide some periods of vapor reversal in winter but such drying can be of little help. Refrigerators, however, if lined with cement or other vapor permeant material, will allow slight amounts of vapor to pass and to that extent reduce the accumulation of moisture that may have penetrated the barrier. While this is helpful, emphasis must be placed on an adequate warm side barrier not greater than 0.1 perm.

Summer air cooling for comfort does not involve serious vapor problems and vapor control measures are not essential. Normally the cooled air is little, if any, colder than the dew-point temperature of the outside atmosphere and there are no areas of condensation. However, the interior vapor pressure is often below that outside and therefore, vapor, which diffuses inward, adds to the cooling load. Vapor barriers in walls installed for winter needs, are a help in reducing this element of the cooling load.

## CHAPTER 11

## INFILTRATION AND VENTILATION

Causes of Infiltration, Infiltration Due to Wind Pressure, Infiltration Due to Temperature Difference, Sealing of Vertical Openings, Infiltration Measurement, Natural Ventilation, Wind Forces, Temperature Difference Forces, Heat Removal, Effect of Unequal Openings, Combined Wind and Temperature Forces, Types of Openings, General Ventilation Rules, Ventilation of Animal Shelters, Garage Ventilation

Infiltration is the air leakage through cracks and interstices, around windows and doors, and through floors and walls. Its magnitude depends on the structural design, workmanship, and condition of the building. The rate of infiltration cannot be controlled by the inhabitants of the building to any considerable extent. Natural ventilation is the controlled displacement of air through openings, such as windows, doors and ventilators as well as through combustion heating devices.

### CAUSES OF INFILTRATION

The air leakage which takes place through various apertures in buildings must be estimated in heating and cooling calculations and enough heating or cooling capacity provided to offset the heat lost or gained by the air leakage. The rate of air flow into and out of a building depends on the magnitude of the pressure difference between the inside and outside of the structure and on the resistances presented to this pressure difference. The pressure difference exerted on the building walls by the air may be caused either by wind or by a difference in density of the air inside and outside the building. The effect of the wind depends on the interrelation of the speed and direction of the wind and the exposure of the building. The effect of the difference in the density of the air depends on the magnitude of the inside-outside temperature difference, the height of the rooms, the shape of the openings, and their elevation in the room or building. The effect of the difference in density is often referred to as the chimney or stack effect. The pattern of air flow through any part of the structure depends on both the pressure difference and the openings. In general, when the pressure difference is the result of wind pressure, air will enter the building through openings in the windward walls and leave through openings in the leeward walls or through ventilating ducts in the roof. When the pressure difference is caused by the inside-outside temperature difference the flow will be along the path of least resistance from inlets at lower levels to outlets at higher levels in a heated building or in the opposite direction for an air-conditioned building.

An exact estimate of the amount of infiltration under design conditions is difficult to make. The complicating factors include (1) variations in building construction, particularly as to width of crack or size of openings through which air leakage takes place; (2) the variations in wind velocity and direction; (3) the exposure of the building with respect to air leakage openings, and with respect to adjoining buildings; (4) the

variations in outside temperatures which influence the chimney effect; (5) the relative area and resistance of openings on the windward and leeward sides, and on the lower floors and on the upper floors; and (6) the influence of a planned air supply and the related outlet vents. Tight construction is essential for preventing large heat loss due to infiltration.

### INFILTRATION DUE TO WIND PRESSURE

The wind causes a pressure to be exerted on one or two sides of a building. As a result, air comes into the building on the windward side through cracks or porous construction, and a similar quantity of air leaves on the leeward side through like openings. In general, the resistance to air movement is similar on the windward to that on the leeward side. This causes a building up of pressure within the building, and a lesser air leakage than that experienced in single wall tests as determined in the laboratory. It is assumed

TABLE 1. INFILTRATION THROUGH WALLS<sup>a</sup>

<sup>a</sup> The values given in this table are 20 percent less than test values to allow for building up of pressure in rooms, and are based on test data reported in the papers listed in chapter footnotes.

<sup>b</sup> Constructed of porous brick and lime mortar—workmanship poor.

<sup>c</sup> Two coats prepared gypsum plaster on brick.

<sup>d</sup> Furring, lath, and two coats prepared gypsum plaster on brick.

<sup>e</sup> Wall construction: Bevel siding painted or cedar shingles, sheathing, building paper, wood lath and three coats gypsum plaster.

that actual building leakages, owing to this building up of pressure, will be 80 percent of laboratory test values. While there are cases where this is not true, tests in actual buildings substantiate the factor for the general case. Mechanical ventilating systems are frequently designed to produce positive or negative pressures in an enclosure, which are greater or lower than prevalent wind pressures. In such designs, if the specified rate at which air is to be supplied to, or removed from, the enclosure by positive means, exceeds the infiltration rate, it is common practice to use the greater value in determining the heating capacity to warm the outside air.

### Infiltration Through Walls

Data on infiltration through brick and frame walls are given in Table 1.<sup>1</sup> The brick walls listed in this table are walls which show poor workmanship, and which are constructed of porous brick and lime mortar. For good workmanship, the leakage through hard brick walls with cement-lime mortar does not exceed one-third the values given. These tests indicate that plastering reduces the leakage by about 96 percent; a heavy

coat of cold water paint, 50 percent; and three coats of oil paint carefully applied, 28 percent. The infiltration through walls ranges from 6 to 25 percent of that through windows and doors in a 10-story office building, with imperfect sealing of plaster at the baseboards of the rooms. With perfect sealing the range is from 0.5 to 2.7 percent; or a practically negligible quantity, which indicates the importance of good workmanship in proper sealing at the baseboard. It will be noted from Table 1 that the infiltration through properly plastered walls can be neglected.

The value of building paper, when applied between sheathing and shingles, is indicated by Fig. 1, which represents the effect on outside construction only, without lath and plaster. The effectiveness of plaster properly applied is no justification for the use of low grade building paper, or of the poor construction of the wall containing it. Not only is it diffi-

FIG. 1. INFILTRATION THROUGH VARIOUS TYPES OF SHINGLE CONSTRUCTION

cult to secure and maintain the full effectiveness of the plaster, but also it is highly desirable to have two points of high resistance to air flow with an air space between them. The infiltration indicated in Fig. 1 is that determined in the laboratory, and should be multiplied by the factor 0.80 to give proper working values.

### Window and Door Leakage

There are two methods of estimating air leakage through window and door cracks, namely, (1) the crack method, and (2) the air change method. The crack method is generally regarded as being more accurate than the air change method, provided the variables, such as crack width and clearance, can be properly evaluated.

### Crack Method

The crack method is based on known air leakage factors for various types of windows, and widths of crack and clearance. The wind velocity and length of crack are also considered when the crack method is employed.

|                                                | Heavy casement section, projected, 3/4-in. crack <sup>j</sup>                                                                                   | 8                             | 24  | 38  | 54  | 73  | 92  |
|                                                | Hollow Metal, vertically pivoted window <sup>k</sup>                                                                                            | 30                            | 88  | 145 | 186 | 231 | 243 |

<sup>a</sup> The values given in this table, with the exception of those for double-hung and hollow metal windows are 20 percent less than test values to allow for building up of pressure in rooms, and are based on test data, reported in the papers listed in chapter footnotes.

<sup>b</sup> The values given for frame leakage are per foot of sash perimeter, as determined for double-hung wood windows. Some of the frame leakage in masonry walls originates in the brick wall itself, and cannot be prevented by calking. For the additional reason that calking is not done perfectly and deteriorates with time, it is considered advisable to choose the masonry frame leakage values for calked frames as the average determined by the calked and non-calked tests.

<sup>c</sup> The fit of the average double-hung wood window was determined as 1/4-in. crack and 3/4-in. clearance by measurements on approximately 600 windows under heating season conditions.

<sup>d</sup> The values given are the totals for the window opening per foot of sash perimeter, and include frame leakage and so-called elsewhere leakage. The frame leakage values included are for wood frame construction, but apply as well to masonry construction assuming a 50 percent efficiency of frame calking.

<sup>e</sup> A 1/4-in. crack and clearance represent a poorly fitted window, much poorer than average. <sup>f</sup> Windows tested in place in building, so that no reduction from test values is necessary, as mentioned in footnote <sup>a</sup>.

<sup>g</sup> Industrial pivoted window generally used in industrial buildings. Ventilators horizontally pivoted at center or slightly above, lower part swinging out.

<sup>h</sup> Architecturally projected made of same sections as industrial pivoted, except that outside framing member is heavier, and it has refinements in weathering and hardware. Used in semi-monumental buildings such as schools. Ventilators swing in or out and are balanced on side arms. 1/4-in. crack is obtainable in the best practice of manufacture and installation, 3/4-in. crack considered to represent average practice.

<sup>i</sup> Of same design and section shapes as so-called heavy section casement, but of lighter weight. 1/4-in. crack is obtainable in the best practice of manufacture and installation, 3/4-in. crack considered to represent average practice.

<sup>j</sup> Made of heavy sections. Ventilators swing in or out and stay set at any degree of opening. 1/4-in. crack is obtainable in the best practice of manufacture and installation, 3/4-in. crack considered to represent average practice. Known as Intermediate Windows by steel window manufacturers.

<sup>k</sup> With reasonable care in installation, leakage at contacts where windows are attached to steel frame-work and at mullions, is negligible. With 3/4-in. crack, representing poor installation, leakage at contact with steel framework is about one third, and at mullions, about one-sixth of that given for industrial pivoted windows in the table.

The amount of infiltration for various types of windows is given in Table 2.<sup>3</sup> The fit of double-hung wood windows is determined by crack and clearance. Crack thickness is equivalent to one-half the difference between the inside window frame dimension and the outside sash width. The difference between the width of the window frame guide and the sash thickness is considered as the clearance. The length of the perimeter opening or crack for a double-hung window is equal to three times the width, plus two times the height, or in other words, it is the outer sash perimeter length, plus the meeting rail length. All of the window crack in any given

room is not necessarily used in estimating the infiltration heat loss by the crack method. The length of crack to be selected in any given case depends on the number of exposed sides, as explained in Chapter 12.

Values of leakage shown in Table 2 for the average double-hung wood window were determined by using, on nine windows tested in the laboratory, the average measured crack and clearance of a large number of windows found in a field survey. In addition, the table gives figures for a poorly fitted window. All of the figures for double-hung wood windows are for the unlocked condition. Just how a window is closed, or fits when it is closed, has considerable influence on the leakage. The leakage will be high if the sash are short, if the meeting rail members are warped, or if the frame and sash are not fitted squarely to each other. It is possible to have a window with approximately the average crack and clearance that will have a leakage at least double that of the figures shown. Values for the average double-hung wood window in Table 2 are considered to be easily obtainable figures, provided the workmanship on the window is good. Should it be known that the windows under consideration are poorly fitted, the larger leakage values should be used. Locking a window generally decreases its leakage, but in some cases may push the meeting rail members apart and increase the leakage. On windows with large clearances, locking will usually reduce the leakage.

Wood casement windows may be assumed to have the same unit leakage as for the average double-hung wood window when properly fitted. Locking, a normal operation in the closing of this type of window, maintains the crack at a low value.

For metal pivoted sash, the length of crack is the total perimeter of the movable or ventilating sections. Frame leakage on steel windows may be neglected when they are properly grouted with cement mortar into brick work or concrete. When they are not properly sealed, the linear feet of sash section in contact with steel work at mullions should be figured at 25 percent of the values given in Table 2 for industrial pivoted windows.

When storm sash are applied to well fitted windows, some reduction in infiltration is secured; the application of the sash provides an air space which reduces the heat transmission and helps prevent the frosting of the windows.<sup>3</sup> By applying storm sash to poorly fitted windows, a reduction in leakage of 50 percent may be obtained, the effect, so far as air leakage is concerned, being roughly equivalent to that obtained by the installation of weatherstrips.

### Door Leakage

Doors vary greatly in fit because of their large size and tendency to warp. For a well fitted door, the leakage values for a poorly fitted double-hung wood window may be used. If poorly fitted, twice this figure should be used. If weatherstripped, the values may be reduced one-half. A single door which is frequently opened, as might be the case in a store, should have a value applied which is three times that for a well fitted door. This extra allowance is for opening and closing losses, and is kept from being greater by the fact that doors are not used as much in the coldest and windiest weather.

The infiltration rate through swinging and revolving doors is generally a matter of judgment by the engineer making cooling load determinations, and in the absence of adequate research data, the values given in Table 3 represent current engineering practice. Some tests of infiltration through swinging and revolving doors have been reported.<sup>4</sup> The data in Table 3

are indicative of what might be expected in this connection, but it should be noted that Table 3 is based on a no-wind condition, and therefore not directly applicable to heating design.

A wide range of infiltration rates would be expected for swinging doors because of variations in the indoor-outdoor pressure difference caused by wind, temperature differences, and the degree to which a heating or an air-conditioning system tended to raise or lower the inside pressure by blower action. The frequency of door usage would also affect the amount of leakage per passage.

### Air Change Method

The amount of air leakage may be estimated by assuming a certain number of air changes per hour for each room, the number of changes assumed being dependent upon the type, use, and location of the room, as

TABLE 3. INFILTRATION THROUGH 72-INCH REVOLVING DOOR AND 36-INCH SWINGING DOOR<sup>a,b</sup>

(Cubic Feet per Person per Passage)

| USAGE                      | FREELY-REVOLVING DOOR | DOOR EQUIPPED WITH BRAKE |
|----------------------------|-----------------------|--------------------------|
| Infrequent.....            | 75                    | 60                       |
| Average.....               | 60                    | 50                       |
| Heavy.....                 | 40                    | 40                       |
| 36-Inch Swinging Door..... | 20 to 100             |                          |

<sup>a</sup> These figures are based on the assumption that there is no wind pressure and that swinging doors are in use in one wall only. Any swinging doors in other walls should be kept closed to insure air conditioning in accordance with these recommended standards.

<sup>b</sup> From Application Engineering Standards for Air Conditioning for Comfort 1947, Air Conditioning & Refrigeration Institute, Inc., Washington, D. C. and from experimental data of National Bureau of Standards. Used by permission.

indicated in Table 4. Where it is not possible to determine or pre-determine with accuracy the width of crack or clearance of windows, or when other sources of air leakage cannot readily be evaluated, as is often the case, the use of the air change method may be justified.<sup>5</sup>

The values in Table 4 may be used with reasonable accuracy for residences, and are the requirements for each room. The total infiltration allowance for the entire building should be one-half the sum of the infiltration allowances of the individual rooms, since whatever air enters on the windward side, generally leaves the building on the leeward side, and the infiltration requirements therefore do not exist simultaneously on all sides or in all rooms. An allowance of one air change per hour for all sources of air leakage for the entire volume may be considered average for a well constructed residence.

The air leakage, due to opening and closing of doors in vestibules, is sometimes based on the air change method, even though the air leakage estimates for other rooms are based on the crack method. Except for vestibules and reception halls, it is not advisable to attempt to apply the air change method to factories and industrial and commercial buildings, because of wide variations in the type and percentage of fenestration which is the principal source of air leakage in such buildings.

### INFILTRATION DUE TO TEMPERATURE DIFFERENCE

The air exchange due to temperature difference, inside to outside, is a chimney effect, causing air to enter through openings at lower levels, and to leave at higher levels<sup>6</sup> when the building is heated or causing flow in the reverse direction when the building is cooled. This air exchange is usually of considerable importance in tall, single-story buildings with openings near the ground level and near the ceiling; it should also be considered in tall, multi-story buildings unless the sealing between various floors is nearly perfect; and may be appreciable in one-story buildings with basements and attics.

The flow of air through a building under the influence of indoor-outdoor temperature difference is quite complex except for single-story structures without a basement or attic. It can best be understood by visualizing the building as a complex chimney with a number of passages and a number of restrictions. The basement represents the lower section of this imaginary chimney with air moving inward through cracks in the walls and around

TABLE 4. AIR CHANGES TAKING PLACE UNDER AVERAGE CONDITIONS IN RESIDENCES, EXCLUSIVE OF AIR PROVIDED FOR VENTILATION<sup>a</sup>

| KIND OF ROOM OR BUILDING    | NUMBER OF AIR CHANGES TAKING PLACE PER HOUR | KIND OF ROOM OR BUILDING                    | NUMBER OF AIR CHANGES TAKING PLACE PER HOUR |
|-----------------------------|---------------------------------------------|---------------------------------------------|---------------------------------------------|
| Rooms, 1 side exposed.....  | 1                                           | Rooms with no windows or outside doors..... | 1/2 to 3/4                                  |
| Rooms, 2 sides exposed..... | 1 1/2                                       | Entrance Halls.....                         | 2 to 3                                      |
| Rooms, 3 sides exposed..... | 2                                           | Reception Halls.....                        | 2                                           |
| Rooms, 4 sides exposed..... | 2                                           | Bath Rooms.....                             | 2                                           |

<sup>a</sup> For rooms with weatherstripped windows or storm sash, use 1/2 these values, where applicable, but never less than 1/2 air change.

windows and doors. The air then moves upward through cracks and openings in the floor which acts like a damper in the chimney. Above the floor the chimney has many parallel passages consisting of the several rooms and the hollow wall spaces in certain types of construction. These separate passages are all interconnected by cracks and also communicate with the outside through cracks and fissures. The ceiling acts as another damper with air flowing upward through various cracks and openings. This condition is repeated in every story of a multi-story building and can be further complicated by open stairways, elevator shafts, and utility ducts. The attic finally represents the union of all the parallel passages in the chimney with the outward flow of air being again restricted by the roof construction.

Since the chimney effect in a building produces a negative pressure and an inward flow of air at the lower levels and positive pressure and outward flow at the higher levels, a neutral zone<sup>7</sup> exists near midheight where there is no pressure difference between indoors and outdoors, if the openings are about uniformly distributed in a vertical direction. At the neutral zone there would be no air flow through openings in the outside walls as a result of temperature differences.

The infiltration caused by the indoor-outdoor temperature differences can be calculated by means of the crack method described earlier in this chapter for determining the infiltration caused by wind pressure. This is done by determining the equivalent wind velocity that would produce the same rate of infiltration as was caused by the prevailing temperature difference. It is recommended that one-half the total crack length of the

building be used for this computation. To determine the infiltration caused by the temperature difference, one-half the crack length of the building is multiplied by the infiltration coefficient from Table 2 corresponding to the equivalent wind velocity computed from the following equation developed from basic relationships between velocity, pressure, density and temperature.

$$V_e = B\sqrt{h(t_i - t_o)} \quad (1)$$

where

- $V_e$  = equivalent wind velocity corresponding to the temperature difference ( $t_i - t_o$ ), miles per hour.
- $h$  = height of rooms, feet.
- $t_i$  = inside temperature, Fahrenheit.
- $t_o$  = outside temperature, Fahrenheit.
- $B$  = a constant to account for leakage through floor and ceiling and for the number of stories in the building.

The constant  $B$  would be 0.12 for a single-story building or for any story of a multi-story building whose floor and ceiling were impervious to air, whereas the value of  $B$  was found to be approximately unity for a single-story frame building with basement and attic having double wood flooring, plastered ceiling, and the walls finished with plasterboard on the inside. The value of this constant would increase as the the number of stories increased and for stories farther removed from the neutral zone in either direction in buildings that lacked perfect sealing between stories.

### Sealing of Vertical Openings

In tall, multi-story buildings, every effort should be made to seal off vertical openings, such as stair-wells and elevator shafts, from the remainder of the building. Stair-wells should be equipped with self-closing doors, and, in exceptionally high buildings, should be closed off into sections of not over 10 floors each. Plaster cracks should be filled. Elevator enclosures should be tight, and solid doors should be used.

If the sealing of the vertical openings is made effective, no allowance need be made for the chimney effect. Instead, the greater wind movement at the greater heights makes it advisable to install additional heating surface on the upper floors above the level of neighboring buildings, this additional surface being increased as the height is increased. One arbitrary rule is to increase the heating surface on floors above neighboring buildings by an amount ranging from 5 percent to 20 percent. This extra heating surface is required only on the windward side and on windy days, and hence, automatic temperature control is especially desirable with such installations.

In stair-wells that are open through many floor levels, although closed off from the remainder of each floor by doors and partitions, the stratification of air makes it advisable to increase the amount of heating surface at the lower levels, and to decrease the amount at higher levels. One rule is to calculate the heating surface of the entire stair-well in the usual way, and to place 50 per cent of this in the bottom third, the normal amount in the middle third, and the balance in the top third.

### Infiltration and Air for Combustion

Infiltration in buildings normally supplies the air required for combustion by fuel-burning appliances, but in some cases weatherstripping, sealing and calking may reduce infiltration to the point that special openings must be provided to supply adequate air to the heating appliances. This need for combustion air is recognized in various building codes. For instance, the State Building Construction Code of New York State for One- and Two-Family Dwellings<sup>8</sup> requires that an air inlet area not less than the area of the smoke pipe connection be provided if adequate air supply at all times is not assured. Similarly the same code for multiple

FIG. 2. THE JUMP OF WIND FROM WINDWARD FACE OF BUILDING. (A—LENGTH OF SUCTION AREA; B—POINT OF MAXIMUM INTENSITY OF SUCTION; C—POINT OF MAXIMUM PRESSURE)

dwellings requires a permanent opening to the outdoor air for rooms containing fuel-burning appliances having a gross capacity in excess of 250,000 Btu per hour.

### NATURAL VENTILATION

Ventilation by natural forces finds application in industrial plants, public buildings, schools, dwellings, garages, and in farm buildings.

The natural forces available for moving air into, through, and out of buildings are: (a) wind forces, and (b) the difference in temperature between the air inside and outside a building. The air movement may be caused by either of these forces acting alone, or by a combination of the two, depending upon atmospheric conditions, building design, and location.

The ventilating results obtained will vary, from time to time, due to variation in the velocity and direction of the wind, and the temperature difference. The arrangement, location, and control of the ventilating openings should be such that the two forces act cooperatively rather than in opposition.

### WIND FORCES

In considering the use of natural wind forces for producing ventilation, account must be taken of: (1) average wind velocity; (2) prevailing wind direction; (3) seasonal and daily variations in velocity and direction; and (4) local wind interference by nearby buildings, hills or other obstructions of similar nature.

Values are given in Table 3, Chapter 13 for the average wind velocities for the months June to September in various localities throughout the United States, while Table 1, Chapter 12, lists similar values for the winter. In almost all localities, the summer wind velocities are lower than those in the winter, and in about two-thirds of the localities the prevailing direction is different during the summer and winter. While the tables give no average velocities below 5 mph, there will be times when the velocity is lower, even in localities where the seasonal average is considerably above 5 mph. There are relatively few places where the velocity falls below one-half of the average for many hours per month. Consequently, if the natural ventilating system is designed for wind velocities of one-half of the average seasonal velocity, it should prove satisfactory in almost every case.

Equation 3 may be used for calculating the quantity of air forced through ventilation openings by the wind, or for determining the proper size of such openings to produce given results:

$$Q = EAV \quad (3)$$

where

- $Q$  = air flow, cubic feet per minute.  
 $A$  = free area of inlet openings, square feet.  
 $V$  = wind velocity, feet per minute, = miles per hour  $\times 88$ .  
 $E$  = effectiveness of openings. ( $E$  should be taken at 0.50 to 0.60 for perpendicular winds, and 0.25 to 0.35 for diagonal winds.)<sup>9</sup>

The precision of results obtained by the use of Equation 3, depends upon the placing of the openings, as the formula assumes that ventilating openings have a flow coefficient slightly greater than that of a square-edged orifice. If the openings are not advantageously placed with respect to the wind, the flow per unit area of the openings will be less and, if unusually well placed, the flow will be slightly more than that given by the formula. Inlets should be placed to face directly into the prevailing wind, while outlets should be placed in one of the five places listed:

1. On the side of the building directly opposite the direction of the prevailing wind.
2. On the roof in the low pressure area caused by the jump of the wind (see Fig. 2).
3. On the sides adjacent to the windward face where low pressure areas occur.
4. In a monitor on the side opposite from the wind.
5. In roof ventilators or stacks.

### TEMPERATURE DIFFERENCE FORCES<sup>7</sup>

The stack effect produced within a building, when the outdoor temperature is lower than the indoor temperature, is due to the difference in weight

of the warm column of air within the building and cooler air outside. The flow due to stack effect is proportional to the square root of the draft head, or approximately

$$Q = 9.4A \sqrt{h(t_i - t_o)} \quad (4)$$

where

- $Q$  = air flow, cubic feet per minute.  
 $A$  = free area of inlets or outlets (assumed equal), square feet.  
 $h$  = height from inlets to outlets, feet.  
 $t_i$  = average temperature of indoor air in height  $h$ , Fahrenheit.  
 $t_o$  = temperature of outdoor air, Fahrenheit.  
 9.4 = constant of proportionality, including a value of 65 percent for effectiveness of openings. This should be reduced to 50 percent (constant = 7.2) if conditions are not favorable.

### HEAT REMOVAL

In problems of heat removal, knowing the amount of heat to be removed and having selected a desirable temperature difference, the amount of air to be passed through the building per minute, to maintain this temperature difference, can be determined by means of Equation 5.

$$Q = \frac{H}{C_p \times \rho \times 60(t_i - t_o)} = \frac{H}{1.08(t_i - t_o)} \quad (5)$$

where

- $Q$  = air removed, cubic feet per minute.  
 $H$  = heat removed, Btu per hour.  
 $C_p$  = specific heat of air at constant pressure, 0.24.  
 $\rho$  = density of standard air, 0.075 pounds per cubic foot.  
 $t_i - t_o$  = indoor-outdoor temperature differences, Fahrenheit.

### EFFECT OF UNEQUAL OPENINGS

The largest flow per unit area of openings is obtained when inlets and outlets are equal, and the preceding equations are based on this condition. Increasing outlets over inlets, or vice-versa, will increase the air flow, but not in proportion to the added area. When solving problems having an unequal distribution of openings, use the smaller area, either inlet or outlet, in the equations, and add the increase as determined from Fig. 3.

### COMBINED FORCES OF WIND AND TEMPERATURE

Equations have already been given for determining the air flow due to temperature difference and wind. It must be remembered that when both forces are acting together, even without interference, the resulting air flow is not equal to the sum of the two estimated quantities. The flow through any opening is proportional to the square root of the sum of the heads acting on that opening.

When the two heads are about equal in value, and the ventilating openings are operated so as to coordinate them, the total air flow through the building is about 10 percent greater than that produced by either head acting independently under conditions ideal to it. This percentage decreases rapidly as one head increases over the other. The effect of the larger head will predominate.

The wind velocity and direction, the outdoor temperature, or the indoor

distribution, cannot be predicted with certainty, and refinement in calculations is not justified; consequently, a simplified method can be used. This may be done by using the equations and calculating the flows produced by each force separately, under conditions of openings best suited for coordination of the forces. Then, by determining the ratio of the flow produced by temperature difference to the sum of the two flows, the actual flow due to the combined forces can be approximated from Fig. 4.

**Example 1:** Assume a drop forge shop, 200 ft long, 100 ft wide, and 30 ft high. The cubical content is 600,000 cu ft, and the height of the air outlet over that of the inlet is 30 ft. Oil fuel of 18,000 Btu per lb is used in this shop at the rate of 15 gph (7.75 lb per gal). Desired summer temperature difference is 10 deg, and the prevailing wind is 8 mph perpendicular to the long dimension. What is the necessary area for the inlets and outlets, and what is the rate of air flow through the building?

FIG. 3. INCREASE IN FLOW CAUSED BY EXCESS OF ONE OPENING OVER ANOTHER

**Solution for Temperature Difference Only:** The heat  $H = 15 \times 7.75 \times 18,000 = 2,092,500$  Btu per hr.

By Equation 5, the air flow required to remove this heat with an average temperature difference of 10 deg is

$$Q = \frac{H}{1.08(t_i - t_o)} = \frac{2,092,500}{1.08 \times 10} = 193,750 \text{ cfm.}$$

This is equal to about 20 air changes per hour. From Equation 4, the inlet (or outlet) opening area should be

$$A = \frac{Q}{9.4\sqrt{h(t_i - t_o)}} = \frac{193,750}{9.4\sqrt{30 \times 10}} = 1190 \text{ sq ft.}$$

The flow per square foot of inlet or outlet would be  $193,750 \div 1190 = 162.5$  cfm, with all windows open.

**Solution for Wind Only:** With 1,190 sq ft of inlet openings distributed around the sidewalls, there will be about 400 sq ft in each long side and 195 sq ft in each end. The outlet area will be equally distributed on the two sides of the monitor, or 595 sq ft on each side. With the wind perpendicular to the long side, there will be 400 sq

ft of opening in its path for inflow, and 595 in the lee side of the monitor for outflow with the windward side closed. The air flow, as calculated by Equation 3, will be:

$$Q = 0.60 \times 400 \times 704 = 168,960 \text{ cfm.}$$

This gives 16.9 air changes per hour, which should be more than ample when there is no heat to be removed.

**Solution for Combined Heads:** Since the windward side of the monitor is closed when the wind is blowing, the flow due to temperature difference must be calculated for this condition, using Fig. 3. This chart shows that, when inlets are twice the size of the outlets, in this case 1,190 sq ft in the sidewalls and 595 sq ft in the monitor, the flow will be increased 26.5 percent over that produced by equal openings. Using

FIG. 4. DETERMINATION OF FLOW CAUSED BY COMBINED FORCES OF WIND AND TEMPERATURE DIFFERENCE

the smaller opening and the flow per square foot obtained previously, the calculated amount for this condition will be

$$595 \times 163 \times 1.265 = 122,700 \text{ cfm.}$$

Adding the two computed flows:

$$\begin{array}{rcl} \text{Temperature Difference} & = & 122,700 = 42 \text{ percent.} \\ \text{Wind} & = & 168,960 = 58 \text{ percent.} \end{array}$$

$$\begin{array}{rcl} \text{Total} & = & 291,660 = 100 \text{ percent.} \end{array}$$

From Fig. 4 it is determined that, when the flow due to temperature difference is 42 percent of the total, the actual flow due to the combined forces, will be about 1.6 times that calculated for temperature difference alone, or 196,300 cfm.

The original flow due to temperature difference alone was 193,750 cfm with all openings in use. The effect of the wind is to increase this to 196,300 cfm, even though half of the outlets are closed.

A factor of judgment is necessary in the location of the openings in a building, especially those in the roof, where heat, smoke, and fumes are to be removed. Usually, windward monitor openings should be closed, but if

the wind is low enough for the temperature head to overcome it, all windows may be opened.

### TYPES OF OPENINGS

Types of openings may be classified as: (1) windows, doors, monitor openings and skylights; (2) roof ventilators; (3) stacks connecting to registers; and (4) specially designed inlet or outlet openings. The various types and principles of operation are discussed in following paragraphs.

#### Windows, Doors and Skylights

Windows have the advantage of transmitting light, as well as providing ventilating area, when open. Their movable parts are arranged to open in various ways; they may open by sliding either vertically or horizontally, by tilting on horizontal pivots at or near the center, or by swinging on pivots at the top, bottom or side. Regardless of their design, the air flow per square foot of opening may be considered to be the same under the same conditions. The type of pivoting should receive consideration from the standpoint of weather protection, and certain types may be advantageous in controlling the distribution of incoming air. Deflectors are sometimes used for the same purpose, and these devices should be considered a part of the ventilation system.

#### Roof Ventilators

The function of a roof ventilator is to provide a storm and weather-proof air outlet. These are actuated by the same forces of wind and temperature head which create flow through other types of openings. The capacity of a ventilator depends upon four things: (1) its location on the roof; (2) the resistance it and the duct work offer to air flow; (3) the height of draft; and (4) the efficiency of the ventilator in utilizing the kinetic energy of the wind for inducing flow by centrifugal or ejector action.

For maximum flow induction, a ventilator should be located on that part of the roof where it will receive the full wind without interference. If ventilators are installed within the suction region created by the wind passing over the building, or in a light court, or on a low building between two high buildings, their performance will be seriously influenced. Their normal ejector action, if any, may be completely lost.

The base of the ventilator should be of a taper-cone design to produce the effect of a bell-mouth nozzle whose coefficient of flow is considerably higher than that of a square-entrance orifice. If a grille is provided at the base, or if the base or structural members present obstructions, additional resistance is introduced, and the base opening should be increased in size accordingly.

Air inlet openings located at lower levels in the building, should be at least equal to, and preferably larger than, the combined throat areas of all roof ventilators. The air discharged by a roof ventilator depends on wind velocity and temperature difference, and, in general, its performance will be the same as any monitor opening located in the same place but, due to the four capacity factors already mentioned, no simple formula can be devised for expressing ventilator capacity.

Roof ventilators may be classified as stationary, pivoting or oscillating, and rotating. Generally, these have a round throat, but the continuous-ridge ventilator would fall in the stationary classification. When selecting roof ventilators, some attention should be given to ruggedness of construc-

tion, storm-proofing features, dampers and damper operating mechanisms, possibility of noise, original cost, and maintenance.

Natural ventilation units may be used to supplement power-driven supply fans, and under favorable weather conditions it may be possible to stop the power-driven units. Units are not subject to code tests for ratings. Generally, they must be selected from manufacturers' tables. It is, therefore, very important to consider the reliability of the ratings used.

#### Controls

Gravity ventilators may have dampers controlled by hand, thermostat, or wind velocity, in combination with a fan. The thermostat station may be located anywhere in the building, or it may be located within the ventilator itself. The purpose of wind velocity control is to obtain a definite volume of exhaust regardless of the natural forces, the fan motor being energized when the natural exhaust capacity falls below a certain minimum, and again shut off when the wind velocity rises to the point where this minimum volume can be supplied by natural forces.

#### Stacks

Stacks or vertical flues are really chimneys which function through the effects of the wind and temperature difference. Like the roof ventilator, the stack outlet should be located so that the wind may act upon it from any direction. With little or no wind, the chimney effect depends entirely on temperature difference to produce a removal of air from the rooms where the inlet openings are located.

### GENERAL VENTILATION RULES

A few of the important considerations, in addition to those already outlined, are:

1. Inlet openings in the building should be well distributed, and should be located on the windward side near the bottom, while outlet openings are located on the leeward side near the top. Outside air will then be supplied to the zone to be ventilated.
2. Inlet openings should not be obstructed by buildings, trees, sign boards, etc., outside, nor by partitions inside.
3. Greatest flow per square foot of total opening is obtained by using inlet and outlet openings of nearly equal areas.
4. In the design of window ventilated buildings, where the direction of the wind is quite constant and dependable, the orientation of the building, together with amount and grouping of ventilation openings, can be readily arranged to take full advantage of the force of the wind. Where the wind's direction is quite variable, the openings should be arranged in sidewalls and monitors so that, as far as possible, there will be approximately equal areas on all sides. Thus, no matter what the wind's direction, there will always be some openings directly exposed to the pressure force, and others to a suction force, and effective movement through the building will be assured.
5. Direct short circuits between openings on two sides at a high level may clear the air at that level without producing any appreciable ventilation at the level of occupancy.
6. In order that temperature difference may produce a motive force, there must be vertical distance between openings. That is, if there are a number of openings available in a building, but all are at the same level, there will be no motive head produced by temperature difference, no matter how great that difference might be.
7. In order that the force of temperature difference may operate to maximum advantage, the vertical distance between inlet and outlet openings should be as great as possible. Openings in the vicinity of the neutral zone are less effective for ventilation.
8. In the use of monitors, windows on the windward side should usually be kept closed, since, if they are open, the inflow tendency of the wind counteracts the outflow

tendency of temperature difference. Openings on the leeward side of the monitor result in cooperation of wind and temperature difference.

9. In an industrial building where furnaces that give off heat and fumes are to be installed, it is better to locate them in the end of the building exposed to the prevailing wind. The strong suction effect of the wind at the roof near the windward end will then cooperate with temperature difference, to provide for the most active and satisfactory removal of the heat and gas-laden air.

10. In case it is impossible to locate furnaces in the windward end, that part of the building in which they are to be located should be built higher than the rest, so that the wind, in splashing therefrom, will create a suction. The additional height also increases the effect of temperature difference to cooperate with the wind.

11. The intensity of suction, or the vacuum produced by the jump of the wind, is greatest just back of the building face. The area of suction does not vary with the wind velocity, but the flow due to suction is directly proportional to wind velocity.

12. Openings much larger than the calculated areas are sometimes desirable, especially when an increase in occupancy may occur, or when extremely hot days may be anticipated. In the former case, free openings should be located at the level of occupancy for psychological reasons.

13. In single story industrial buildings, particularly those covering large areas, natural ventilation must be accomplished by taking air in and out of the roof openings. Openings in the pressure zones can be used for inflow, and openings in the suction zone, or openings in zones of less pressure, can be used for outflow. The ventilation is accomplished by the manipulation of openings to get air flow through the zones to be ventilated.

### VENTILATION OF ANIMAL SHELTERS<sup>10</sup>

Animal shelters require ventilation to remove moisture, odors and, in the case of dairy stables, excess heat.

**Outlets.** Outlet flues for natural draft systems should be round or approximately square. A thermal resistance ( $1/U$ ) of not less than two is required in their side walls. They should extend at least two feet above the highest part of the roof. Only one outlet is recommended for each room or pen. The use of several outlet flues may result in excessive up-drafts in some flues, and down-drafts in others.

If flues have roofs or covers, these should be high enough to provide unobstructed openings on all sides, equal in height to one-half the least dimension of the flue, Fig. 5. A level, heavily insulated ceiling under the flue roof, and over the entire area of the flue, is important.

**Inlets.** Inlets should direct the incoming air vertically upward so as to avoid drafts on the animals, and to insure immediate mixing of incoming air with the room air. A reasonably uniform distribution around the stable or pen is desirable. Inlet flues, that deliver air close to the side walls, stimulate convection currents, which is desirable. When so placed, they also tend to bathe the side walls with cool air, thus reducing temperature difference between the inside and outside of the wall.

From the standpoint of air movement, insulation of inlet flues is not important. Condensation is, however, likely to occur on them, unless the thermal resistance of their walls is at least two.

Controls or throttling devices in inlet flues are seldom required. If used, they are best applied to the inlets and limited to the side of the building facing prevailing winter winds. They should be so made that an opening, at least one inch wide by the width of the flue, will always remain open.

Amounts of heat and water produced by livestock vary not only with the different kinds of animals, but also with age, weight, feed consumption and production. These facts, and the vagaries of the weather, make exact

calculations impossible. The following practical recommendations are based on numerous, carefully checked observations.

It is desirable to keep the relative humidity of livestock shelters below 85 percent. Temperatures may be as indicated in the discussion for each kind of animal.

### Dairy Stables

The most usually accepted temperatures for dairy stables, where cows are confined in stanchions or tie stalls, are from 45 to 55 F. These temperatures are readily maintained in winter weather by the body heat of the herd in well constructed, well stocked and well ventilated stables. Stable volume in excess of 600 cu ft, and exposed wall area in excess of 130 sq ft per 1000 lb animal weight are, in general, undesirable.

Side walls should have an overall thermal resistance of from 2 to 5, depending on the temperature zone and wind exposure. Thermal re-

FIG. 5. RECOMMENDED TYPE OF COVER FOR WOODEN OUTLET FLUE

The opening  $H$  should equal one-half the least dimension of the flue. Heavy insulation of the level deck is essential.

distance of the ceiling should be 50 percent greater than that of the side walls. In stables of this size and so insulated, a ventilation rate of 3200 to 3800 cu ft per (hr) (1000 lb of animal) usually insures good conditions.

The following recommendations do not apply to so-called pen stables or loafing barns in which there is a thick manure and bedding pack on the floor, and in which doors are normally kept open.

**Outlets.** One flue will serve a stable 200 ft long. In stables over 120 ft long, the flue should be about midway between the ends or, if the stable is L-shaped, near the angle. In shorter stables, it may be at any convenient location.

The exhaust point in the stable should be not more than 18 in. above the floor. This permits removal of only the coolest air, and prevents rapid fluctuations in stable temperature.

A basic rule for finding the cross-section of the outlet flue is

$$A_o = \frac{176 N}{\sqrt{h}} \quad (6)$$

where

$A_o$  = area of the outlet flue, square inches.

$N$  = weight of animal population, thousands of pounds.  
 $h$  = vertical distance from top of inlet flues to top of outlet flue, feet.

For large flues the flue area obtained from the basic formula may well be reduced according to the chart, Fig. 6, because of a decrease in friction.

**Example 2:** Assume a stable in which the vertical height from the top of the inlets to the top of the outlet flue is 32.5 ft, and in which 38 cows, averaging 1300 lb, will be housed. Determine required size of outlet flue.

**Solution:** From Equation 6

$$A_o = \frac{176 \times (38 \times 1,300)}{\sqrt{32.5}} = 1525 \text{ sq in.}$$

From Fig. 6 the factor to be applied to this area is 94.5 percent. Therefore, the area of flue required is  $1525 \times 0.945 = 1441 \text{ sq in.}$

**Inlets.** Inlet flues, each approximately 60 sq. in. in area, have given good results. One such flue should be provided for each 3500 lb animal weight. They should deliver air from points 12 to 18 in. below the ceiling.

FIG. 6. MODIFICATION OF FLUE AREA FOR OUTLETS EXCEEDING 1000 Sq IN.

### Sheep Barns

Shelters used for breeding and feeding stock usually have enough openings, so that no special provision for ventilation is required. Barns for winter lambing flocks, however, require ventilation systems. Fermentation in the floor pack of manure produces heat, vapor and odor. These must be added to the ventilation load regularly produced by the animals.

**Outlets.** In practice, results obtained by the basic formula, Equation 7, when modified by the use of the chart, Fig. 6 have given good results:

$$A_o = \frac{4A_i}{\sqrt{h}} \quad (7)$$

where

$A_o$  = area of the outlet, square inches.

$A_i$  = floor area, square feet.

$h$  = vertical height from top of inlet openings to top of outlet flue, feet.

The bottom of the outlet flue should be 15 to 24 in. above the surface of the manure pack.

**Inlets.** Provide one inlet, 60 sq in. in area, for each 150 sq-ft of floor

### Infiltration and Ventilation

area. Inlets should be well distributed around the side walls, and designed to deliver air near the ceiling (see section on Dairy Stables).

### Swine Barns

Community swine barns, because of the extent of slop feeding and the absence of daily cleaning of the pens, are the most difficult farm buildings to ventilate satisfactorily. Farrowing pens, to which supplemental heat is supplied, present less of a problem. In all cases, good floor drainage to remove urine and excess spilled water is important.

Temperatures of from 50 to 55 F are usually recommended for farrowing pens. It is desirable to maintain temperatures above freezing in all other pens in community houses. For barns that are well stocked and adequately ventilated, this requires walls with an overall thermal resistance of from 3 to 6, and ceilings with 40 to 50 percent greater resistance.

**Outlets.** The outlet flue should draw air from a level of 15 to 18 in. above the floor. Equation 8 is the basic formula for flue area, and gives reasonably good results when modified according to the chart, Fig. 6.

$$A_o = \frac{5 \times A_i}{\sqrt{h}} \quad (8)$$

**Inlets.** At least one inlet flue should be used for each pen. Swine are given or select definite nesting places, and care must be exercised to avoid having inlets located over them.

Total inlet area should be approximately 70 percent of outlet area. The area of individual inlets is best determined from the total area required, and the number that can be so installed as to meet previous specifications. Inlets should deliver air from points 12 to 15 in. below the ceiling, or from a level deflector on a sloping ceiling.

### Poultry Laying Houses

From the standpoint of ventilation, poultry laying houses may be divided into cold houses and warm houses. The former are uninsulated, except in the ceiling. The inside-outside temperature difference is seldom more than 5 F deg. In the warm house, because of insulation or supplemental heat, the temperature seldom falls below 32 F, and is usually above 45 F.

**Outlets.** The outlet flue is best placed near the middle of the pen. It is advisable to limit the length of pens to 80 ft.

The area of the outlet flue may be determined from Equation 9, and modified according to the chart, Fig. 6.

$$A_o = \frac{2.5 \times A_i}{\sqrt{h}} \quad (9)$$

For a cold house, the bottom of the flue should be at the level of the insulated ceiling. In warm houses, the bottom of the flue should be 12 to 15 in. above the level of the floor litter.

**Inlets.** Inlets may be approximately 60 sq in. in area. The total inlet area may be equal to 70 percent of the outlet area. Inlets in cold and in warm houses should deliver air from points 12 to 24 in. above the floor. In cold houses which normally do not have storm sash, windows may be

raised enough to give the desired area, and be fitted with baffle boards to direct the air straight and upward.

In houses less than 20 ft in width, all inlets may be on one side. In wider houses, a rather uniform distribution of inlets is essential.

### GARAGE VENTILATION

Because of hazards resulting from carbon monoxide and other physiologically harmful or combustible gases or vapors in garages, the importance of proper ventilation of these buildings cannot be over-emphasized. During the warm months of the year, garages are usually ventilated adequately because the doors and windows are kept open. The A.S.H.A.E. Code of Minimum Requirements for Heating and Ventilating Garages,<sup>11</sup> adopted in 1935, specifies that openings for natural ventilation shall be distributed as uniformly as possible in at least two outside walls, and that the total area of such openings shall be equivalent to at least 5 percent of the floor area. The code further states that where it is impracticable to operate such a system of natural ventilation, a mechanical system shall be used, and shall provide for either the supply of 1 cfm of outdoor air for each square foot of floor area, or for exhaust of the same amount of air, discharging it to the outside as a means of flushing the garage.

Cooperative research<sup>12</sup> on garage ventilation, undertaken by the A.S.H.A.E. Committee on Research at Washington University, St. Louis, Mo., and at the University of Kansas, and tests conducted at the A.S.H.A.E. Research Laboratory, have resulted in authoritative papers on the subject.

Some of the conclusions based on work at these laboratories are:

1. Upward ventilation results in a lower concentration of carbon monoxide at the breathing line and a lower temperature above the breathing line, than does downward ventilation for the same rate of carbon monoxide production, air change, and the same temperature at the 30-in. level.
2. A lower rate of air change and a smaller heating load are required with upward than with downward ventilation.
3. In the average case, upward ventilation results in a lower concentration of carbon monoxide in the occupied portion of a garage, than that obtained with mixing of the exhaust gases and the air supplied. However, the variations in concentration from point to point, together with the possible failure of the advantages of upward ventilation to accrue, suggest the basing of garage ventilation on complete mixing, and an air change sufficient to dilute the exhaust gases to the allowable concentration of carbon monoxide.
4. The rate of carbon monoxide production by an idling car is shown to vary from 25 to 50 cfh, with an average rate of 35 cfh.
5. An air change of 350,000 cfh per idling car is required to keep the carbon monoxide concentration down to one part in 10,000 parts of air.

### Individual Exhaust Ducts

Motor vehicle servicing areas may be provided with underground or overhead exhaust systems discharging outdoors. Each service location should be provided with a flexible branch duct, the inlet end of which is sized to slip over the tail pipe of the engine, or over any deflector attached to the tail pipe. The minimum branch size and ventilation rate for the largest class of vehicle regularly serviced at each location are shown in Table 4.

Where each tail pipe exhaust branch is provided with an automatic device to close the branch inlet when it is not in use, the capacity of the fan for the system should be based on the maximum number of branches in simultaneous use. Where the branch inlets are open when not in use, the

## CHAPTER 12

### HEATING LOAD

General Procedure, Design Outdoor Weather Conditions, Inside Temperatures, Attic Temperatures, Temperatures in Unheated Spaces, Ground Temperatures, Basement Temperatures and Heat Loss, Heat Losses from Floor Slabs, Transmission Heat Loss, Infiltration Heat Loss, Selection of Wind Velocities, Auxiliary Heat Sources, Intermittently Heated Buildings, Residence Heat Loss Problems

PRIOR to designing a heating system, an estimate must be made of the maximum probable heat loss of each room or space to be heated, based on maintaining a selected inside air temperature during periods of design outdoor weather conditions. The heat losses may be divided into two groups, namely: (1) the transmission losses or heat transmitted through the confining walls, floor, ceiling, glass or other surfaces; and (2) the infiltration losses or heat required to warm outside air which leaks in through cracks and crevices, around doors and windows, opening of doors and windows, or heat required to warm outside air used for ventilation.

### GENERAL PROCEDURE

The general procedure for calculating heat losses of a structure is:

1. Select the design outdoor weather conditions: temperature, wind direction and wind velocity. The data on climatic conditions given in Table 1 and the isotherms of average design temperature in Fig. 1 will be helpful, but should be used with judgment as suggested in the section Design Outdoor Weather Conditions.

2. Select the inside air temperature, which is to be maintained in each room during the coldest weather. (See Table 2).

3. Estimate temperatures in adjacent unheated spaces and the attic. The attic temperature need not be estimated if the combined roof and ceiling coefficient is used.

4. Select or compute the heat transmission coefficients for outside walls and glass; also for inside walls, floors, or top-floor ceilings, if these are next to unheated space; include roof if next to heated space. (See Chapter 9. If the design wind velocity is appreciably different from 15 mph, the appropriate change in the heat transmission coefficients in Tables 6 to 9 and 15 to 19 of Chapter 9 can be found in Table 21 of that chapter.)

5. Measure net area of outside wall, glass and roof next to heated spaces, as well as any cold walls, floors or ceilings next to unheated space. Such measurements are made from building plans, or from the actual building, using inside dimensions.

6. Compute the heat transmission losses for each kind of wall, glass, floor, ceiling and roof in the building by multiplying the heat transmission coefficient in each case by the area of the surface in square feet, and the temperature difference between the inside and outside air. (See Items 1, 2, and 3).

7. Select unit values and compute the heat equivalent of the infiltration of cold air taking place around outside doors and windows. These unit values depend on the kind or width of crack, wind velocity, and the temperature difference between the inside and outside air; the result expresses the heat required to warm up the cold air leaking into the building per hour. (See Chapter 11).

8. When positive ventilation using outdoor air is provided by an air heating or an air conditioning unit, the heat required to warm the outside air to room temperature must be provided by the unit; if mechanical exhaust from the room is provided, in amount equal to the outside air drawn in by the unit, the natural infiltration losses must also be provided for by the unit. If no mechanical exhaust is used, and the

outdoor air supply equals or exceeds the amount of natural infiltration which would occur without ventilation, the natural infiltration may be neglected.

9. The sum of the heat losses by transmissions (Item 6) through the outside walls and glass, as well as through any cold floors, ceilings or roof plus the heat equivalent (Item 7) of the cold air entering by infiltration, or required to replace mechanical exhaust, represents the total heat loss equivalent for any building.

10. In buildings which have a reasonably steady internal heat release of appreciable magnitude from sources other than the heating system, a computation of this heat release under design conditions should be made for deduction from the total of the heat losses computed in items 1-9. This is especially important for heating systems of high initial cost or those for which a demand charge is based on installed capacity.

### DESIGN OUTDOOR WEATHER CONDITIONS

There are no hard and fast rules for selecting the design outdoor weather conditions to be used for a given locality or type of building or heating system, and the selection is to some extent a matter of judgment and experience. The appropriate design temperature in a given locality may vary with heat capacity and degree of insulation of a particular structure, the amount of protection from the wind, the length of time that nightly minimum temperatures persist, whether the particular building is being used day and night, and perhaps other factors. For heating systems that depend primarily on electrical energy as a source of heat it will often be desirable, for economic reasons, to make a more careful analysis of the factors that affect design weather conditions than would otherwise be justified.

The outside design temperature seldom is taken as the lowest temperature, or even the lowest daily mean temperature ever recorded in a given locality. Such temperatures rarely recur in successive years. Likewise the wind direction and velocity occurring at the time of design outside temperature may be different from the average velocity and prevailing direction during the winter.

The A.S.H.A.E. Technical Advisory Committee on Weather Design Conditions has recommended the adoption for heating load calculations of an outside design temperature which is equalled or exceeded during 97½ percent of the hours in December, January, February and March. Complete design temperature data based on this formula are not available, but Column 8, Table 1, lists this recommended design temperature based on airport station readings for the period indicated, generally the five years, 1935-1939. In most cases these stations are outside of the city and these data apply primarily to rural areas. In general the use of the airport data for buildings within an adjacent city will not make an appreciable difference in design load.

Because of the limited data available in Column 8 of Table 1, design temperatures in common use are listed in Column 10 for the United States. Many of those values were furnished by A.S.H.A.E. members, the remainder were taken from an *ACRMA* Bulletin,<sup>1</sup> manufacturers' publications, and other sources,<sup>2</sup> and a few were estimated.

The map in Fig. 1 shows isotherms of outdoor winter design temperature which are based on the values in Column 10 of Table 1 with some modifications where other data indicated that Column 8 furnishes a more reasonable design temperature. These isotherms have also been modified slightly in accordance with the elevations of the various cities. The isotherms are drawn on 10 deg temperature intervals, in most cases, and are so placed that interpolation between isotherms will provide the proper design temperature for cities between the isotherms. Thus, a city located half-way be-

<sup>a</sup> United States data compiled from U. S. Weather Bureau Records for years indicated, and Canadian data from the Climatological Atlas of Canada for years indicated.

<sup>b</sup> Col. 2. The stations followed by letter A are airport stations; all others are city office stations and are followed by letter C.

<sup>c</sup> Col. 3. The elevations marked c are ground elevations of the station. All other elevations given are the actual elevations of the thermometer bulb above mean sea level.

<sup>d</sup> Col. 4. The periods of record indicated apply only to the lowest temperature ever recorded shown in Col. 5, and generally extend from a summer month of the first year indicated through the spring months of the last year indicated. The periods marked by \* terminated in December of the year indicated.

<sup>e</sup> Average of readings of one lowest temperature obtained for each year for period of record. For Canada, in some cases, more than one location have been used.

<sup>f</sup> For period October to April, inclusive.

<sup>g</sup> It should be noted that Col. 8 in the United States section of the table applies only to airports, as these data for city stations are not available at this time. The temperature shown is the minimum hourly outdoor temperature which has been equalled or exceeded 97½ percent of the total hours in December, January and February for the period of record. It is pointed out that in most cases the airport stations are outside of the city and these data would apply primarily to rural areas.

<sup>h</sup> Col. 9 indicates the maximum wind velocity which occurred at temperatures the same as, and lower than, the temperatures shown in Col. 5.

<sup>i</sup> Col. 10 records design temperatures in use by A.S.H.A.E. Members as reported by Chapter Secretaries for the various stations. Where these were not available the design temperatures from an ACRMA publication and various other sources have been inserted.

<sup>j</sup> The wind velocities indicated in Col. 11 were furnished by the U. S. Weather Bureau and corrected through Feb. 1948.

<sup>k</sup> A bulletin prepared by A.S.H.A.E. and U. S. Weather Bureau for annual weather data of city of Detroit indicates 6 as design temperature based on Dec. to March, inclusive.

<sup>l</sup> Computed for Reading by Karl Shelley and O. F. Smith.

<sup>m</sup> The winter design temperatures for Canadian cities for bases of 1, 2½, 5 and 10 percent are the Fahrenheit temperature values at or below which 1, 2½, 5 and 10 percent of the January hourly outdoor temperatures occur, for the 10 years 1941 to 1950. The tabulated values are based on hourly temperature observations for some of the cities and upon the difference between the mean monthly temperature and the design temperature for the remainder of the cities listed.

<sup>n</sup> Most of the wind speeds are based on periods ending in 1947 which are somewhat shorter than the periods for the minimum temperatures. The three months, December, January and February were used.

FIG. 1. ISOOTHERMS OF WINTER OUTDOOR DESIGN TEMPERATURE

tween the 0 F and 10 F isotherms would normally have a design temperature of 5 F although sharp changes in elevation must be taken into consideration in mountainous areas where large differences in climate may occur within relatively small distances. This map will be of considerable value in selecting design temperatures for cities and towns not listed in Table 1. The design temperatures in Column 10 of Table 1 are often used with a design wind velocity of 15 mph. However, Column 11 shows that the

average wind velocity from December through February is 15 mph or higher in only 7 of the cities listed and Column 9 shows that a wind velocity of 15 mph did not occur in any city listed for temperatures equal to or lower than those shown in Column 8 for the years 1935-1939. Consequently, it will often be desirable to modify the U values in Tables 6 to 9 and 15 to 19 of Chapter 9 to correspond to lower wind velocities. Correction factors for wind velocities can be found in Table 21 of Chapter 9.

Column 6 in Table 1 lists the average annual minimum temperature which is the average of readings of the one lowest temperature occurring for each year the weather station has been in existence. A comparison of the temperatures listed in Columns 6, 8, and 10 of Table 1 offers some guidance in selecting a suitable outdoor design temperature for particular cities. For the 63 cities in the United States having temperatures listed in all three columns the average annual minimums in Column 6 average 2.3 deg warmer than the design temperature in common use listed in Column 10 whereas the design temperatures in Column 8 average 11.0 deg warmer than those in Column 10. There are variations of 6 deg or more in either direction from these average differences, however, for a few cities in this group.

Designers are cautioned against attempting to compensate for internal vagrant heat sources in a structure, the heat generated by electrical equipment, the approximations that may exist in heat transmission factors and infiltration rates, and the safety factors used in selecting heating plant capacity by adjusting the design temperature difference between indoors and outdoors. These factors should be accounted for by more careful analysis of their existence and magnitude in computing the heating load that must be carried by the heating plant itself.

### INSIDE TEMPERATURES

The inside air temperature which must be maintained within a building is understood to be the dry-bulb temperature at the breathing line, 5 ft above the floor, or at the seating level, 30 in. above the floor, and not less than 3 ft from the outside walls. Inside air temperatures usually specified, vary in accordance with the intended use of the building. Table 2 presents values which conform to good practice.

The proper dry-bulb temperature to be maintained depends upon the relative humidity and air motion, as explained in Chapter 6. In other words, a person may feel warm or cool at the same dry-bulb temperature, depending on the relative humidity and air motion. The optimum winter *effective temperature* for sedentary persons, as determined at the A.S.H.V.E. Research Laboratory, is 67-68 ET.

As explained in Chapter 6 for so-called still air conditions, a relative humidity of approximately 50 percent is required to produce an effective temperature of 68 ET when the dry-bulb temperature is 72.5 F. However, even where provision is made for artificial humidification, the relative humidity is seldom maintained higher than 40 percent during the extremely cold weather, and where no provision is made for humidification, the relative humidity may be 20 percent or less. Consequently, in using the figures listed in Table 2, consideration should be given to the actual relative humidity to be maintained, if provision is to be made for humidification. If no humidification is to be provided, the higher temperatures

may not even produce comfort on cold days; if humidity is to be maintained at 50 percent, the lower temperatures will apply.

In rooms having large glass areas, when sun is not shining, or in rooms with walls having a high transmission coefficient, the lowered surface temperature will cause a feeling of coolness even though the air temperature in the room is at or above the temperatures indicated in the table. In rooms of this character, it is desirable to design for even higher temperatures than those listed, unless a compensating higher temperature surface is installed to offset the low temperature surfaces.

TABLE 2. WINTER INSIDE DRY-BULB TEMPERATURES USUALLY SPECIFIED\*

| TYPE OF BUILDING               | DEG F | TYPE OF BUILDING                        | DEG F |

\* The most comfortable dry-bulb temperature to be maintained depends on the relative humidity and air motion. These three factors considered together constitute what is termed the *effective temperature*. (See Chapter 6.) When relative humidity is not controlled separately, optimum dry-bulb temperature for comfort will be slightly higher than shown in Table 2.

The inside temperatures specified in Table 2 may be used for panel heated spaces as well as for spaces heated by warm air, radiators or convectors. It is true that warm panel surfaces tend to produce a comfortable environment at a lower room air temperature than when warm panels are not present, but field experience in the United States has indicated that actual reductions in air temperature are slight in operation.

**Temperature at Proper Level.** In making the actual heat loss computations, however, for the various rooms in a building it is often necessary to modify the temperatures given in Table 2 so that the air temperature at the proper level will be used. By *air temperature at the proper level* is meant, in the case of walls, the air temperature at the mean height between floor and ceiling; in the case of glass, the air temperature at the mean height of the glass; in the case of roof or ceiling, the air temperature at the mean height of the roof or ceiling above the floor of the heated room; and in the case of floors, the air temperature at the floor level.

**Temperature at Ceiling.** The air temperature at the ceiling is generally higher than at the breathing level due to stratification of air resulting from the tendency of the warmer or less dense air to rise. An allowance for this fact should be made in calculating ceiling heat losses, particularly in the case of high ceilings. However, the exact allowance to be made may be somewhat difficult to determine as it depends on many factors, including (1) the type of heating system, (2) ceiling height, and (3) the inside-outside temperature differential. The type of heating system is par-

ticularly important, as the temperature gradient from floor to breathing-level to ceiling may depend to a large extent on whether direct radiation, unit heaters or warm air is used, and in the latter case, whether the air is moved mechanically or by gravity. The temperature of the heating medium is also a factor.

It is impracticable to establish rigid rules for determining the temperature difference to use in all cases. However, for residences and structures having ceiling heights under 10 ft, the comparatively small temperature differential between the breathing level and ceiling generally may be

TABLE 3. APPROXIMATE TEMPERATURE DIFFERENTIALS BETWEEN BREATHING LEVEL AND CEILING, APPLICABLE TO CERTAIN TYPES OF HEATING SYSTEMS\*

| CEILING HEIGHT (Ft) | BREATHING LEVEL TEMPERATURE (5 FT ABOVE FLOOR) |      |      |      |      |      |      |      |      |      |

\* The figures in this table are based on an increase of 1 percent per foot of height above the breathing level (5 ft) up to 15 ft and  $\frac{1}{10}$  of one degree for each foot above 15 ft. This table is generally applicable to forced air types of heating systems. For direct radiation or gravity warm air, increase values 50 percent to 100 percent.

neglected without serious error. For higher ceilings, an allowance of approximately 1 percent per foot of height above the breathing level may be made for ceiling heights up to 15 ft and approximately  $\frac{1}{10}$  of 1 deg per foot of height above this level. The values in Table 3 are calculated on this basis. For direct radiation and gravity warm air systems, the allowance should be increased from 50 percent to 100 percent over those given in Table 3. These rules should, however, be used with considerable discretion, and they do not apply to some types of heating systems such as those using panel and baseboard radiation, where very low temperature differences between the floor and the ceiling may exist.

**Temperature at Floor Level.** According to tests at the University of Illinois,<sup>3, 4, 5, 6</sup> the temperature at the floor level ranged from about 2 to 6 deg below that at the breathing level, or somewhat greater than the difference between the breathing level and ceiling temperatures. Tests at the University of Wisconsin<sup>7</sup> indicated a somewhat smaller differential between the floor and breathing level temperatures. As a general rule, if the breathing level to ceiling temperature differential is neglected (as with ceiling heights under 10 ft), the breathing level to floor differential may also be neglected, as the two are somewhat compensating, especially where both floor and ceiling losses are calculated for the same space. In other cases, the 10 ft temperature differentials in Table 3 may be used in arriving at the floor heat loss, these differentials to be subtracted from the breathing level temperature.

### ATTIC TEMPERATURES

Frequently, it is necessary to estimate the attic temperature, and in such cases Equation 1 can be used for this purpose:

$$t_a = \frac{A_c U_c t_i + t_o (A_r U_r + A_w U_w + A_g U_g)}{A_c U_c + A_r U_r + A_w U_w + A_g U_g} \quad (1)$$

where

$t_a$  = attic temperature, Fahrenheit degrees.

$t_i$  = inside temperature near top floor ceiling, Fahrenheit degrees.

$t_o$  = outside temperature, Fahrenheit degrees.

$A_c$  = area of ceiling, square feet.

$A_r$  = area of roof, square feet.

$A_w$  = area of net vertical attic wall surface, square feet.

$A_g$  = area of attic glass, square feet.

$U_c$  = coefficient of transmission of ceiling, based on surface conductance of 2.20 (upper surface, see Chapter 9). 2.20 = reciprocal of one-half the air space resistance.

$U_r$  = coefficient of transmission of roof, based on surface conductance of 2.20 (lower surface, see Chapter 9).

$U_w$  = coefficient of transmission of vertical wall surface.

$U_g$  = coefficient of transmission of glass.

**Example 1.** Calculate the temperature in an unheated attic, assuming the following conditions:  $t_i = 70$ ;  $t_o = 10$ ;  $A_c = 1000$ ;  $A_r = 1200$ ;  $A_w = 100$ ;  $A_g = 10$ ;  $U_c = 0.50$ ;  $U_r = 0.40$ ;  $U_w = 0.30$ ;  $U_g = 1.13$ .

**Solution:** Substituting these values in Equation 1:

$$t_a = \frac{(1000 \times 0.40 \times 70) + 10[(1200 \times 0.50) + (100 \times 0.30) + (10 \times 1.13)]}{(1000 \times 0.40) + (1200 \times 0.50) + (100 \times 0.30) + (10 \times 1.13)}$$

$$t_a = \frac{34,413}{1041} = 33.1 \text{ F.}$$

Equation 1 neglects the effect of any interchange of air such as would take place through attic vents or louvers intended to preclude attic condensation. However, according to tests,<sup>8</sup> such venting of attics by means of small louvers or other small openings does not appreciably reduce the attic temperature and may be neglected without serious error.

Neither does this equation take into consideration such factors as heat exchange between chimney and attic or solar radiation to and from the roof. Because of these latter effects, actual attic temperatures are frequently higher than the calculated values using Equation 1. The attic temperature may be calculated in the usual manner by means of Equation 1, allowing the full value of the roof. The error resulting from this assumption will generally be considerably less than if the roof were neglected (as is sometimes the practice) and the attic temperature assumed to be the same as the outside temperature. When relatively large louvers are installed, as is customary in the southern states, the attic temperature is often assumed as the average between inside and outside.

For a shorter, approximate method of calculating heat losses through

attics, the combined ceiling and roof coefficient may be used, as described in Chapter 9.

### TEMPERATURES IN UNHEATED SPACES

The heat loss from heated rooms into unheated rooms or spaces must be based on the estimated or assumed temperature in such unheated spaces. This temperature will lie in the range between the inside and outside temperatures, depending on the relative areas of the surfaces adjacent to the heated room and those exposed to the outside. If the respective surface areas adjacent to the heated room and exposed to the outside are approximately the same, and if the coefficients of transmission are approximately equal, the temperature in the unheated space may be assumed to be the mean of the inside and outside design temperatures. If, however, the surface areas and coefficients are unequal, the temperature in the unheated space should be estimated by means of Equation 2.

$$t_u = \frac{t_i(A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.}) + t_o(A_aU_a + A_bU_b + A_cU_c + \text{etc.})}{A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.} + A_aU_a + A_bU_b + A_cU_c + \text{etc.}} \quad (2)$$

where

$t_u$  = temperature in unheated space, Fahrenheit degrees.

$t_i$  = inside design temperature of heated room, Fahrenheit degrees.

$t_o$  = outside design temperature, Fahrenheit degrees.

$A_1, A_2, A_3$ , etc. = areas of surface of unheated space adjacent to heated space, square feet.

$A_a, A_b, A_c$ , etc. = areas of surface of unheated space exposed to outside, square feet.

$U_1, U_2, U_3$ , etc. = coefficients of transmission of surfaces of  $A_1, A_2, A_3$ , etc.

$U_a, U_b, U_c$ , etc. = coefficients of transmission of surfaces  $A_a, A_b, A_c$ , etc.

**Example 2:** Calculate the temperature in an unheated space adjacent to a heated room having surface areas ( $A_1, A_2$ , and  $A_3$ ) in contact therewith of 100, 120, and 140 sq ft and coefficients ( $U_1, U_2$ , and  $U_3$ ) of 0.15, 0.20, and 0.25, respectively. The surface areas of the unheated space exposed to the outside ( $A_a$  and  $A_b$ ) are respectively 100 and 140 sq ft, and the corresponding coefficients are 0.10 and 0.30. The sixth surface is on the ground and is neglected in this example. Assume  $t_i = 70$  and  $t_o = -10$ .

**Solution:** Substituting in Equation 2:

$$t_u = \frac{70[(100 \times 0.15) + (120 \times 0.20) + (140 \times 0.25)] + -10[(100 \times 0.10) + (140 \times 0.30)]}{(100 \times 0.15) + (120 \times 0.20) + (140 \times 0.25) + (100 \times 0.10) + (140 \times 0.30)}$$

$$t_u = \frac{4660}{126} = 37 \text{ F.}$$

The temperatures in unheated spaces having large glass areas and having two or more surfaces exposed to the outside (such as sleeping porches and sun parlors), generally are assumed to be the same as outside.

### GROUND TEMPERATURES

Ground temperatures to be assumed for estimating basement heat losses usually will differ in the case of basement walls and floors, the temperatures under the floors generally being higher than those adjacent to walls. Factors affecting these temperatures will be discussed.

#### Temperatures Under Basement Floors

The temperature of the ground under basement floors<sup>9</sup> is affected by heat sources within the basement and is not influenced by atmospheric

conditions. In computing losses through basement floors, the ground temperatures may be assumed to be the same as water temperatures at depths of 30 to 60 ft given in Fig. 3, Chapter 35. Test observations indicate that heat losses through basement floors frequently are over-estimated.<sup>10</sup>

#### Temperatures Adjacent to Basement Walls

Ground temperatures near the surface and under open spaces vary with the climate, the season of the year and the depth below the surface. The nearer the surface (during the cold weather) the lower will be the ground temperature. Frost will penetrate to a depth of over 4 ft in some localities if not protected by snow. A thick blanket of snow will result in a higher ground temperature near the surface. Therefore, in localities where the ground is covered with a heavy blanket of snow throughout the

TABLE 4. BELOW GRADE HEAT LOSSES FOR BASEMENT WALLS AND FLOORS

| GROUND WATER TEMPERATURE <sup>a</sup> | BASEMENT FLOOR LOSS <sup>b</sup><br>Btu/Sq Ft | BELOW GRADE WALL LOSS <sup>b</sup><br>Btu/Sq Ft |
|---------------------------------------|-----------------------------------------------|-------------------------------------------------|
| 40                                    | 3.0                                           | 6.0                                             |
| 50                                    | 2.0                                           | 4.0                                             |
| 60                                    | 1.0                                           | 2.0                                             |

<sup>a</sup> See Fig. 3, Chapter 35.

<sup>b</sup> Based on basement temperature of 70 F and U of 0.10.

winter, the ground temperatures near the surface will be higher than when little or no snow is present.

Complete data on ground temperatures adjacent to buildings are not available, but since the recommended transmission coefficient for basement walls in contact with the soil is only 0.10, any reasonable, assumed ground temperature will not materially affect the calculated heat loss.

### BASEMENT TEMPERATURES AND HEAT LOSS

The allowance to be made for basement heat loss depends on whether the basement is to be heated or not.

If the basement is *heated* to a specified temperature, the heat loss should be calculated in the usual manner, based on the proper wall and floor coefficients (see Chapter 9) and the outside air and ground temperatures. Heat loss through windows and walls above grade should be based on outside temperatures and the proper air-to-air coefficients. Heat loss through basement walls below grade should be based on the floor and wall coefficients for surfaces in contact with the soil, and on the proper ground temperature.

The heat loss values for below grade basement walls and floors given in Table 4 are sufficiently precise for general practice.

If a basement is completely below grade and is *not heated*, the temperature in the basement normally will range between that in the rooms above and the ground temperature. Basement windows will, of course, lower the basement temperature when it is cold outside, and heat given off by the heating plant will increase the basement temperature. In any case, the exact basement temperature is indeterminate if the basement is not heated. In general, it is found that the transient heat from the heating plant warms the air near the basement ceiling sufficiently to make it un-

necessary to make an allowance for floor heat loss from rooms located over the basement.

The temperature in crawl spaces below floors will vary widely depending on the number and size of wall vents, the amount of warm piping present and type of piping insulation. It is necessary, therefore, to evaluate the conditions and to select an appropriate temperature by judgment.

### HEAT LOSSES FROM FLOOR SLABS

Two types of concrete floors used in basementless houses are (a) the unheated floor, relying for warmth on heat delivered above floor level by the heating system, and (b) the heated floor containing heated pipes or ducts that constitute a radiant slab or portion thereof for complete or partial heating of the house.

For type (a) the floor heat loss, economically considered, is of minor importance since it comprises generally about 10 percent of the total heat loss of the house. From the comfort standpoint, however, it may be most important, since houses with cold floors are not successfully heated. In this connection, it should be remembered that a well insulated floor does not assure comfort if down-drafts from windows or exposed walls create pools of chilly air over considerable areas of the floor. For this reason a floor of type (a) should not be used in a severe climate except with a heating system that delivers enough heat near the floor to counteract the down-drafts of the exterior walls and the heat transmission through the floor.

The results of some experiments<sup>10, 11</sup> with type (a) unheated floor slabs indicate that the heat loss from a concrete slab floor on grade is more nearly proportional to the perimeter than to the area of the floor, and that the heat loss can be estimated by means of the equation:

$$H_F = FP (t - t_o) \quad (3)$$

where

$H_F$  = heat loss of the floor, Btu per hour.

$P$  = perimeter or exposed edge of the floor, linear feet.

$F$  = heat loss coefficient, Btu per (hour) (linear foot of exposed edge) (degree difference in temperature between the inside air and the outside air). ( $F$  ranges between 0.81 for a floor with no edge insulation to 0.55 for a floor with edge insulation).

$t$  = inside air temperature, Fahrenheit.

$t_o$  = outside air temperature, Fahrenheit.

In most instances the values given in Table 5 for edge loss are of sufficient precision for use.<sup>12</sup> The insulation shown extending under the floor horizontally for 2 ft can also be located along the foundation wall with equal effectiveness if the insulation extends 24 in. below the floor level.

**Example 3:** Calculate the heat loss from the floor of a 12 ft x 15 ft room with two exposures. The floor is an unheated concrete slab which is insulated at the edge with 2 in. of insulation extending horizontally for a distance of 2 ft from the edge, and the house is located in an area with an outside design temperature of -15 F.

**Solution:** From Table 5 the heat loss per foot of exposed edge is 45 Btu per hr. The length of exposed edge is 12 ft + 15 ft = 27 ft, and the total edge loss 27 x 45 = 1215 Btu per hr.

Floors of type (b) containing heating pipes or ducts, are now in common

use. The heat loss downward into the ground and outward through the edges of the floor slab is called the reverse loss.

The results<sup>13</sup> of an investigation in which a warm-air perimeter duct was embedded in four types of concrete floor slab and foundation constructions has verified the indication that Equation 3 can be used to calculate the reverse loss when warm-air perimeter heating ducts are used. To make the results of this application more usable, values corresponding to those shown in Table 5 for unheated floors are given in Table 6 for concrete floors with a warm-air perimeter duct.

The desirability of edge insulation is apparent. One inch of water-resistant material is the minimum thickness of edge insulation that should be used, but a 2-in. thickness is recommended.<sup>12, 14, 15</sup> The values of edge loss in Table 6 indicate that the reverse heat loss of heated slabs is likely to be about 20 percent of the total heat loss of many types of present day

TABLE 5. HEAT LOSS OF CONCRETE FLOORS AT OR NEAR GRADE LEVEL PER FOOT OF EXPOSED EDGE

\* This construction not recommended; shown for comparison only.

houses, and may exceed 20 per cent if only one inch of insulation is used at the edge of the floor.

The concrete floor slab is usually placed on a gravel fill 4 in. thick or more, both to insulate the floor from the earth and to retard the rise of ground water by capillarity. A waterproof membrane should be installed over the gravel fill. Obviously, it is important that such floors be laid several inches above grade, and that effective subsoil drainage be provided to avoid slabs soaked by rain or melting snow, and consequent excessive heat loss.

### TRANSMISSION HEAT LOSS

The basic formula for the loss of heat by transmission through any surface is given in Equation 4:

$$H_t = AU (t - t_o) \quad (4)$$

where

$H_t$  = heat loss transmitted through the wall, roof, ceiling, floor, or glass, Btu per hour.

$A$  = area of wall, glass, roof, ceiling, floor, or other exposed surface, square feet.

- $U$  = coefficient of transmission, air to air, Btu per (hour) (square foot) (Fahrenheit degree temperature difference) (Chapter 9).
- $t$  = inside temperature near surface involved (this may not necessarily be the so-called breathing line temperature), Fahrenheit degrees.
- $t_o$  = outside temperature, or temperature of adjacent unheated space or of the ground, Fahrenheit degrees.

**Example 4:** Calculate the transmission loss through an 8 in. brick wall having an area of 150 sq ft, if the inside temperature  $t$  is 70 F and the outside temperature  $t_o$  is -10 F.

**Solution:** The coefficient of transmission ( $U$ ) of a plain 8 in. brick wall is 0.50 (Chapter 9, Table 8). The area ( $A$ ) is 150 sq ft. Substituting in Equation 4:

$$H_t = 150 \times 0.50 \times [70 - (-10)] = 6000 \text{ Btu per hour.}$$

| 10                            | 75                                                       | 70                                                           | 55                                                           |
| 20                            | 62                                                       | 57                                                           | 45                                                           |

<sup>a</sup> Factors include loss downward through inner area of slab.

### Transmission Loss Through Ceilings and Roofs

The transmission heat loss through top floor ceilings, attics, and roofs may be estimated by either of two methods:

- By substituting in Equation 4 the ceiling area  $A$ , the inside-outside temperature difference ( $t - t_o$ ) and the proper value of  $U$ :
  - Flat roofs.** Select the coefficient of transmission of the ceiling and roof from Tables 15 or 16, Chapter 9, or use appropriate coefficients in Equation 1 if side walls extend appreciably above the ceiling of the floor below.
  - Pitched roofs.** Select the combined roof and ceiling coefficient from Table 18, Chapter 9 or calculate the combined roof and ceiling coefficient by means of Equations 4 and 5, Chapter 9, where these formulas are applicable as explained in Chapter 9.
- By estimating the attic temperature (based on the inside and outside design temperatures) by means of Equation 1, and substituting for  $t_o$  in Equation 4, the value of  $t_o$  thus obtained, together with the ceiling area  $A$  and the ceiling coefficient  $U$ . This applies to *pitched roofs*. In the case of *flat roofs* it is not necessary to calculate the attic temperatures, as the ceiling-roof heat loss can be determined as suggested in paragraph 1a.

### INFILTRATION HEAT LOSS

The infiltration heat loss includes (1) the *sensible heat loss* or the heat required to warm the outside air entering by infiltration, and (2) the *latent heat loss* or the heat equivalent of any moisture which must be added.

### Heating Load

#### Sensible Heat Loss

The formula for the heat required to warm the outside air which enters a room by infiltration to the temperature of the room, is given in Equation 5:

$$H_s = 0.240 Qd (t - t_o) \quad (5)$$

where

$H_s$  = heat required to raise temperature of air leaking into building from  $t_o$  to  $t$ , Btu per hour.

0.240 = specific heat of air.

$Q$  = volume of outside air entering building, cubic feet per hour (see Chapter 11).

$d$  = density of air at temperature  $t_o$ , pounds per cubic foot.

It is sufficiently accurate to use  $d = 0.075$  in which case Equation 5 reduces to

$$H_s = 0.018 Q (t - t_o) \quad (5a)$$

The volume  $Q$  of outside air entering per hour depends on the wind velocity and direction, the width of crack or size of openings, the type of openings and other factors, as explained in Chapter 11. Where the crack method is used for estimating leakage, it is more convenient to express the air leakage heat loss in terms of the crack length:

$$H_s = B L (t - t_o) \quad (5b)$$

where

$B$  = air leakage per (hour) (foot of crack) (Chapter 11) for the wind velocity and type of windows or door crack involved, multiplied by 0.018.

$L$  = length of window or door crack to be taken into consideration, feet.

**Example 5:** What is the infiltration heat loss per hour through the crack of a 3 x 5 ft average, double-hung, non-weatherstripped, wood window, based on a wind velocity of 15 mph? Assume inside and outside temperatures to be 70 F and zero, respectively.

**Solution:** According to Table 2, Chapter 11, the air leakage through a window of this type (based on  $\frac{1}{8}$  in. crack and  $\frac{1}{4}$  in. clearance) is 39 cu ft per (ft of crack) (hour). Therefore,  $B = 39 \times 0.018 = 0.70$ . The length of crack  $L$  is  $(2 \times 5) + (3 \times 3)$ , or 19 ft;  $t = 70$  and  $t_o = 0$ . Substituting in Equation 5b,

$$H_s = 0.70 \times 19 \times (70 - 0) = 931 \text{ Btu per hour.}$$

#### Crack Length to be Used for Computations

For designers who prefer to use the crack method, the basis of calculation is as follows: The amount of crack used for computing the infiltration heat loss should be not less than half of the total length of crack in the outside walls of the room. For a building having no partitions, air entering through the cracks on the windward side must leave through the cracks on the leeward side. Therefore, take one-half the total crack for computing each side and end of the building. In a room with one exposed wall, take all the crack; with two exposed walls, take the wall having the

most crack; and with three or four exposed walls, take the wall having the most crack; but in no case take less than half the total crack.

In small residences the total infiltration loss of the house is generally considered to be equal to the sum of the infiltration losses of the various rooms. However, this is not necessarily accurate as at any given time infiltration will take place only on the windward side or sides and not on the leeward side. Therefore, for determining the total heat requirements of larger buildings it is more accurate to base the total infiltration loss on the wall having the most total crack, but in no case on less than half of the total crack in the building.

#### Number of Air Changes to be Used for Computations

Since a certain amount of judgment is required regarding quality of construction, weather conditions, use of room and other factors in estimating infiltration by any method, some designers base infiltration upon an estimated number of air changes rather than upon the length of window cracks. Table 4 of Chapter 11 indicates air changes commonly used, but should be taken only as a guide.

When calculating infiltration losses by the air change method, Equation 5a may be used by substituting for  $Q$  the volume of the room multiplied by the number of air changes obtained from Table 4, Chapter 11. For further discussion of the method see section on Air Change Method in Chapter 11.

#### Latent Heat Loss

When it is intended to add moisture to air leaking into a room in order to maintain proper winter comfort conditions, it is necessary to determine the heat required to evaporate the water vapor added. This heat may be calculated by the equation

$$H_1 = Qd(W_i - W_o)h_{fg} \quad (6)$$

where

$H_1$  = heat required to increase moisture content of air leaking into building from  $m_o$  to  $m_i$ , Btu per hour.

$Q$  = volume of outside air entering building, cubic feet per hour.

$d$  = density of air at temperature  $t_i$ , pounds per cubic foot.

$W_i$  = vapor density of inside air, pounds per pound of dry air.

$W_o$  = vapor density of outside air, pounds per pound of dry air.

$h_{fg}$  = latent heat of vapor at  $m_i$ , Btu per pound.

If the latent heat of vapor  $h_{fg}$  is assumed to be 1060 Btu per lb, Equation 6 reduces to:

$$H_1 = 79.5 Q (W_i - W_o) \quad (6a)$$

Equations 5a, 5b and 6a may also be used for determining the sensible and latent heat gains due to infiltration in cooling load computations.

#### SELECTION OF WIND VELOCITIES

The effect of wind on the heating requirements of any building should be given consideration for two reasons:

1. Wind movement increases the heat transmission of walls, glass, and roof, affecting poor walls to a much greater extent than good walls.

2. Wind increases materially the infiltration of cold air through the cracks around doors and windows, and even through the building materials themselves (see Tables 1 and 2, Chapter 11).

Theoretically, as a basis for design, the most unfavorable combination of temperature and wind velocity should be chosen. It is entirely possible that a building might require more heat on a windy day with a moderately low outside temperature, than on a quiet day with a much lower outside temperature. However, the combination of wind and temperature, which is the worst, would differ with different buildings, because wind velocity has a greater effect on buildings which have relatively high infiltration losses. It would be possible to compute the heating load for a building for several different combinations of temperature and wind velocity which records show to have occurred, and to select the worst combination, but designers generally do not feel that such a degree of refinement is justified.

Therefore, where Table 1 lists the maximum wind velocity occurring during the coldest 2½% of the winter hours for each locality, this value should be the basis for estimating infiltration losses. When using the air change method it will not be necessary to consider the wind velocities. Designers employing the crack method generally use values corresponding to a 15-mile wind. The effect of the wind velocity on the transmission coefficient can be evaluated from Table 21 of Chapter 9.

#### Exposure Factors

Many designers use empirical exposure factors to increase the calculated heat loss of rooms or spaces on the side or sides of the building exposed to the prevailing winds. However, the use of exposure factors is unnecessary when the GUIDE method of calculating heat losses is used. Therefore, exposure factors may be regarded as *factors of safety* for the rooms or spaces exposed to the prevailing winds, to allow for additional capacity for these rooms or spaces, or to *balance the radiation*, particularly in the case of multi-story buildings. Tall buildings may have severe infiltration heat losses, induced by their stack effect (see Chapter 11), which will require special consideration. Although the exposure allowance frequently is assumed to be 15 percent, the actual allowance to be made, if any, must to a large extent be a matter of experience and judgment of the designer, since there are at present no authentic test data available from which rules could be developed for the many conditions encountered in practice.

#### AUXILIARY HEAT SOURCES

The heat supplied by persons, lights, motors and machinery always should be ascertained in the case of theaters, assembly halls, and industrial plants, but allowances for such heat sources must be made only after careful consideration of all local conditions. In many cases, these heat sources should not affect the size of the heating plant at all, although they may have a marked effect on the operation and control of the system. In general, where audiences are present, the heating system must have sufficient capacity to bring the building to the stipulated inside temperature before the audience arrives. In industrial plants, quite a different condition exists, and heat sources, if always available during occupancy, may be substituted for a portion of the heating installation. In no case should the actual heating installation (exclusive of heat sources) be reduced below that required to maintain at least 40 F in the building.

## Electric Motors and Machinery

Motors and the machinery which they drive, if both are located in the room, convert all of the electrical energy supplied into heat. This heat is retained in the room if the product manufactured is not removed until its temperature is the same as the room temperature.

If power is transmitted to the machinery from the outside, then only the heat equivalent of the brake horsepower supplied is used. In some mills this is the chief source of heating, and it is frequently sufficient to overheat the building even in zero weather, thus requiring cooling by ventilation the year round. Table 7 shows the heat output equivalent

TABLE 7. HEAT EQUIVALENTS OF VARIOUS SOURCES\*

|                                                            |            |
|------------------------------------------------------------|------------|
| Machinery (Motor in room) = Motor Hp/efficiency x 2544     | Btu/hr.    |
| Machinery (Motor outside room) = Motor Hp x 2544           | Btu/hr.    |
| Electric Lights = Kilowatts x 3413                         | Btu/hr.    |
| Gas (Producer = 150) (Manufactured = 535) (Natural = 1000) | Btu/cu ft. |

\* Additional values are given in Chapter 13, Table 26.

of various sources of heat in a factory. For information concerning the heat supplied by persons, refer to data given in Chapter 6, and also Table 25, Chapter 13. For appliances see Table 26, Chapter 13.

## INTERMITTENTLY HEATED BUILDINGS

In the case of intermittently heated buildings additional heat is required for raising the temperature of the air, the building materials and the material contents of the building to the specified inside temperature. The rate at which this additional heat must be supplied depends upon the heat capacity of the structure and its material contents, and upon the time in which these are to be heated.<sup>15</sup>

This additional heat may be computed and allowed for as conditions require, but inasmuch as the heating system proportioned for taking care of the heat losses will usually have a capacity about 100 percent greater than that required for average winter weather, and inasmuch as most buildings may either be continuously heated or have more time allowed for heating up during the few minimum temperature days, no allowance usually is made, except in the size of boilers or furnaces. For churches, auditoriums and other intermittently heated buildings, additional capacity should be provided.

## RESIDENCE HEAT LOSS PROBLEMS

The following *Examples 6 and 7* will illustrate the procedure for calculating the heat loss of a residence, uninsulated and insulated, in accordance with the recommendations given in this chapter.

*Example 6:* Calculate the heat loss of the residence shown in Fig. 2 located in the vicinity of Chicago. From Table 1, design outdoor conditions are -10 F and 12 mph wind velocity. Inside temperature from Table 2 is assumed to be 70 F. The attic is unheated. Assume ground temperature to be 50 F (see Fig. 3, Chapter 35) under basement and garage floors and 32 F adjoining basement walls. Estimate infiltration losses by the air change method. No wall, ceiling or roof insulation is to be considered in this problem, but all first and second floor windows, except in the garage,

## NOTES FOR TABLE 8.

- <sup>a</sup> The inside-outside temperature difference is 70 - (-10) or 80 F except where otherwise noted.
- <sup>b</sup> Volume of infiltration, cfh = (no. air changes) x (floor or ceiling area) x (ceiling height).
- <sup>c</sup> From Equation 5a.
- <sup>d</sup> The ceiling heat losses are calculated by estimating the attic temperature and then calculating the loss through the ceiling using the proper temperature difference. This unheated attic is not ventilated during winter months. The attic temperature is estimated from Equation 1 to be 30.2 F when the outside temperature is -10 F and room temperature is 70 F. The temperature difference is then 70 - 30.2 or 39.8 deg. For the insulated residence, attic temperature becomes 4.6 F and temperature difference 70 - 4.6 = 65.4 deg.
- <sup>e</sup> Temperature in garage assumed to be 35 F.
- <sup>f</sup> Coefficient for wall adjoining garage calculated on basis of metal lath and plaster on both sides of studs (U = 0.39).
- <sup>g</sup> One half of value from Table 4, Chapter 11, for storm windows or weatherstripping.
- <sup>h</sup> Exposed on two sides, weatherstripped windows offset by fire-place. Use 1 1/4.
- <sup>i</sup> Window on one side weatherstripped but double-doors are hard to close tightly. Hence, conservative value of 1 1/2.
- <sup>j</sup> Assuming kitchen vent, door to vestibule usually open, allow full table value of 1 1/4.
- <sup>k</sup> One-half value in Table 4, Chapter 11, increased to 1 1/4 by nearby outside door in vestibule.
- <sup>l</sup> Full value in Table 4, Chapter 11, to allow for frequent opening of outside door.
- <sup>m</sup> Two sides exposed, large doors but large volume. Use value 1 1/4 as given in Table 4, Chapter 11.
- <sup>n</sup> Two small unweatherstripped windows in protected location, but fireplace, indicate 1 change.
- <sup>o</sup> Heat losses from these rooms into garage are heat gains for garage.
- <sup>p</sup> Neglect heat loss to basement, as losses from boiler, piping, etc., will probably keep basement near, if not above, 70 F.
- <sup>q</sup> Upstairs hall ceiling figures with downstairs. Heat should be provided downstairs for both.
- <sup>r</sup> Linear feet of exposed edge.

FIG. 2. FLOOR PLANS OF RESIDENCE

## Heating Load

TABLE 9. SUMMARY OF HEAT LOSSES OF UNINSULATED RESIDENCE (Btu Per Hour)

| ROOM OR SPACE                 | WALLS              | CEILING AND ROOF   | FLOOR | GLASS AND DOOR | INFILTRATION | TOTALS  |
|-------------------------------|--------------------|--------------------|-------|----------------|--------------|---------|

| Design Totals                 | 33,850             | 21,720             | 2,900 | 17,410         | 24,620       | 100,500 |
| Operating Totals <sup>c</sup> | 33,850             | 21,720             | 2,900 | 17,410         | 12,310       | 88,190  |
| Percentages <sup>d</sup>      | 38.4               | 24.6               | 3.3   | 19.7           | 14.0         | 100.0   |

<sup>a</sup> Wall heat loss of 2110 Btuh minus wall heat gains of 1280, 700 and 1160 Btuh. Heat gains of 960 and 0 Btuh. <sup>c</sup> Based on 1/4 computed infiltration. <sup>d</sup> Based on operating totals.

are to have storm sash. The building is constructed as follows (heat transmission coefficients U are parentheses):

**Walls:** Brick veneer, building paper, wood sheathing, studding, metal lath and plaster (0.28). Walls of dormer over garage, same except wood siding in place of brick veneer (0.26).

**Attic Walls:** Brick veneer, building paper, wood sheathing on studding (0.42).

**Basement Walls:** 10 in. concrete (0.10).

**Roof:** Asphalt shingles on wood sheathing on rafters (0.53).

**Ceiling (Second floor):** Metal lath and plaster (0.69).

**Windows:** Double-hung wood windows averaging 70 percent glass (0.45; from Chapter 9, Table 20, Section D, the U value for wood windows with storm sash is 0.53 x application factor; by interpolation this factor is 0.85). Steel casement sash in garage and basement (1.13; from Chapter 9, Table 20, U is 1.13 for all glass and the application factor is 1.00). French doors in dining room 50 percent glass, no storm doors (0.85; from Chapter 9, Table 20, U is 1.13 for all glass; by interpolation the application factor is 0.75).

**Floor (Bedroom D):** Maple finish flooring on yellow pine sub-flooring; metal lath and plaster ceiling below (0.25).

**Floor (Basement and Garage):** 4 in. stone concrete on 3 in. cinder concrete (0.10).

**Solution:** The calculations for this problem are given in Table 8, and a summary

TABLE 10. SUMMARY OF HEAT LOSSES OF INSULATED RESIDENCE (Btu Per Hour)

| ROOM OR SPACE                 | WALLS             | CEILING AND ROOF  | FLOOR | GLASS AND DOOR | INFILTRATION | TOTALS |

<sup>a</sup> Wall heat loss of 980 Btuh minus wall heat gains of 590, 320 and 540 Btuh. <sup>b</sup> Heat gains 690 and 220 Btuh. <sup>c</sup> Based on 1/4 computed infiltration. <sup>d</sup> Based on operating totals.

of the results in Table 9. The values in column F of Table 8 were obtained by multiplying together the figures in columns C, D, and E. The heat losses are calculated to the nearest 10 Btu. See reference notes for Table 7 for further explanation of data.

Attention is called to the summary of heat losses (Table 9) for the uninsulated residence. As storm windows are used in this instance the glass and door transmission heat losses of 19.8 percent are relatively small. The infiltration losses of 14.0 percent are also comparatively small because the storm windows are equivalent to weatherstripping. In this problem, the wall, ceiling and floor transmission losses comprise 66.2 percent of the total.

**Example 7:** Calculate the heat loss of residence shown in Fig. 2 based on the same conditions as in *Example 6* but having construction improved or insulated to obtain coefficients as follows:

Walls, 0.13; Walls of Dormer over Garage, 0.12; Attic Walls, 0.28; Walls Adjoining Garage, 0.18; Basement Walls (Recreation Room), 0.10.

Roof, 0.53.

Ceiling (Second Floor), 0.15.

Windows (Same as in *Example 6*).

Floor (Bedroom D), 0.18.

**Solution:** The procedure for calculating the heat losses is similar to that for *Example 6*. A summary of the results is given in Table 10.

## COOLING LOAD

Cooling Load Calculations; Design Conditions; Instantaneous Heat Load; Solar Radiation; Periodic Heat Flow; Tables for Calculating Solar Heat Gain Through Walls, Roofs and Glass; Instantaneous Heat Gain vs. Cooling Loads; Load from Interior Partitions, Ceiling and Floors; Load from Outside Air, Ventilation and Infiltration; Effect of Outside Air on Load; Heat Sources Within Conditioned Space; Moisture Transfer Heat Load; Miscellaneous Heat Loads; Apparatus Dew Point and Required Air Quantity Through Conditioning Equipment; Minimum Entering Air Temperature; Example Cooling Load Calculation

THE variables affecting cooling-load calculations are numerous, often difficult to define precisely, and always intricately inter-related. Most of the components of the cooling load vary in magnitude over a wide range during a 24-hour period, and as the cyclic changes in load components are not usually in phase with each other, careful analysis is required to establish the resultant maximum cooling load for a building or zone. A zoned system must often handle peak loads in different zones at different hours.

Economic considerations must be of particular influence in the selection of equipment for cooling season operation in comfort air conditioning, and this fact, coupled with present inadequacies in available data and knowledge of the air-conditioning art, places a premium on the experienced judgment essential to successful design or practice. Variations in the weather, building occupancy, and other factors affecting load, necessitate carefully coordinated controls to regulate simultaneously the components and the equipment in order to maintain the desired room conditions.

The calculation procedures presented in this chapter deal with the various instantaneous rates of heat gain, both sensible and latent, in a conditioned space. There may be an appreciable difference between the *net instantaneous rate of heat gain* and the *total cooling load* at any instant. This difference is caused by the storage and subsequent release of heat by the structure and its contents. This thermal-storage effect may be quite important in determining an economical cooling equipment capacity. The lack of any adequate means of treating this storage quantitatively in its entirety for a complete structure, must be recognized in judging the procedures and data presented for calculating individual components of the net rate of instantaneous heat gain.

Solar heating calculations involve the same principles as cooling load calculations. Many of the data on solar radiation given in this chapter can be used in calculations for solar heating.

## COOLING LOAD CALCULATIONS

Summer cooling load calculations, whether for industrial or comfort applications, require consideration of the following factors:

A. *Design Conditions:* (1) indoor conditions; (2) outdoor conditions; (3) ventilation rate.

B. *Instantaneous Heat Load, Sensible and Latent:* (1) load from solar radiation,

sky radiation and from outdoor-indoor temperature differential for glass areas and exterior, walls and roofs, modified by periodic heat flow or lag factors depending on the type of structure; (2) load due to heat gain through interior partitions, ceilings and floors; (3) load due to ventilation, either natural or mechanical; (4) load due to heat sources within the conditioned space such as people, lights, power equipment, and appliances; (5) load due to moisture transfer through permeable building materials; (6) miscellaneous heat sources.

#### C. Determination of Air Quantity and Apparatus Dew Point.

These factors will be discussed in turn. The material presented leads to an illustrative procedure for a cooling-load calculation, and a numerical example is given to demonstrate the calculations involved.

### DESIGN CONDITIONS

#### Indoor Conditions

Indoor air conditions for human health and comfort have been and continue to be the subject of much discussion and research.

The effective temperature index, explained in Chapter 6 is probably the best available source of design criteria for comfort air conditioning systems for buildings or enclosures in which the air and inside surface

TABLE 1. DESIGN ROOM CONDITIONS USUALLY SPECIFIED FOR SUMMER AVERAGE PEAK LOAD IN COMFORT AIR CONDITIONING<sup>a</sup>

| TYPE OF INSTALLATION           | DRY-BULB TEMP | WET-BULB TEMP <sup>b</sup> | RELATIVE HUMIDITY PER CENT | GRAINS PER LB <sup>b</sup> | EFFECTIVE TEMP <sup>c</sup> |
|--------------------------------|---------------|----------------------------|----------------------------|----------------------------|-----------------------------|
| 1. Ample Capacity.....         | 78            | 65                         | 50                         | 72.7                       | 72.2                        |
| 2. Practical Application.....  | 80            | 67                         | 51                         | 78.5                       | 74.0                        |
| 3. Occupancy—15 to 40 min..... | 82            | 68                         | 49                         | 80.0                       | 75.3                        |

<sup>a</sup> Values in Table 1 are for peak load conditions. It is general practice to operate a system at approximately 76 F and 50 percent relative humidity at other than peak load.

<sup>b</sup> Psychrometric data for standard barometric pressure.

<sup>c</sup> Fig. 10, Chapter 6, air movement 15 to 25 fpm.

temperatures remain substantially equal; a condition that can safely be assumed for most ordinary comfort air conditioning installations. Other sources of design specifications are to be found in the requirements of codes and ordinances, and in the varied long-term experiences of manufacturers, contractors, and engineering specialists.

Past experience, cumulative over many years, indicates that indoor design conditions for which summer air-conditioning equipment is selected, should not exceed a temperature of 80 F or a relative humidity of 50 percent for the average job in the United States. If these conditions are exceeded, complaints of discomfort may be expected, especially with continuous occupancy. For very brief occupancy only, a slightly higher peak-load design temperature may be employed. In regard to the lower limit of humidity, complaints are not encountered for store installations operated down to 35 percent relative humidity or, for office jobs, somewhat lower. These observations apply to normal commercial practice in this country only; for extremes, such as tropical or very hot regions, it is regarded as more practicable to design for a peak-load outdoor-indoor temperature difference of about 15 to 20 F.

Table 1 offers typical design conditions for average requirements encountered. The values in line 1 would also apply in general for localities having a summer outdoor design temperature of 90 F or less; and the 15 to 40 min occupancy values, or even somewhat higher dry-bulb tem-

peratures, would indicate acceptable conditions for very hot localities. Table 1 is to be used with good judgment, for there is no universal rule which may be applied to indoor design conditions.

Guarantees of conditions to be maintained for summer operation are based upon a definite set of load conditions. At other than the guarantee load, the conditions produced by a system are determined by the balance of imposed load and equipment capacity, and by the method adopted for regulating the system operation. Complete specifications of indoor design conditions would include part-load and overload operation, particularly from the viewpoint of economy.

In the field of industrial air conditioning, indoor design conditions are established by the requirements of goods and processes, in addition to the comfort and efficiency of the workers. Many typical indoor design conditions for products in industrial air conditioning are given in Chapter 45.

The load calculations for either comfort or industrial air conditioning are usually made in accordance with a guarantee. In comfort applications, for example, this is frequently 80 F and 51 percent relative humidity or 78 F and 50 percent relative humidity. The system is normally operated at 75 or 76 F and approximately 50 percent relative humidity at all times as long as the equipment has capacity to maintain these conditions. During very hot weather, the room temperature will rise above the control point and the equipment will operate continuously. Normally, industrial jobs are operated at design conditions at all times if the optimum conditions are selected for the benefit of the product.

The indoor design conditions suggested have had reference to conditions to be maintained at the level of occupancy. For extremely high ceilings in public or industrial buildings, only the zone from 10 to 15 ft above the floor may be cooled to the full extent. The air temperature at the ceiling would be much higher, and this should be kept in mind when calculating the convective portion of the roof heat gain. A reduction of outdoor-to-indoor air temperature differential may be assumed in such instances; radiation from the inner roof surface is not diminished.

#### Outdoor Conditions

Summer climatic conditions and suggested design wet-bulb and dry-bulb temperatures are given in Table 2 for various locations in the United States. The highest temperature ever recorded is for the period of record shown. In some cases it should be noted that this period of record is comparatively short, and higher temperatures may be expected. In making comparisons for other localities than those shown in Table 2, due consideration must be given to elevation.

Column 6 of Table 2 indicates the design dry-bulb temperature suggested by the A.S.H.A.E. Technical Advisory Committee on Weather Design Conditions. This temperature is the maximum hourly outdoor temperature which has been equalled or exceeded 2½ percent of the total hours of June, July, August and September for the period of record, in this case the 5-year period 1935-1939, and should not be confused with the period of record given in Column 4 which applies only to highest temperature ever recorded. Since all of these data (Column 4) are based on airport records, they are not necessarily applicable to cities.

The data given in Columns 7 and 8 were obtained from local A.S.H.A.E. Chapter Secretaries, and represent the design temperatures in local use. Where such information was not available, it was taken from a publication of the A.R.I.<sup>1</sup> and from various other sources.

The Technical Advisory Committee on Weather Design Conditions has suggested that wet-bulb design temperature be taken as that wet-bulb temperature which has been equalled or exceeded in 5 percent of the hours during months of the period of record. While not available for the 1956 edition of *THE GUIDE*, due to the tremendous task of compiling these data, it is hoped that they will be available for some stations for future editions.

The wind velocity to be used in design should be that wind velocity which accompanies the design temperatures in each instance, but since these data are not available, the average summer wind velocities for the period of record were taken from U. S. Weather Bureau records revised to 1948. It is pointed out that this is not necessarily the velocity which coincides with the design temperatures, but it may serve as a guide to the designer.

Other weather data, such as *daily range of temperature*, are useful particularly when making cooling load calculations for an early morning peak on an east exposure. Daily range of temperature is the difference between the average of the daily maximum dry-bulb temperatures and the average of the daily minimum temperatures. This range is highest in semi-arid or desert regions and at high elevations, and lowest near the oceans or very large lakes. The daily range of temperature (Fahrenheit degrees) in July for the principal areas of the United States can be approximated from the following tabulation:

|                        |          |                                           |          |
|------------------------|----------|-------------------------------------------|----------|
| East Sea Shore.....    | 12 to 18 | East of Mississippi River.....            | 19 to 24 |
| Gulf Sea Shore.....    | 12 to 18 | Mississippi River to Rocky Mountains..... | 24 to 33 |
| Great Lakes Shore..... | 18 to 21 | Rocky Mountain Area.....                  | 33 to 42 |
| West Sea Shore.....    | 15 to 20 | West Coastal States.....                  | 20 to 36 |

### Ventilation Rate

The introduction of outside air is necessary for the ventilation of conditioned spaces. Chapter 6 suggests *minimum* outdoor-air requirements for representative applications; but it is to be emphasized that minimum requirements are not necessarily *adequate* requirements for all psychological attitudes and physiological responses. Where maximum economy in space and load are essential, as in submarines or other restricted spaces, as little as 1 cfm of outside air per person has been found to be sufficient provided that satisfactory ventilation is simultaneously obtained by an adequate decontamination of recirculated air.<sup>2</sup>

Local codes and ordinances frequently specify ventilation requirements for public places and for industrial installations. For operating rooms, minimum requirements for safe practice are given in a *National Board of Fire Underwriters' pamphlet*.<sup>3</sup> This pamphlet does not require 100 percent outside air in operating rooms, although 100 percent outside air is normally used and recommended.

Recommended and minimum ventilation rates for the most common applications are summarized in Table 3. For further general applications, a basis of estimating the cfm per person may be taken as:

|                            |                |            |
|----------------------------|----------------|------------|
| 1. People not smoking..... | 7½ Recommended | 5 Minimum  |
| 2. People smoking.....     | 40 Recommended | 25 Minimum |

The cooling load due to the introduction of outside air for ventilation is determined once the indoor and outdoor design conditions are fixed. Calculations will be discussed subsequently.

## Notes for Table 2

- \* Data compiled from U. S. Weather Bureau Data and various other sources.
- <sup>b</sup> Column 2. The station designation AP or CO indicates airport or city office station, respectively.
- <sup>c</sup> Column 3. The elevations marked c are ground elevations of the station. All other elevations given are the actual elevations of the thermometer bulb above mean sea level, corrected to 1948.
- <sup>d</sup> The periods of record indicated apply only to the highest temperature ever recorded shown in Column 5, and do not necessarily include all of the summer months of the first year indicated. The last year indicated includes July or August, except those marked d which terminate prior to July of that year.
- <sup>e</sup> It should be noted that Column 6 in the United States section of the table applies only to airports, as these data for city stations are not available at this time. The temperature shown is the maximum hourly outdoor temperature which has been equalled or exceeded 24 percent of the total hours of June, July, August and September for the 5-year period 1935-1939 inclusive. It is pointed out that in most cases the airport stations are outside of the city, and that these data would apply primarily to rural areas.
- <sup>f</sup> Columns 7 and 8 in the United States section and Columns 9 and 10 in the Canadian section of the table record wet and dry-bulb temperatures in use by A.S.H.A.E. members as reported by Chapter secretaries for various stations. Where such values were not available, the design temperatures published by API or obtained from various other sources have been inserted.
- <sup>g</sup> The average wind velocities in Column 9 in the United States section were furnished by the U. S. Weather Bureau, corrected to 1948. In general these velocities are averages for the months of June through September.
- <sup>h</sup> The bulletin published by the A.S.H.A.E. for the annual weather data of Detroit indicates 73 F as the design wet-bulb temperature which has been equalled or exceeded 5 percent of the hours for period 1935-39.
- <sup>i</sup> Blank spaces indicate data not available.
- <sup>j</sup> The data for Canada were compiled by D. W. Boyd and Morley Thomas from the records of the Meteorological Division, National Research Council of Canada.
- <sup>k</sup> The highest temperature ever recorded in the Canadian section of the table is for the 30 year period, 1921-1950, where available. In some cases the stations have been relocated and in a few instances some year, are missing.
- <sup>l</sup> In the Canadian section of the table, the summer design dry-bulb temperatures for the basis of 1, 2, 5 and 10 percent are the Fahrenheit temperature values at or above which these percentages of all the July hourly outdoor temperatures occur, for the years 1941-1950 inclusive.
- <sup>m</sup> Most of the wind speeds are based on the periods ending in 1947 which are somewhat shorter than the periods for the highest temperatures. The three months June, July and August were used.

## INSTANTANEOUS HEAT LOAD

The total cooling load is frequently divided for convenience into two components, *sensible heat* and *latent heat*. While this subdivision is not imperative, past practice has found it convenient.

A gain of *sensible heat* is considered to occur when there is a direct addi-

tion of heat to the enclosure by any one or all of the mechanisms of conduction, convection, and radiation. A gain of *latent heat* is considered to occur when there is an addition of water vapor to the air of the enclosure. For example, when the humidity in an enclosure is increased by water vapor emitted by human occupants, or by water vapor resulting from a process such as cooking, the heat required to vaporize the water does *not* come from the air. Maintenance of a constant humidity ratio in a sealed enclosure requires the condensation of water vapor in the cooling apparatus at a rate equal to its rate of addition within the enclosure. The rate of heat removal from this condensing vapor would be substantially equal to the product of the rate of condensation and the latent heat of condensation; this product, expressed in Btu per hour, would be called a *latent heat load*.

As a further example, the infiltration of outdoor air with a high dry-bulb temperature and a high humidity ratio, and the corresponding escape of room air at a lower dry-bulb temperature and a lower humidity ratio, would increase both the *sensible heat load* and the *latent heat load*.

### SOLAR RADIATION

#### Magnitude of Solar Radiation

If a plane surface were set perpendicular to the sun's rays (*i.e.*, for *normal incidence*) outside the earth's atmosphere, it would receive solar radiation of about 420 Btu per (hr) (sq ft). A similarly oriented surface, at the surface of the earth, would receive considerably less solar energy because a large part of the radiation is scattered in passing through the air, moisture, smoke, and dust which comprise the earth's atmosphere, and also, because some of the atmospheric constituents, notably water vapor, ozone, and carbon dioxide, absorb solar radiation. The intensity of solar radiation varies with wave length, reaching a peak at about 0.5 microns (a micron equals 1/1000 of a millimeter) and, for practical purposes, is confined to the radiation spectrum between 0.3 and 2.3 microns. The effects of scattering and absorption vary with the wave length, but to make an exact analysis of these phenomena is impracticable in air-conditioning estimates. The important principle to remember is that the total radiation  $I_t$ , received by a surface at the earth, is the sum of  $I_D$  and  $I_d$ , where

$I_D = K I_{Dn}$  = the *direct* or *beamed* solar radiation, Btu per (hour) (square foot of receiving surface).

$I_{Dn}$  = the direct solar radiation normal to the sun's rays, Btu per (hour) (square foot of receiving surface).

$I_d$  = the *sky* or *diffuse* solar radiation, Btu per (hour) (square foot of receiving surface). This comes principally from the atmosphere itself as a consequence of scattering. Vertical surfaces also receive solar radiation by reflection of direct and diffuse radiation from the ground and other objects. Such radiation is usually diffuse. The diffuse radiation strikes at all angles.

$I_t$  = total incident solar radiation, Btu per (hour) (square foot of receiving surface).

$K$  = cosine of the angle of incidence,  $\theta$ . For a vertical surface,  $\theta$  is defined in Fig. 1.

Standardized, practical-purpose values of the *direct* solar radiation  $I_{Dn}$  incident upon a plane *perpendicular* to the sun's rays at the earth's surface,

FIG. 1. DEFINITION OF SOLAR ANGLES

have been proposed by Moon.<sup>4</sup> Table 4 gives these values. They are representative of a *clear* summer day at sea-level elevation, and are nearly identical with values derived from suggested design sol-air temperatures for Lincoln, Nebraska.<sup>5</sup> Values typical of a humid industrial area derived from sol-air data for New York City<sup>6</sup> are also given in Table 4. Day-to-day changes in the amount of dust and water vapor in the atmosphere cause large differences in solar intensity values observed on cloudless days at a given locality. For example, it has been observed in Cleveland that

<sup>a</sup> Moon's<sup>1</sup> proposed standard for sea level, 20 mm precipitable water vapor, 300 dust particles per cu cm, 2.8 mm Hg partial pressure of ozone.

<sup>b</sup> For 40 deg north latitude on about August 1.

<sup>c</sup> Based on observations by ASHAE Laboratory at Cleveland on cloudless days during which the observed normal incidence values closely approximated the normal incidence values tabulated.

<sup>d</sup> Derived from recommended design sol-air temperatures<sup>4</sup> for New York City for a horizontal surface with absorptivity of 1.0.

values of the order of those given for industrial atmospheres are usually associated with dry-bulb and wet-bulb temperatures near the design values of 95 F and 75 F (67 F dew-point). On the other hand, values approaching or exceeding those for a clear atmosphere are often encountered during Cleveland summers, but with dew-point and maximum dry-bulb temperatures 10 to 15 deg lower. Considerable judgment, therefore, is required in selecting solar intensity values for design purposes.

Data regarding the irradiation of vertical and horizontal surfaces by diffuse or sky radiation are few. Suggested design values for a 40-deg latitude on August 1 (18 deg declination, north) are given in Table 4 for the two types of atmospheres. These are based upon observations made on cloudless days in Cleveland over a period of several summers. Since less extensive data were available for industrial atmospheres, there is more uncertainty regarding these values. In both instances, the values include an unknown amount of ground reflection, which may be expected to vary with location. It should be noted that clouds which do not obscure the sun tend to increase diffuse radiation values. Nearby buildings may reduce diffuse irradiation by partial shading.

#### Calculation Tables

The irradiation of a surface by the sun is the product of  $I_{Dn}$ , the direct normal radiation (see Table 4), and the cosine  $K$  of the incident angle,  $\theta$ . For horizontal surfaces, the cosine  $K$  equals the sine of the solar altitude.

For vertical walls,  $K$  is a function of the solar altitude  $\beta$  and the wall solar azimuth  $\gamma$ , thus

$$K = \cos \theta = \cos \beta \cos \gamma \quad (1)$$

These three angles are defined in Fig. 1. Values of  $K$  are given in Table 5 and values of  $\beta$  and  $\gamma$  are given in Table 6 for 18 deg north declination (August 1).

To compute  $K$  values for orientations other than those given in Table 5, third angle  $\phi$ , the solar azimuth, is required. In this discussion,  $\phi$  will be measured east from south in the morning, and west from south in the afternoon. Hence,  $\phi$  values are equal to 90 deg minus the  $\gamma$  values for an east or west facing wall, except when Table 6 shows the south walls to be in the shade. In this case  $\phi$  equals  $90 + \gamma$ , that is,  $\phi$  is greater than 90 deg.

The wall azimuth  $\psi$  is the angle, measured east from south to the perpendicular to the wall for walls which have an easterly component, and west from south for those having a westerly component. For example,  $\psi$  for a wall facing northeast is 135 deg.

The wall solar azimuth  $\gamma$  may be found according to the following schedule:

For walls facing east of south:

$$\gamma = \phi - \psi \text{ a.m.}$$

$$\gamma = \phi + \psi \text{ p.m.}$$

For walls facing west of south:

$$\gamma = \phi + \psi \text{ a.m.}$$

$$\gamma = \phi - \psi \text{ p.m.}$$

Treat negative values of  $\gamma$  as if they were positive. If  $\gamma$  is greater than 90 deg, the wall is in the shade.

Values of  $K$  for other seasons and latitudes may be found in the literature,<sup>7</sup> or may be computed from data given in *Hydrographic Office Bulletin* No. 214, Tables of Computed Altitude and Azimuth<sup>8</sup> and the Ephemeris of the Sun.<sup>9</sup> Table 7 shows the variation of solar declination during the months ordinarily requiring cooling.

**Example 1:** Find the solar azimuth  $\phi$  at 6:30 p.m. at 40 deg north latitude on August 1st.

**Solution:** From Table 6 in the column of  $\gamma$  for a wall facing west  $\phi$  for 6:00 p.m. is 90 + 14 = 104 deg, and at 7:00 p.m. is 90 + 24 = 114 deg. By interpolation,  $\phi$  for 6:30 p.m. is 109 deg west of south (at 5:30 a.m.  $\phi$  would be 109 deg east of south.)

**Example 2:** Find  $K$  for a wall facing 18 deg east of south at 10:00 a.m. on August 1 at 50 deg north latitude.

**Solution:** The wall azimuth is 18 deg. The solar azimuth is 48 deg east (Table 6). The wall solar azimuth is 48 - 18 or 30 deg. From Table 6,  $\beta$  is 50 deg. Then

$$K = \cos \beta \cos \gamma = \cos 50 \times \cos 30 = 0.643 \times 0.866 = 0.557.$$

TABLE 7. APPROXIMATE SOLAR DECLINATIONS IN DEGREES

| DATE     | DECLINATION | DATE    | DECLINATION | DATE     | DECLINATION |
|----------|-------------|---------|-------------|----------|-------------|
| April 1  | 4.5         | June 1  | 22.0        | Aug. 1   | 18.0        |
| April 15 | 10.0        | June 15 | 23.5        | Aug. 15  | 14.0        |
| May 1    | 15.0        | July 1  | 23.0        | Sept. 1  | 8.5         |
| May 15   | 19.0        | July 15 | 21.5        | Sept. 15 | 3.0         |

**Example 3:** Find  $K$  for the wall in *Example 2* at 3:00 p.m.

**Solution:** The solar azimuth is 65 deg west. The wall solar azimuth is therefore 65 + 18 = 83 deg. The angle  $\beta$  is 42 deg.

$$K = \cos 42 \times \cos 83 = 0.743 \times 0.122 = 0.091.$$

**Example 4:** Find the total solar irradiation for the wall for the conditions of *Example 2*.

**Solution:** Use clear atmosphere solar intensities. At 50 deg altitude, the direct normal radiation is 273 Btu per (hr) (sq ft). Then,

$$I_D = K \times I_{Dn} = 0.557 \times 273 = 152.0 \text{ Btu per (hr) (sq ft).}$$

By linear interpolation, the diffuse irradiation is

$$I_d = 25 + \frac{1}{3} (33 - 25) = 26.6 \text{ Btu per (hr) (sq ft).}$$

The total solar irradiation is

$$I_t = 152.0 + 26.6 = 178.6 \text{ Btu per (hr) (sq ft).}$$

### PERIODIC HEAT FLOW THROUGH WALLS AND ROOFS

The calculation of heat flow, through a structural section of a building exposed to the weather, requires consideration of the diurnal cycles of solar irradiation and air temperature. These cycles and other factors lead to a periodic variation in the instantaneous rate of heat flow into the weather surface, and a related periodic variation in the rate of heat flow into the air conditioned space. Because of heat capacity and other factors, these heat flow cycles are, in general, out of time phase and unequal in amplitude.

In order to calculate the rate of heat entry into the weather surface of a building, it is necessary to know:

1. The intensity of direct solar radiation striking the surface.
2. The absorptivity (or reflectivity) of the surface for direct solar radiation.
3. The intensity of diffuse or sky solar radiation striking the surface.
4. The absorptivity (or reflectivity) of the surface for diffuse or sky solar radiation.
5. The rate at which the surface emits radiation to the sky and other surroundings.
6. The rate at which the surface absorbs the low temperature radiation emitted by the sky and other surroundings by virtue of their temperatures and radiating characteristics.
7. The temperature of the surrounding air.
8. The temperature of the outer building surface.
9. The unit convective conductance for heat transfer between the air and the building surface.

### The Sol-Air Temperature

The complex interrelationship of the above factors can be considerably simplified through the use of the sol-air temperature concept. The sol-air temperature  $t_a$  is the temperature of the outdoor air, which, in the absence of all radiation exchanges, would give the same rate of heat entry into the surface as would exist with the actual combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with the outdoor air.

The sol-air temperature data<sup>5, 6, 10</sup> as developed by Mackey and Wright for an industrial atmosphere were used as a basis for preparing Table 8 showing summer design sol-air temperatures. Sol-air temperatures may also be estimated from experimental observation of surface temperatures

TABLE 8. SUMMER DESIGN SOL-AIR TEMPERATURES USED FOR TABLES 9 AND 10

<sup>a</sup>  $\alpha$  = surface absorptivity, dimensionless: roof = 0.9; dark walls = 0.9, and light walls = 0.5.  $f_{co}$  = unit convective conductance = 4.0 Btu per (hr) (F deg).

<sup>b</sup> values in this column are magnitudes of  $t_o$ , the outdoor air temperature.

of walls and roofs which appear in the literature.<sup>11, 12</sup> Both analytical and experimental studies have been made on the problem<sup>10</sup> of heat flow through walls and roofs. Those concerned with a further study of the details of cooling-load estimates in particular relation to periodic heat flow will find much of value and interest in the reports of experimental studies of these problems.<sup>10, 11, 12, 13, 14, 15</sup> The reader may also refer to the Cooling Load chapter of THE GUIDE 1952 for the theory of heat flow through walls and roofs.

#### PRACTICAL TABLES FOR CALCULATING SOLAR HEAT GAIN THROUGH WALLS AND ROOFS

The analytical<sup>10</sup> method reported by Mackey and Wright was used by Stewart<sup>16</sup> to obtain temperature differentials based on Table 8 and shown in Tables 9 and 10. These analytical procedures, as well as those using Tables 9 and 10, presented here, yield generally higher rates of heat gain

than reported for Pittsburgh in early A.S.H.A.E. experimental studies. Current authoritative opinion indicates a preference for analytical calculations. Thermal and physical properties of materials used in these tables are given in a paper.<sup>16</sup> The rate of heat flow is obtained by multiplying the overall heat transmission coefficient of the structure by the equivalent temperature differential obtained from the tables.

Tables 9 and 10 were developed by using an outside surface conductance of 4.0 and an inside film conductance of 1.65 Btu (hr) (sq ft) (F deg). A reduction was made in the temperature differentials for roofs amounting to some 20 percent of solar radiation as explained by Stewart.<sup>16</sup> This was to compensate for several factors, one of which is the radiant heat lost to the sky which is not included in the Mackey and Wright method. Recent experimental work by Parmelee<sup>17</sup> and previous work by Brunt<sup>18</sup> gives data showing the magnitude of this radiant heat loss from a roof or wall to the sky. Temperature differentials for roofs probably would be reduced below those shown in Table 9 whenever the radiant heat lost to the sky is included in calculation of sol-air temperature. The temperature differentials for roofs were based on an inside surface conductance of 1.65 because the charts prepared by Mackey and Wright<sup>10</sup> used this value, and it was not considered practicable to repeat their work using a different film coefficient. An examination of the values given in their paper indicates that the temperature differential would be changed very little even if a value 1.20 were used instead of 1.65. But to obtain the heat flow rates through roofs, more accurate values will be obtained if the overall heat transmission coefficient is calculated using 1.2 as the inside film conductance for summer.

The roof coefficients of transmission for summer shown in Table 11 are based on surface conductances  $f_{ro}$  of 4.0 for an outside roof surface and 1.20 for an inside ceiling surface. The outside conductance 4.0 is used for summer because it corresponds to a wind velocity of approximately 7.5 mph averaged for rough and smooth surfaces, and is more representative of summer wind velocities. Also, the lower wind velocity should be used in order to be on the safe side in determining the sol-air temperature. The inside conductance 1.20 is used because the convective portion of the film conductance for downward heat flow from a horizontal surface is appreciably less than the winter conductance for heat flowing upward.

Since there is little difference in wall transmission coefficients for summer, based on the conductances of 4.0 and 1.65, and the winter coefficients, based on 6.0 and 1.65, it is recommended that the overall coefficient  $U$ , for walls, be taken directly from the tables in Chapter 9 in which they are based on an outside film conductance of 6.0, corresponding to a 15 mph wind velocity.

#### Advantages of Equivalent Temperature Differential Method

The advantages of the equivalent temperature differential method of determining the total heat transmission are given in following paragraphs, and are apparent from Examples 5 to 7.

1. The total sensible heat flow is obtained by multiplying the overall heat transmission coefficient,  $U$ , and the equivalent temperature differential indicated in Tables 9 and 10.
2. The temperature differentials listed for a few representative types of construction may be used on all classes of walls and roofs, even though the overall heat transmission coefficient is different, provided the structure has thermal and physical properties similar to one of those listed in Tables 9 and 10.
3. Adjustments can be made, according to instructions given in the footnotes, for room and outdoor conditions different from those on which the tables are based.

TABLE 9. TOTAL EQUIVALENT TEMPERATURE DIFFERENTIALS FOR CALCULATING HEAT GAIN THROUGH SUNLIT AND SHADED ROOFS

| DESCRIPTION OF ROOF CONSTRUCTION*                                                                                              | SUN TIME |        |          |          |          |          |          |          |          |  |

\* Includes  $\frac{1}{2}$  in. felt roofing with or without slag. May also be used for shingle roof. <sup>b</sup>Nominal thickness of the wood.

## NOTES FOR TABLE 9

Explanation:  $\left\{ \begin{array}{l} \text{Total heat transmission from solar} \\ \text{radiation and temperature difference} \\ \text{between outside and room air. Btu} \\ \text{per (hr) (sq ft) of roof area} \end{array} \right\} = \left\{ \begin{array}{l} \text{Equivalent temperature} \\ \text{differential from above} \\ \text{table} \end{array} \right\} \times \left\{ \begin{array}{l} \text{Heat transmission} \\ \text{coefficient for sum-} \\ \text{mer Btu per (hr)} \\ \text{(sq ft) (F deg)} \end{array} \right\}$

1. Source. Calculated by Mackey and Wright method (see reference list) and adjusted after studying ASHRAE original test data. Estimated for about August 1 in 40 deg north latitude. (For sol-air temperatures used in calculations see Table 8.) For typical design day where the maximum outdoor temperature is 95 F and minimum temperature at night is approximately 75 F (daily range of temperature, 20 F) mean 24 hr temperature 84 F for a room temperature of 80 F. All roofs have been assumed a dark color which absorbs 90 percent of solar radiation, and reflects only 10 percent.

2. Application. These values may be used for all normal air conditioning estimates; usually without correction, in latitude 0 deg to 50 deg north or south when the load is calculated for the hottest weather. Note 5 explains how to adjust the temperature differential for other room and outdoor temperatures.

3. Peaked Roofs. If the roof is peaked and the heat gain is primarily due to solar radiation, use for the area of the roof, the area projected on a horizontal plane.

4. Attics. If the ceiling is insulated and if a fan is used in the attic for positive ventilation, the total temperature differential for a roof exposed to the sun may be decreased 25 percent.

5. Corrections. For temperature difference when outdoor maximum design temperature minus room is different from 15 deg. If the outdoor design temperature minus room temperature is different from the base of 15 deg, correct as follows: When the difference is greater (or less) than 15 deg add the excess to (or subtract the deficiency from) the above differentials.

For outdoor daily range of temperature other than 20 deg. If the daily range of temperature is less than 20 deg, add 1 deg for every 2 deg lower daily range; if the daily range is greater than 20 deg, subtract 1 deg for every 2 deg higher daily range. For example, the daily range in Miami, Florida is 12 deg or 8 deg less than 20 deg, therefore, the correction is + 4 deg at all hours of the day.

Light Colors. Credit should not be taken for light colored roofs except where the permanence of the light color is established by experience, as in rural areas or where there is little smoke. When the exterior surface of roof exposed to the sun is a light color, such as white or aluminum (which absorb approximately 50 percent and reflect 50 percent of the solar radiation) add to the temperature differential for roof in shade 55 percent of the difference between the roof in sun and roof in shade. When the roof exposed to the sun is a medium color such as light grey, blue or green, or bright red, add 30 percent of this difference.

For solar transmission in latitudes other than 40 deg north, and in other months. The table values of temperature differentials will be approximately correct for a roof in the following months:

| NORTH LATITUDE |                                      | SOUTH LATITUDE |                                    |
|----------------|--------------------------------------|----------------|------------------------------------|
| Latitude (deg) | Months                               | Latitude (deg) | Months                             |
| 0              | All Months                           | 0              | All Months                         |
| 10             | All Months                           | 10             | All Months                         |
| 20             | All Months except Nov, Dec, Jan      | 20             | All Months except May, June, July  |
| 30             | Mar, Apr, May, June, July, Aug, Sept | 30             | Sept, Oct, Nov, Dec, Jan, Feb, Mar |
| 40             | April, May, June, July, Aug          | 40             | Oct, Nov, Dec, Jan, Feb            |
| 50             | May, June, July                      | 50             | Nov, Dec, Jan                      |

For other months, the total temperature differential ( $t_x$ ) may be approximated by the use of the following formula:

$$t_x = t_s + \frac{I_x}{I_y} (t_v - t_s)$$

where  $t_s$  = temperature differential for the same roof in shade for desired time of day; obtained from Table 9.

$I_y$  = maximum solar transmission through glass, Btu per (hr) (sq ft) for flat skylight in Aug., 40 deg north latitude (Note: this is maximum value irrespective of time).

$I_x$  = same as  $I_y$  except use the maximum value for flat skylight, for month, and latitude desired for  $t_x$ .

$t_v$  = temperature differential for particular roof exposed to sun for the desired time of day from Table 9.

(Note that this makes adjustment only for solar radiation and that there may be additional correction for outdoor temperature.)

## Examples of Use of Equivalent Temperature Tables

Example 5: Given: A roof is constructed of 6 in. of stone concrete with 2 in. of insulating board and tar felt roofing  $\frac{1}{2}$  in. thick, and is exposed to the sun. The location is the central part of the United States. Find the rate of heat flow into building at 2:00 p.m. during July for an outdoor design temperature 95 F, and an inside temperature 80 F.

Solution: From Table 9 in 2 p.m. column for 6 in. concrete plus 2 in. insulation, find the total equivalent temperature differential 34 deg. The overall heat transmission coefficient for summer is taken from Table 11 and is found to be 0.13. The heat flow rate equals  $34 \times 0.13 = 4.42$  Btu per (hr) (sq ft).

Example 6: For the conditions of Example 5, find the rate of heat flow into building at 2:00 p.m. during July for design temperatures of 105 F (outdoor) and 78 F (indoor). Daily range of temperature 30 deg, i.e., outdoor temperature minimum of 75 F which occurs at 4:00 or 5:00 a.m.; this being 30 deg less than the maximum.

Solution: Make correction in equivalent temperature differential in accordance with Note 5 in Table 9 as follows:

The correction for 27 deg design temperature difference is  $(27 - 15) = + 12$ .

The correction for 30 deg daily range is  $\left( -\frac{30 - 20}{2} \right) = - 5$ .

Net total correction is  $+ 12 - 5 = + 7$ .

The heat flow rate at 2:00 p.m. is  $(34 + 7) \times 0.13 = 5.32$  Btu per (hr) (sq ft).

## NOTES FOR TABLE 10

Explanation:  $\left( \frac{\text{Total heat transmission from solar radiation and temperature difference between outside and room air, Btu per (hr) (sq ft wall area)}}{\text{Equivalent temperature differential from above table}} \right) \times \left( \frac{\text{Heat transmission coefficient for wall, Btu per (hr) (sq ft) (F deg)}}{\text{table}} \right)$

## NOTES:

1. **SOURCE.** Same as Table 9. A north wall has been assumed to be a wall in the shade; this is practically true. Dark colors on exterior surface of walls have been assumed to absorb 90 percent of solar radiation and reflect 10 percent; white colors absorb 50 percent and reflect 50 percent. This includes some allowance for dust and dirt since clean, fresh white paint normally absorbs only 40 percent of solar radiation.

2. **APPLICATION.** These values may be used for all normal air conditioning estimates, usually without corrections, when the load is calculated for the hottest weather. Correction for latitude (Note 3) is necessary only where extreme accuracy is required. There may be jobs where the indoor room temperature is considerably above or below 80 F, or where the outdoor design temperature is considerably above 95 F, in which case it may be desirable to make correction to the temperature differentials shown. The solar intensity on all walls other than east and west varies considerably with time of year.

3. **CORRECTIONS.** Outdoor minus room temperature. If the outdoor maximum design temperature minus room temperature is different from the base of 15 deg, correct as follows: When the difference is greater (or less) than 15 deg, add the excess to (or subtract the deficiency from) the above differentials.

Outdoor daily range temperature. If the daily range of temperature is less than 20 deg, add 1 deg to every 2 deg lower daily range; if the daily range is greater than 20 deg, subtract 1 deg for every 2 deg higher daily range. For example, the daily range in Miami, Florida is 12 deg, or 8 deg less than 20 deg; therefore, the correction is +4 deg.

Color of exterior surface of wall. Use temperature differentials for light walls only where the permanence of the light wall is established by experience. For cream colors use the values for light walls. For medium colors interpolate half way between the dark and light values. Medium colors are medium blue, medium green, bright red, light brown, unpainted wood, natural color concrete, etc. Dark blue, red, brown, green, etc., are considered dark colors.

For latitudes other than 40 deg north, and in other months. These table values will be approximately correct for the east or west wall in any latitude (0 deg to 50 deg North or South) during the hottest weather. In the lower latitudes when the maximum solar altitude is approximately 80 deg to 90 deg (the maximum occurs at noon) the temperature differential for either a south or north wall will be approximately the same as a north, or shade wall. The temperature differential ( $t_x$ ) for any wall facing, and for any latitude for any month may be approximated as follows:

$$t_x = t_z + \frac{I_1}{I_2} \times (t_w - t_z)$$

where  $t_z$  = temperature differential for the same wall in shade for desired time of day; obtained from Table 10.

$I_1$  = maximum solar radiation intensity transmitted through glass, Btu per (hr) (sq ft) for particular wall facing, in July, 40 deg north latitude (note: this is maximum value irrespective of time).

$I_2$  = same as  $I_1$  except use the maximum value for wall facing, for month, and latitude desired for  $t_x$ .

$t_w$  = temperature differential for particular wall facing, for the desired time of day from above table. (Note that this makes adjustment only for solar radiation, and that there may be additional correction for outdoor temperature.)

4. **FOR INSULATED WALLS** use same temperature differentials as used for uninsulated walls.

<sup>a</sup> The summer coefficients are considered temporary, and have been calculated with an outdoor wind velocity of 8 mph. For summer an inside surface conductance of 1.2 has been used instead of the regular 1.65 value. In all of these roofs a 4 ply felt roof has been assumed 1/2 in. thick, thermal conductivity = 1.33. Pitch and slag have been assumed as an additional thickness of 1/2 in. which has been assigned thermal conductivity = 1.0. In both cases thermal conductivity refers to one inch thickness.

<sup>b</sup> 87 1/2 percent gypsum, 12 1/2 percent wood fiber. Thickness indicated includes 1/2 in. gypsum board. This is a poured roof.

<sup>c</sup> Nominal thickness of wood is specified, but actual thickness was used in calculations.

<sup>d</sup> If corkboard insulation is used, the coefficient  $U$  may be decreased 10 percent.

A method of determining heat flow rates, when structure is not given in Tables 9 or 10, is illustrated in Example 7.

Example 7: A 4 in. stone concrete roof covered with an average depth of 4 in. cinder concrete ( $k = 4.9$ ) on which is placed a 1/2 in. thick felt roof with 1/2 in. pitch and slag surface, is exposed to the sun. The location is the central part of the United States.

Design temperatures are: outdoor 95 F; daily range 20 deg; indoor temperature 80 F. Find the heat flow rate at 2:00 p.m. for a day in July.

Solution: For the purpose of selecting the equivalent temperature differential, this construction is assumed to be equal approximately to an uninsulated 6 in. concrete roof, for which the equivalent temperature is found to be 38 deg in the 2:00 p.m. column of Table 9. Calculate the overall heat transmission coefficient  $U$  (see Equation 3 of Chapter 9) of the roof as follows:

$$U = \frac{1}{\frac{1}{1.2} + \frac{4}{12} + \frac{4}{4.9} + \frac{0.375}{1.33} + \frac{0.50}{1.00} + \frac{1}{4.0}} = 0.33.$$

The heat flow rate is then  $38 \times 0.33$  equals 12.5 Btu per (hr) (sq ft).

FIG. 2. INSTANTANEOUS HEAT-BALANCE CONDITIONS ON A GLASS SECTION

## TABLES FOR CALCULATING SOLAR HEAT GAIN THROUGH GLASS AREAS

### Basic Principles

In order to set forth the principles involved in calculating heat flow through glass areas, the general instantaneous heat-balance relation will be presented. It will be shown schematically in Fig. 2. The net heat gain for the indoor space is the result of several contributing phenomena. Some observations concerning the behavior of glass with respect to radiant energy will lead to a better understanding of the heat-balance relation. To various degrees glass transmits radiation having wave lengths between 0.29 and 4.75 microns. Of the portion not transmitted, part is absorbed, and the remainder is reflected. Outside these limits glass is opaque, absorbing approximately 94 percent and reflecting 6 percent. Only a negligible amount of radiant energy from a surface at 450 F has a wave length shorter than 4.75 microns. It is therefore convenient to treat all forms of solar radiant energy separately from radiant energy from other

sources, so long as the temperature of these sources is not over approximately 450 F.

The complete heat-balance for a glass section can be expressed for a unit time interval as follows:

$$\left[ \begin{array}{c} \text{Total heat flow,} \\ \text{through glass section} \end{array} \right] = \left[ \begin{array}{c} \text{Transmitted,} \\ \text{solar radiation} \end{array} \right] \pm \left[ \begin{array}{c} \text{Heat flow by convective} \\ \text{and radiative exchanges at} \\ \text{the indoor surface} \end{array} \right] \quad (2a)$$

The second term of the right side of Equation 2a can also be expressed by a heat balance equation as follows:

$$\left[ \begin{array}{c} \text{Heat flow by convective} \\ \text{and radiative exchanges} \\ \text{at the indoor surface} \end{array} \right] = \left[ \begin{array}{c} \text{Absorbed} \\ \text{solar} \\ \text{radiation} \end{array} \right] \pm \left[ \begin{array}{c} \text{Radiative exchanges be-} \\ \text{tween outer surface of glass} \\ \text{and outdoor surroundings} \end{array} \right] \\ \pm \left[ \begin{array}{c} \text{Convective exchanges} \\ \text{between outer surface of} \\ \text{glass and outdoor air} \end{array} \right] \pm \left[ \begin{array}{c} \text{Heat storage} \\ \text{within the} \\ \text{glass section} \end{array} \right] \quad (2b)$$

Equations 2a and 2b can be combined and expressed in symbolic terms by Equation 2c. Tabular values of the two bracketed terms of Equation 2a are presented later in this section for various types of glass for specific design conditions.

$$(q/A) = [\tau_D I_D + \tau_d I_d] + [\alpha_D I_D + \alpha_d I_d + \epsilon_{go} R_{go} - \epsilon_{ro} R_{ro} - f_{co} (t_{go} - t_o) - S], \quad \text{Btu per (hr) (sq ft)} \quad (2c)$$

where

- $(q/A)$  = instantaneous rate of heat flow, Btu per (hour)(square foot).  
 $\tau_D, \tau_d$  = transmittance of glass for direct and diffuse solar radiation, respectively.  
 $I_D, I_d$  = incident direct and diffuse solar radiation, respectively, Btu per (hour)(square foot).  
 $\alpha_D, \alpha_d$  = absorptance of glass for direct and diffuse solar radiation, respectively.  
 $\epsilon_{go}$  = emissivity of glass at temperature  $t_{go}$ .  
 $R_{go}$  = low temperature radiant energy falling on glass from outdoor surroundings, Btu per (hour)(square foot).  
 $R_{ro}$  = low temperature radiant energy emitted by a surface with emissivity equal to 1.0 at temperature  $t_{ro}$ .  
 $f_{co}$  = outdoor convective conductance, Btu per (hour)(square foot)(Fahrenheit degree).  
 $t_{go}$  = temperature of outdoor surface of glass, Fahrenheit degrees.  
 $t_o$  = temperature of outdoor air, Fahrenheit degrees.  
 $S$  = rate at which glass stores energy, Btu per (hour)(square foot).

Transmissivity and absorptivity vary with both wave length of the incident radiation and incident angle. Values of  $\tau$  and  $\alpha$  for a single sheet of the average ordinary drawn window glass are given in Table 12 for a standard distribution of solar energy.<sup>4</sup> Values for two air-spaced sheets are also given. Normal incidence transmittance values for some commonly-used types and combinations are given in Table 15. Some variation in these values can be expected in practice due to variations in manufacture and in solar energy distribution. However, a change in transmissivity causes an approximately equal and opposite change in absorptivity. Hence, the total heat flow is not greatly altered. Transmittance data for other types of glass and various patterns of 8-in. glass block are given in A.S.H.A.E. research papers.<sup>19, 20, 21, 22, 23</sup>

As stated earlier in this chapter, present data as to the value of  $R_{ro}$  are inadequate, so for the present it is suggested that  $f_{co}$  be increased to include radiation, and the term  $\epsilon_{go} R_{go} - \epsilon_{ro} R_{ro}$  be disregarded. It is not

practicable to give values of  $S$  in this chapter. However, for ordinary glass, the value of  $S$  is small.

Fig. 3 is a graphical solution, for single glass, of Equation 2b. Only absorbed solar radiation is considered, although low temperature radiation exchange and heat storage can be added algebraically to  $\alpha_d I_d$ , if such data are available. The small thermal resistance of the glass has been neglected. The heat flow rates are for a 75 F indoor temperature, an indoor surface conductance for convection  $f_{ci}$  as given by Equation 3, and an equivalent surface conductance for radiation  $f_{ri}$  as given by Equation 4. Indoor surfaces seen by the glass are assumed to radiate as a black body at room air temperature.

$$f_{ci} = 0.27 (t_{gi} - t_i)^{0.25} \quad (3)$$

$$f_{ri} = 0.162 \left[ \left( \frac{t_{gi} + 460}{100} \right)^4 - \left( \frac{t_i + 460}{100} \right)^4 \right] / (t_{gi} - t_i) \quad (4)$$

where

- $t_{gi}$  = temperature of indoor surface of glass, Fahrenheit.  
 $t_i$  = temperature of indoor air, Fahrenheit.

A more complete treatment of the problem is given in an A.S.H.A.E. research paper.<sup>22</sup>

**Example 8:** Find the total heat gain at 10 a.m. sun time for a single unshaded sheet of common window glass in a wall facing 18 deg east of south on August 1 at 50 deg north latitude. The indoor temperature is 75 F, the outdoor temperature is 83 F. Use clear atmosphere radiation values and  $f_{co} = 4.0$ .

**Solution:** From Example 2,  $K$  is 0.557; hence, the angle of incidence,  $\theta$ , is 56 deg 9 min. From Example 4,  $I_D = 152.0$ ,  $I_d = 26.6$ . By interpolation in Table 12,  $\tau_D$  is found to be 0.81,  $\alpha_D$  is 0.06;  $\tau_d$  and  $\alpha_d$  are 0.79 and 0.06, respectively.

The heat gain due to transmitted solar radiation is

$$(q/A)_\tau = 152.0 \times 0.81 + 26.6 \times 0.79 = 144.1 \text{ Btu per (hr)(sq ft).}$$

The heat gain by convection and radiation from the indoor surface is found from Fig. 3:

$$t_o + \frac{\alpha_d I_d}{f_{co}} = 83 + \frac{0.06 (152.0 + 26.6)}{4} = 85.7 \text{ F}$$

from which

$$(q/A)_{cr} = 11.5 \text{ Btu per (hr)(sq ft).}$$

From Equation 2a the total heat flow is

$$(q/A) = 144.1 + 11.5 = 155.6 \text{ Btu per (hr)(sq ft).}$$

### Design Tables for Flat Glass

Tables 13 and 14 give design values of instantaneous rates of heat gain for single unshaded common window glass for a solar declination of 18 deg. This corresponds to a nominal August 1 day. The tables are based upon the solar intensity values for a clear atmosphere as given in Table 4. Table 13 represents the first bracketed term of Equation 2a; therefore, the values are dependent only upon values of  $I$  and  $\tau$ . Table 14 is the second term of Equation 2a, and is based upon a 80 F indoor temperature and a

dry-bulb temperature cycle, with a 95 F maximum as tabulated. *The total heat gain is the sum of the Table 13 and Table 14 values.* In preparing Table 14, convection and radiation heat exchange were combined, and a combined surface conductance of 4.0 used. Corrections to be applied for other design temperatures are given in Table 23 in a later section, Effect of Deviation from Design Conditions.

Tables 13 and 14 may be used for other types of glass with good accuracy, by using the factors given in Table 15. Table 13 values are multiplied by the appropriate factor given in Table 15 to obtain heat gain due to transmitted solar radiation. For glasses having a transmittance for normally incident radiation differing from the table values, factors may be found by linear interpolation. To obtain instantaneous rates of heat gain by convection and radiation, two steps are required. First, Table 14 values are multiplied by the appropriate coefficient of  $X$  listed in Table 15. Second, Table 16 values are multiplied by the appropriate coefficient of  $Y$  listed

\* Values of Y for 8 and 9 p.m. are zero.

<sup>b</sup> For N, NE, E, W, NW and horizontal use 40 deg North Latitude values.

in Table 15, and added to the first value. All convection and radiation gain values for double glass were computed for a  $\frac{1}{4}$ -in. air space. No great error is involved in cooling load estimates if these are used for double glass with other air spaces.

*Example 9:* Find the total instantaneous heat gain through a single sheet of regular plate glass in a southwest wall at 2 p.m. sun time and 40 deg north latitude on August 1. The maximum dry-bulb temperature for design is 98 F; the atmosphere is clear. The indoor temperature is 80 F.

*Solution:* From Table 13 the heat gain due to transmitted radiation is 148 Btu per (hr) (sq ft) for common window glass; from Table 15, the factor for regular plate glass is 0.87. The coefficient of X in Table 15 is 1.0, while X is found from Table 14 for common window glass for the same hour, orientation and latitude. The coefficient of Y in Table 15 is 0.25, while the Y value is found from Table 16 for a southwest wall at 2:00 p.m. and 40 deg north latitude. The correction for design dry-bulb temperature is found from Table 23 to be 1.0 Btu per (hr) (sq ft) per degree difference from 95 F design temperature. The total instantaneous heat gain is, from Equation 2a,

$$q = 0.87 \times 148 + 1.0 \times 19 + 0.25 \times 27 + 1.0 (98 - 95) \\ = 157.5 \text{ Btu per (hr) (sq ft).}$$

#### Design Tables for Rolled Figured Glass

Tables 17 and 18 give design values of instantaneous rates of heat gain for a number of common patterns of single vertical sheets of rolled figured glass. The tables are for a solar declination of 18 deg, which corresponds to a nominal August 1 day, and are based upon the solar intensity values for a clear atmosphere as given in Table 4. The values are given in terms of corrections to apply to Tables 13 and 14. The heat gain due to transmitted solar radiation is found by multiplying the Table 13 values by the approximate percentages given in Table 18. To obtain instantaneous rates of heat gain by convection and radiation, Table 16 values are multiplied by the appropriate value of Y from Table 17 and then added to the corresponding Table 14 values. The total instantaneous heat gain is the sum of the gain due to transmitted solar radiation and the gain by convection and radiation.

The values given in Tables 17 and 18 are based upon an A.S.H.A.E. research paper<sup>23</sup> to which the reader is directed for additional data. The values in Tables 17 and 18 may be used with fair precision for other patterns of similar transmittance and surface characteristics. For example, the data for hammered glass may be used for glass having shallow, closely-spaced ribs or for glass having small, closely-spaced circular indentations. Because some patterns have distinct orientation properties, no attempt has been made to give values for non-vertical glass.

#### Design Tables for Glass Block Walls

Tables 20 and 21 give design values of instantaneous rates of heat gain for sunlit walls of Type I pattern 8-in. hollow glass block for a solar declination of 18 deg (see Table 19 for description of block patterns). These tables are based upon the solar intensity values for a clear atmosphere as given in Table 4. For solar energy transmittance data the reader is referred to reference 21. Table 20 presents values of transmitted direct and diffuse solar radiation, while Table 21 gives values of instantaneous rates of heat gain by convection and radiation from the wall. The latter values are for an indoor temperature of 80 F and a 95 F maximum dry-bulb temperature, as indicated in the table, and are based upon experimentally-

TABLE 17. APPLICATION FACTORS TO APPLY TO TABLES 14 AND 16 TO OBTAIN INSTANTANEOUS RATES OF HEAT GAIN FOR VERTICAL SINGLE SHEETS OF ROLLED FIGURED GLASS HAVING NORMAL INCIDENCE TRANSMITTANCES AND LISTED THICKNESSES  
(SMOOTH SIDE INDOORS, FIGURED SIDE OUTDOORS)  
(See Table 18 for Factors to Apply to Table 13 Values)

| GLASS PATTERN                              | NORMAL INCIDENCE TRANSMITTANCE | THICKNESS, INCHES | FACTOR TO APPLY TO TABLE 14 |
|--------------------------------------------|--------------------------------|-------------------|-----------------------------|
| Hammered                                   | 0.75                           | $\frac{1}{32}$    | $1.0(X)^a + 0.50(Y)^b$      |
| Hammered, etched both sides                | 0.67                           | $\frac{1}{32}$    | $1.0(X) + 0.65(Y)^c$        |
| Deep ribs on $\frac{1}{2}$ in. centers     | 0.77 approx.                   | $\frac{1}{32}$    | $1.0(X) + 0.50(Y)^d$        |
| Hammered heat absorbing                    | 0.21                           | $\frac{1}{4}$     | $1.0(X) + 1.15(Y)^e$        |
| Hammered heat absorbing, etched both sides | 0.14                           | $\frac{1}{4}$     | $1.0(X) + 1.40(Y)^e$        |

<sup>a</sup> X values are Table 14 values  
<sup>b</sup> Y values are Table 16 values  
<sup>c</sup> Use 0.40(Y) for east and west glass

<sup>d</sup> Use 0.50(Y) for east and west glass  
<sup>e</sup> Use 0.35(Y) for east and west glass  
<sup>f</sup> Use 0.95(Y) for south glass

TABLE 18. INSTANTANEOUS RATES OF HEAT GAIN DUE TO TRANSMITTED DIRECT AND DIFFUSE SOLAR RADIATION BY UNSHADED ROLLED FIGURED GLASS  
Multiply the Table 13 Values by These Percentage Factors  
For Clear Atmospheres and 18 Degrees Declination, North (August 1) For 30, 40, and 50 Degrees North Latitude  
Note: To obtain total instantaneous heat gain add adjusted Table 13 values to adjusted Table 14 values

<sup>a</sup> For types III, IV, IVA and V patterns and 30, 40 and 50 deg latitudes, multiply east wall values for 6 and 8 a.m. by 1.40, and west wall values for 5, 6 and 7 p.m. by 1.25.

<sup>b</sup> For N, NE, E, W and NW use 40 deg North Latitude values.

determined values of solar energy absorption and temperature difference between the two faces. Because the exact dependence of the latter on weather conditions has not been determined, the values of convection and radiation gain cannot be regarded as exact for the assumed design conditions. Indoor and outdoor convection and radiation heat transfer data are the same as those used for common window glass. Table 23 gives corrections to be applied for other design temperatures.

To obtain transmitted direct and diffuse solar radiation for other types of 8-in. block, the Table 20 values are multiplied by the approximate percentages given in Table 22. Note that corrections are the same for all latitudes, and that they vary only on the surfaces exposed to the direct sun. The convection and radiation gain values for all blocks are so nearly

TABLE 22. INSTANTANEOUS RATES OF HEAT GAIN DUE TO TRANSMITTED DIRECT AND DIFFUSE SOLAR RADIATION BY UNSHADED WALLS OF 8-IN HOLLOW GLASS BLOCK OF TYPES II, III, IV, IVA AND V PATTERNS

Multiply the Table 20 Values for Type I by These Percentage Factors

For Clear Atmospheres and 18 Deg Declination, North (August 1)

For 30, 40, and 50 Deg North Latitude

Note: To obtain total instantaneous heat gain add adjusted Table 20 values to the Table 21 values.

<sup>a</sup> Reduce by 30% for 30 deg N latitude only.

TABLE 23. APPROXIMATE CORRECTIONS TO TABLES 14 AND 21 FOR DEVIATIONS FROM INDOOR AND OUTDOOR DESIGN TEMPERATURES

For each degree the design room temperature exceeds 80 F, subtract correction. For each degree the design outdoor dry-bulb temperature exceeds 95 F, add correction. Apply these corrections to each value in Table 14 or Table 21.

| GLASS TYPE                          | CORRECTION BTU PER (HR) (SQ FT) |
|-------------------------------------|---------------------------------|
| Single Flat or Rolled Figured Glass | 1.0                             |
| Double Flat Glass and Glass Block   | 0.5                             |

the same that a single table suffices. Note, however, that corrections must be made for certain hours for east and west facing walls of some patterns.

**Example 10:** Find the total instantaneous heat gain through an east wall of 8-in. hollow glass block of Type V pattern at 8 a.m. and 50 deg north latitude. The design temperatures are 80 F indoors, and 95 F maximum outdoor dry-bulb, clear atmosphere.

**Solution:** The gain due to transmitted solar radiation is found from Table 20 for Type I pattern. The factor for Type V is found from Table 22. The convection and radiation gain is found from Table 21 (note the footnote).

The total instantaneous heat gain is, from Equation 2a,

$$q = 86 \times 0.65 + 26 \times 1.4 = 92.3 \text{ Btu per (hr)(sq ft).}$$

### Effect of Deviations from Design Conditions

If the indoor temperature differs from 80 F, or the design outdoor dry-bulb temperature differs from 95 F, corrections can be made to the convection and radiation gain values for flat glass, rolled figured glass, and glass block according to the schedule in Table 23.

The effect of the humid industrial type atmosphere is to cause a considerable reduction in heat gain, if all factors except solar intensity remain the same. Reference 22 gives heat gain values for four orientations at 40 deg north latitude on August 1 for several types of flat glass and glass block, and solar intensities typical of humid industrial atmospheres. These data show that the following approximate reductions, based on total gain for the day, can be expected: 20 percent for all types of glass and glass block in east or west facing walls; 10 percent for south facing flat glass; 5 percent for south facing glass block walls.

### Shading of Glass Areas—Design Tables

The effects and possibilities of shading should be carefully investigated whenever the heat gain from glass is a large portion of the cooling load.

Vertical glass, which is not mounted in the plane of the building surface, is partially shaded by the setback. If a vertical window of height  $l$  and width  $w$  be set back from the plane of the building a distance  $s$ , the fraction of the total area of the window which receives direct solar radiation is:

$$G_t = 1 - \frac{r_1 \tan \beta}{\cos \gamma} - r_2 \tan \gamma + \frac{r_1 r_2 \tan \beta \tan \gamma}{\cos \gamma} \quad (5)$$

where

$r_1 = s/l$ ,  $r_2 = s/w$ ,  $\beta$  = solar altitude, and  $\gamma$  is the wall solar azimuth (see Fig. 1)

Values of  $\beta$  and  $\gamma$  for various latitudes and August 1 are given in Table 6. Special cases not covered by the tabulated data may be solved analytically,<sup>24</sup> however, the design conditions chosen will yield a satisfactory approximation if used without correction for any time during the summer period.

**Example 11:** Estimate the total instantaneous rate of heat gain for a west window 3 ft wide by 5 ft high, with a setback of 6 in., for August 1 and 40 deg north latitude at 3:00 pm (sun time).

**Solution:** From Table 13, the instantaneous rate of heat gain, due to transmitted direct and diffuse solar radiation, is 180 Btu per hr. From Table 6,  $\beta$  is 45.5 deg and

### Cooling Load

$\gamma$  is 16 deg. From Equation 5, the fraction of the total window area that is receiving direct solar radiation is:

$$G_t = 1 - \frac{0.1 \tan 45.5}{\cos 16} - 0.167 \tan 16 + \frac{0.0167 \tan 45.5 \tan 16}{\cos 16} \\ = 1 - 0.106 - 0.048 + 0.005 = 0.851$$

In this instance the convection and radiation heat gain is due principally to temperature difference, so that shading has but a small effect on that portion of the absorbed radiation. Hence, the factor 0.851 is applied

TABLE 24. EFFECT OF SHADING UPON INSTANTANEOUS SOLAR HEAT GAIN THROUGH SINGLE THICKNESS OF COMMON WINDOW GLASS

| TYPE OF SHADING                                                                                     | FINISH ON SIDE EXPOSED TO SUN     | FRACTION OF GAIN THROUGH UNSHADOWED WINDOW |
|-----------------------------------------------------------------------------------------------------|-----------------------------------|--------------------------------------------|
| Canvas awning sides open                                                                            |                                   |                                            |

|                                                                                                     |                                   | 0.24                                       |
|                                                                                                     |                                   | 0.15                                       |
|                                                                                                     |                                   | 0.22                                       |

<sup>a</sup> Roller shades are assumed to be opaque. Some white shades may transmit considerable solar radiation. For white translucent shades fully drawn use 0.55 and for half drawn use 0.77.  
<sup>b</sup> Venetian blinds are fully drawn and cover window. It is assumed that the occupant will adjust slats to prevent direct rays from passing between slats. If slats are fully closed (slats set at 90 deg.) use same factors as used for roller shade fully drawn.  
<sup>c</sup> Commercial shade with wide slats. The sun may shine on window through sides of shade. Estimate the exposed portion of glass as unshaded.  
<sup>d</sup> Commercial shade, bronze. Metal slats 0.05 inches wide 17 per inch and set at 17 deg angle with horizontal. At solar altitudes below 40 deg some direct solar rays are allowed to pass between slats, and this amount becomes progressively greater at low solar altitudes.  
<sup>e</sup> Commercial aluminum shade. Slats 0.057 inches wide, 17.5 per inch, set at 17 deg angle with horizontal. At solar altitudes below 40 deg some direct solar rays are allowed to pass between slats and this amount becomes progressively greater at low solar altitude.  
<sup>f</sup> From first paper in Reference 9.

only to the Table 13 value. Note also a small error results from the fact that the diffuse radiation is not shaded to the same extent as the direct radiation. The total instantaneous heat gain therefore is:

$$q = 3 \times 5 (0.851 \times 180 + 26) = 2690 \text{ Btu per (hr)(sq ft)}$$

A window such as the one used in Example 11 would customarily be provided with an additional shading means for use particularly when directly sunlit. Conventional shading devices include awnings, shades, and screens of various types.

Much experimental and analytical work conducted at the A.S.H.A.E.

Research Laboratory<sup>25</sup> as well as earlier experimental work,<sup>24, 26</sup> and other research<sup>27</sup> to determine the effectiveness of various types of window shades, have been used as the basis for the recommended ratios in column 3 of Table 24. A study of absorptivity of the shade to solar radiation and heat transfer from the shade to the outdoors and indoors, was used to determine these ratios.

There are a number of variables affecting these ratios such as color, fit, solar altitude, and angle of incidence of the solar radiation. These values, therefore, must be considered as approximate, only, and will have to be used with considerable judgment. An inside shade is effective to the extent of its reflectivity, since the portion of the solar radiation directly transmitted by the glass that is absorbed by the shade is transferred by convection to the room air, and by radiation to the solid room surfaces.

FIG. 4. ORIGIN OF THE DIFFERENCE BETWEEN THE MAGNITUDES OF THE INSTANTANEOUS HEAT GAIN AND INSTANTANEOUS COOLING LOAD

The radiation absorbed by the interior furnishings and structure reaches the conditioning equipment after a considerable delay in time.

### INSTANTANEOUS HEAT GAINS VS. INSTANTANEOUS COOLING LOADS

The difference between instantaneous heat gain and instantaneous cooling load has been mentioned previously; its practical importance is sufficient to warrant further consideration. Fig. 4 offers a simplified schematic illustration showing how the *radiative* part of the instantaneous heat gain is first absorbed by solid objects, and is not encountered by the conditioning equipment as a cooling load until some later time, when it finally appears in the air stream entering the equipment. While it is true that some lag also is inherent in convective heat transfer and the time required to change the air in the conditioned space, this is usually of the order of a few minutes to perhaps half an hour. Heat storage in the interior furnishings and structure increases according to the proportion of the instantaneous heat gain which is in the form of radiation, and also as the thermal capacitance of the objects and materials involved is increased.

Constituents of the total instantaneous heat gain which have appreciable radiation components include those due to glass areas, exposed walls and roofs, lighting, appliances, and people.

No comprehensive data are presently available for use in design load estimates to evaluate the interior load-lag effect, but several investigators<sup>14, 28, 29, 30</sup> have made a study of the problem and have presented many useful data. Tables 9, 10, 13, 14, 18, 20, and 21 are all based on instantaneous rates of heat transfer. Hence, practical judgment and experience offer the only basis of procedure. Until the needed data become available, it is recommended that the non-continuous load be averaged over two or three hours during the time of maximum load, when determining the total instantaneous cooling load where a large portion of the heat gain is radiant. This suggestion applies only to conditions near the time of maximum heat

gain, as the heat stored within the structure would necessarily appear in the cooling load eventually; but if it appears at a time when the gain from outside is relatively low, the equipment will be able to maintain satisfactory conditions within the range of maximum capacity.

### LOAD FROM INTERIOR PARTITIONS, CEILINGS, AND FLOORS

Whenever a conditioned space is adjacent to another space in which a different temperature prevails, the transfer of heat through the separating structural section must be considered. Calculations are made according to the relation:

$$q = U_1 A_1 (t_b - t_i) \text{ Btu per hour.} \quad (6)$$

where  $U_1$  = coefficient of overall heat transfer between the adjacent and the conditioned space, Btu per (hour) (square foot) (Fahrenheit degree).

$A_1$  = area of separating section concerned, square feet.

$t_b$  = air temperature in adjacent space, Fahrenheit degrees.

$t_i$  = air temperature in conditioned space, Fahrenheit degrees.

Magnitudes of  $U_1$  may be obtained from Chapter 9. The temperature  $t_b$  may have any value over a considerable range, according to conditions in the adjacent space. The temperature in a kitchen or boiler room may be as much as 15 to 50 deg above the outdoor air temperature. It is recommended that actual temperatures be measured in adjoining spaces wherever practicable. Where nothing is known, except that the adjacent space is of conventional construction and contains no heat sources, it is recommended that the difference  $(t_b - t_i)$  be taken as the difference between the outdoor-air and conditioned-space design dry-bulb temperatures *minus* 5 deg. In some cases it may be that the air temperature in the adjacent space will correspond closely to the outdoor air temperature at all times. Under these latter conditions, the heat gain through the partition will be periodic in nature, and the value of a shaded wall should be used from Table 10.

For floors directly in contact with the ground, or over an underground basement that is neither ventilated nor warmed, the heat transfer may be neglected for cooling-load estimates.

### LOAD FROM OUTDOOR AIR, VENTILATION AND INFILTRATION

**Ventilation.** Data for determining the necessary ventilation rate have been presented previously in this chapter. Ventilation required is primarily dependent upon the number of occupants and upon the materials and apparatus within the space which may give off odors. For spaces having ceiling heights 10 ft or less, the total requirement should be checked against the volume, and in no case should the ventilation air rate be less than one air change per hour. In spaces having ceilings higher than 10 ft where the occupant load is low, a check calculation can be made against the volume of the space below an assumed 10-ft ceiling.

Infiltration must never be counted upon to provide ventilation, because on still days there will be little or no infiltration.

**Infiltration.** The principles of infiltration calculations have been discussed in Chapters 11 and 12, with emphasis on the heating season. For the cooling season, infiltration calculations are usually limited to doors and windows.

To compute cooling-load infiltration for windows by the crack method,

use the data of Table 2, Chapter 11, for a wind velocity of 10 mph. Note that for double-hung windows the length of crack is three times the width plus twice the height; while for metal-sash windows the crack length is the total perimeter of the movable or ventilating sections. In calculating window infiltration for an entire structure, it is not necessary to consider the total crack length on all sides of the building, for the wind would not act simultaneously on all sides at once. In no case, however, should less than half of the total crack length be figured. A knowledge of the prevailing wind direction will aid judgment in this consideration.

Cooling-load infiltration for doors<sup>32</sup> may be obtained from Table 3, Chapter 11. For conditions other than those covered, the notes appended to the table will provide a basis for estimates. The tabulated data may also be used as the basis of estimates for interior doors between an air-conditioned and a non-air-conditioned space.

Infiltration load must be included whenever the new air introduced through the system is not sufficient to maintain excess pressure within the enclosure to prevent the infiltration. Whenever economically feasible, it is desirable to introduce sufficient outdoor air through the air-conditioning equipment to maintain a constant outward escape of air, and thus eliminate the infiltration portion of the load. The pressure maintained must, of course, be sufficient to overcome wind pressure through cracks and door openings. When this condition prevails it is not necessary to include any infiltration load. When the quantity of new air introduced through the cooling equipment is not sufficient to build up the required pressure to offset infiltration, the entire infiltration load should be included in the cooling load calculations.

**Total Outside Air Load.** Many cooling coil manufacturers publish tables giving psychrometric data based on the *average* conditions of the leaving air for various coil temperatures, air velocities, and entering dry-bulb and wet-bulb conditions. When these tables are used, it is necessary to calculate the mixed air condition entering the coil, and determine from the tables what coil and air velocity will produce the desired leaving air conditions as required for the space to be conditioned. When cooling coils are listed as 80 to 95 percent efficient, the manufacturer indicates that 20 to 5 percent of the air passes through the coil without being cooled. If data of this nature are used, the uncooled portion of the air must be added to the space load before determining the effective air quantity. See later section on Apparatus Dew Point.

To determine the design cooling load caused by the introduction of outside air, the maximum rate of outside-air entry is first established. In some applications the use of special exhausters from the conditioned space may add to the outdoor-air requirements in determining the maximum rate. Once this design quantity is established, and with the design indoor and outdoor air states known, the cooling load may be computed. There are several methods in use; the more accurate of these require rather detailed calculations. Refer to Chapter 3, and also section on Apparatus Dew Point in this chapter. The following equations are considered to be of sufficient precision for use at usual design conditions, as their accuracy is within 1 percent.

$$\begin{aligned} \text{Sensible Load } q_s &= Q \times 60 \times 0.244 \times 0.075 \left( 1 - \frac{0.00923}{0.62} \right) (t_o - t_i) \\ &= Q \times 1.08 (t_o - t_i), \text{ Btu per hour} \end{aligned} \quad (7)$$

### Cooling Load

313

$$\begin{aligned} \text{Latent Load } q_l &= Q \times 60 \times 0.075 \times 1076 (W_o - W_i) \\ &= Q \times 4840 (W_o - W_i), \text{ Btu per hour} \end{aligned} \quad (8)$$

$$\text{Total Load } q_t = q_s + q_l \quad (9)$$

where

$Q$  = rate of entry of outside air, cubic feet per minute.

$t_o$  = outdoor dry-bulb temperature, Fahrenheit.

$t_i$  = indoor dry-bulb temperature, Fahrenheit.

$W_o$  = outdoor humidity ratio, pounds moisture per pound of dry air.

$W_i$  = indoor humidity ratio, pounds moisture per pound of dry air.

0.075 = standard air density, pounds per cubic foot.

0.244 = a constant approximating the specific heat of dry air corrected for moisture Btu per (pound) (Fahrenheit degree).

1076 = a factor approximating the average Btu released in condensing one pound of water vapor from air.

As explained later in the section on Apparatus Dew Point, some methods of load calculations break down the ventilation air into two parts: one portion which does not contact the coil surfaces (i.e. bypasses the coil) in passing through the coil and thus becomes a part of the room load; and a second portion, the remainder of the air which contacts the coil surfaces and is cooled down to the apparatus dew point. This detailed method explained in the literature by Ashley,<sup>31</sup> is believed to be very easy and accurate to use. Similar equations, therefore, can be written:

$$\begin{aligned} \text{Space Sensible Ventilation Load,} \\ q_{s1} &= Q \times 1.08 (t_o - t_i) \times b \end{aligned} \quad (10)$$

$$\begin{aligned} \text{Space Latent Ventilation Load,} \\ q_{l1} &= Q \times 4840 (W_o - W_i) \times b \end{aligned} \quad (11)$$

$$\begin{aligned} \text{Remaining Sensible Ventilation Load,} \\ q_{s2} &= Q \times 1.08 (t_o - t_i) (1 - b) \end{aligned} \quad (12)$$

$$\begin{aligned} \text{Remaining Latent Ventilation Load,} \\ q_{l2} &= Q \times 4840 (W_o - W_i) (1 - b) \end{aligned} \quad (13)$$

$$q_t = q_{s1} + q_{s2} + q_{l1} + q_{l2} \quad (14)$$

where

$b$  = fraction of air passing through coil which does not contact surfaces, coil bypass factor.

Standard air weight (0.075) lb per cu ft) is recommended for use in all calculations, as this is the basis for rating fans and its consistent use keeps all parts of the calculations in conformity.

### HOW OUTDOOR AIR LOAD AFFECTS ROOM LOAD

Actually, the outdoor air used for ventilation would pass through the conditioning equipment, and be cooled and dehumidified to a lower temperature and humidity ratio than room conditions before entering the room; but for heat-balance purposes the cooling load chargeable to the outdoor air is that corresponding to the difference between the outdoor and indoor air conditions.

One important purpose of the cooling load estimate is to determine the

conditions and quantity of air supplied to the space. All the various sensible and latent heat loads within the space must be included. Infiltration must be included in the space load since this air enters the doors and windows, and its heat and moisture load must be offset by the introduction of cooler, dryer air to the space. However, since outdoor air is taken through the conditioning equipment and cooled, this portion does not become a part of the space load, except a small portion which passes through the coil untreated. To determine the total load on the refrigeration machine, the remaining outdoor air load must be included in the grand total load.

TABLE 25. RATES OF HEAT GAIN FROM OCCUPANTS OF CONDITIONED SPACES<sup>a</sup>

| DEGREE OF ACTIVITY                           | TYPICAL APPLICATION                 | TOTAL HEAT ADULTS, MALE Btu/Hr | TOTAL HEAT ADJUSTED <sup>b</sup> Btu/Hr | SENSIBLE HEAT Btu/Hr | LATENT HEAT Btu/Hr |
|----------------------------------------------|-------------------------------------|--------------------------------|-----------------------------------------|----------------------|--------------------|
| Seated at Rest.....                          | Theater-Matinee.....                | 390                            | 330                                     | 180                  | 150                |
|                                              | Theater-Evening.....                | 390                            | 350                                     | 195                  | 155                |
| Seated, Very Light Work.....                 | Offices, Hotels, Apartments.....    | 450                            | 400                                     | 195                  | 205                |
| Moderately Active Office Work.....           | Offices, Hotels, Apartments.....    | 475                            | 450                                     | 200                  | 250                |
| Standing, Light Work; or Walking Slowly..... | Department Store, Retail Store..... | 550                            | 450                                     | 200                  | 250                |

| Standing; Walking Slowly.....                | Bank.....                           | 490                            | 550                                     | 220                  | 330                |
| Sedentary Work.....                          | Restaurant <sup>c</sup> .....       | 800                            | 750                                     | 220                  | 530                |
| Light Bench Work.....                        | Factory.....                        | 900                            | 850                                     | 245                  | 605                |
| Moderate Dancing.....                        | Dance Hall.....                     |                                |                                         |                      |                    |
| Walking 3 mph; Moderately Heavy Work.....    | Factory.....                        | 1000                           | 1000                                    | 300                  | 700                |
| Bowling.....                                 | Bowling Alley.....                  |                                |                                         |                      |                    |
| Heavy Work.....                              | Factory.....                        | 1500                           | 1450                                    | 465                  | 985                |

<sup>a</sup> Note: Tabulated values are based on 80 F room dry-bulb temperature. For 78 F room dry-bulb, the total heat remains the same, but the sensible heat values should be increased by approximately 10 percent, and the latent heat values decreased accordingly.

<sup>b</sup> Adjusted total heat gain is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is 85 percent of that for an adult male, and that the gain from a child is 75 percent of that for an adult male.

<sup>c</sup> Adjusted total heat value for sedentary work, restaurant, includes 60 Btu per hour for food per individual (30 Btu sensible and 30-Btu latent).

<sup>d</sup> For bowling figure one person per alley actually bowling, and all others as sitting (400 Btu per hour) or standing (550 Btu per hour).

**Example 12:** For outdoor design conditions of 95 F dry-bulb and 75 F wet-bulb, and indoor design conditions of 80 F dry-bulb and 67 F wet-bulb, and for the supply of outdoor air at the rate of 1000 cfm and the exhaust of room air at the corresponding rate, calculate the total, sensible and latent heat gains.

**Solution:** Substituting in Equation 7:

$$q_s = 1000 \times 1.08 (95 - 80) = 16,200 \text{ Btu per hr.}$$

From psychrometric data  $W_o = 0.01413$ ,  $W_i = 0.01122$ .

Substituting in Equations 8 and 9:

$$q_s = 1000 \times 4840 (0.01413 - 0.01122) = 14,100 \text{ Btu per hr.}$$

$$q_t = q_s + q_s = 30,300 \text{ Btu.}$$

### HEAT SOURCES WITHIN THE CONDITIONED SPACE

**People.** The rates at which heat and moisture are given off by human beings under different states of activity are given in Table 25. In many applications these sensible and latent heat gains become a large fraction of

the total load. Appreciable variations in heat-emission rates must be recognized according to the age and sex of the individual; state of activity, environmental influences, and duration of occupancy (since for short occupancy the extra heat and moisture brought in by people may be a significant factor).

While Chapter 6 should be referred to for detailed information, Table 25 in this chapter summarizes practical data representing conditions commonly encountered.

**Lighting.** In general, the instantaneous rate of heat gain from electric lighting<sup>22</sup> may be calculated from the following relation:

$$q_l = \left\{ \frac{\text{total light}}{\text{wattage}} \times \left\{ \frac{\text{use}}{\text{factor}} \times \left\{ \frac{\text{special allow-}}{\text{ance factor}} \right\} \times 3.41, \text{ Btu per hr.} \right. \right. \quad (15)$$

The *total light wattage* is obtained from the ratings of all fixtures installed, both for general illumination and for display use.

The *use factor* is the ratio of the wattage in use, for the conditions under which the load estimate is being made, to the total installed wattage. For commercial applications such as stores, the use factor would be unity.

The *special allowance factor* is introduced to care for fluorescent fixtures, and for fixtures which are either ventilated or installed so that only part of their heat goes to the conditioned space. For *fluorescent fixtures*, the special allowance factor is recommended to be taken as 1.20 in order to allow for power consumed in the ballast. For *ventilated fixtures*, *recessed fixtures*, and the like, manufacturers' or other data<sup>23</sup> must be sought to establish the fraction of the total wattage which may be expected to enter the conditioned space.

**Power.** When equipment of any sort is operated within the conditioned space by electric motors, the heat equivalent of this operation must be considered in the cooling load. The general equation for calculating this load is:

$$q_{em} = \left( \frac{\text{Horsepower Rating}}{\text{Motor Efficiency}} \right) \times \left( \frac{\text{Load}}{\text{Factor}} \right) \times 2544, \text{ Btu per hr.} \quad (16)$$

It is assumed that both the motor and the driven equipment are within the conditioned space. If the motor is without the space, then *do not divide* by the motor efficiency in Equation 16. The *load factor* is merely the fraction of the rated load which is being delivered under the conditions of the cooling-load estimate. *Motor efficiencies* may be approximated as follows: about 50 to 60 percent at  $\frac{1}{2}$  hp rating, increasing to 80 percent at 1 hp, and to 88 percent at 10 hp and above.

**Appliances.** Care must be taken in a cooling-load estimate to take into account the heat gain from all appliances, electrical, gas, or steam. Table 26 presents recommended data.<sup>24</sup> Note that the *maintaining rate* in Table 26 is the heat input required to maintain the appliance at the normal operating temperature even though it is not being used, i.e., no coffee is being made, no toast is being made, no food is being cooked in the fry kettle, etc. The maintaining rate is useful in setting up a lower limit to the heat gain to a room from the appliance when in operation.

Experienced judgment must be used in the application of data given in Table 26. Consideration must be given to the heat contributed by appliances which are in use at the time of peak load. The quantity of heat will depend upon whether products of combustion are vented to a flue, whether they escape into the space to be conditioned, or whether appliances are hooded allowing part of the heat to escape through a stack. There are no generally accepted data available on the effects of venting and shielding

TABLE 26. RATE OF HEAT GAIN FROM APPLIANCES WITHOUT HOODS.<sup>a,b</sup>

heating appliances, but it is believed that when they are properly hooded with a positive fan exhaust system through the hood, 50 percent of the heat will be carried away and 50 percent dissipated in the space to be conditioned. The same effectiveness of the hood should be figured for both latent and sensible heat.

### LOAD FROM MOISTURE TRANSFER THROUGH PERMEABLE BUILDING MATERIALS

The diffusion of moisture through all common building materials is a natural phenomenon which is always present to a greater or lesser degree.

The permeability and permeance values for various building materials are given in Table 2 of Chapter 10, together with an explanation of moisture transmission through these materials.

In the usual comfort air-conditioning application, it is common practice to neglect moisture transfer through walls, for the actual rate is quite small and the corresponding latent-heat load is hardly significant. So-called *vapor barriers* are frequently employed in modern construction for the purpose of keeping moisture transfer to a minimum, and reducing the deteriorating and insulation-destroying effects of moisture.

Industrial jobs, on the other hand, frequently call for a low moisture content to be maintained in a conditioned space. Here the matter of moisture transfer cannot be neglected; indeed, it is quite possible to have the latent-heat load accompanying this transfer be of greater magnitude than any other latent-heat load. The equation for computing this load is:

$$\left(\frac{q_m}{A}\right) = \frac{M}{7000} \times \left(\frac{\text{Vapor Pressure}}{\text{Difference, In. Hg}}\right) \times 1076, \text{ Btu per (hr) (sq ft)} \quad (17)$$

where

$M$  = permeance of the specimen in perms, or grains per (square foot) (hour) (inch of mercury vapor pressure difference).

7000 = grains per pound.

The factor 1076 is defined in list of symbols at Equation 9. (Sensible cooling of the water vapor is included in the factor 1076.)

The only means of preventing moisture transfer is to use a vapor proof wall, or to apply a special lining, which is vapor proof. All openings in moisture proof construction must be equipped with special gaskets to prevent entrance of moisture.

When moisture transfer contributes an appreciable part of the latent-heat load, it is recommended that estimates should be made intentionally liberal in order to avoid later difficulties with insufficient dehumidifying capacity. Storage spaces, for example, would require sufficient dehumidifying capacity to handle the moisture brought in with goods to be stored, in addition to moisture leaking in subsequently.

### MISCELLANEOUS HEAT LOADS

This designation is intended to cover the various small heat gains from exposed piping, ducts, work done by circulating fan, and unforeseen contingencies. Where sufficient data are available, these various heat gains may be estimated individually. In the majority of cases, however, common practice is to lump these factors together and combine them with a *safety*

factor according to the experience and judgment of the estimator. On this basis, a small safety factor is added to the calculated cooling load to compensate for miscellaneous effects. No rules can be given for this procedure, as experience in air conditioning is indispensable for application of suitable safety factors.

### APPARATUS DEW POINT AND REQUIRED AIR QUANTITY THROUGH CONDITIONING EQUIPMENT

In ordinary practice, with commercial apparatus, complete saturation of the air is seldom obtained. Four-row finned cooling coils contact approximately 80 percent of the air, whereas six-row finned coils contact approximately 95 percent of the air. In spray type dehumidifiers of good

FIG. 5. APPARATUS DEW-POINT SHOWN ON A.S.H.A.E. PSYCHROMETRIC CHART

design the air leaves the dehumidifier at 1 to 2 deg higher wet-bulb temperature than the spray water leaving the dehumidifier, and the difference between the dry-bulb and wet-bulb temperatures leaving the dehumidifier may be as low as 1 deg. A spray type dehumidifier having sufficient length of spray chamber and density of spray, together with proper arrangement of nozzles, may approach saturation very closely.

As explained in Chapter 3, and shown in Fig. 5, the slope of the line on the psychrometric chart connecting the room condition with the apparatus dew point on the saturation line, determines the ratio of sensible heat absorbing capacity to the moisture absorbing capacity of the supply air. Therefore the room condition can be maintained as long as the supply air temperature lies on this line, but a greater volume of supply air must be used to satisfy the room load if the cooling coil does not contact 100 percent of the air. For a given room load, the same apparatus dew point will be required whether the cooling appliance contacts all the air or only part of the air.

From the point of view of satisfying the given cooling load requirements, the air passing through the apparatus without being cooled below the dew point temperature produces two effects:

1. The air quantity which must be passed through the dehumidifier must be in-

creased. Thus, if 20 percent of the air passing is contacted, then  $(20 \div 80) \times 100 = 25$  percent more air must be used than would be necessary if all of it were contacted.

2. Passing untreated air may change the room cooling load, which in turn may change the enthalpy-humidity difference ratio (sometimes called the sensible heat factor). If return air only is passed through the dehumidifier or if room air only is bypassed, the room load will not change, but if some outside air is passed through, the room sensible heat gain and room latent heat gain will be changed due to the addition of untreated outside air, which changes the enthalpy-humidity difference ratio. When a load calculation is made, it is necessary to know the percentage of air affected in the dehumidifier, and calculation must be made accordingly.

If the ventilation air is drawn through the dehumidifier before it goes into the room, only that portion of the air not saturated must be included in the room load for the purpose of determining the apparatus dew point and supply air quantity. It should be noted when evaluating the load added by untreated outside air that the temperature difference between room air and outside air, and the moisture content difference between room air and outside air, should be used, rather than the difference between outside air and apparatus dew point, since the rise from the apparatus dew-point to room condition is charged against the dehumidifier as the cooling and dehumidifying load.

The procedure for determining the required air quantity is based upon the thermodynamic principles of Chapter 3 and the use of the A.S.H.A.E. psychrometric chart. Readers are advised to review these principles, paying particular attention to the illustrative examples.

Calculation of the cooling load for a conditioned space is equivalent to making, for the space, a heat balance in which all heat, moisture, and infiltration are treated as directly entering the space. As explained in the section, *Load from Outside Air, Ventilation, and Infiltration*, the outside air load normally does not become a part of the space load, because heat and moisture are removed in the air conditioner before this air gets into the conditioned space. The desired conditions are maintained by considering a certain quantity of air to be withdrawn from the space, passed through the conditioning equipment, and returned to the space with such a temperature and humidity ratio that its net effect will be to counterbalance or remove the given entering amounts of heat and water vapor. This quantity of indoor air, which is considered to be circulated in this manner, is called the *required air quantity* and its determination is normally part of every cooling-load estimate. The procedure is as follows:

1. Determine the total sensible and latent heat loads in Btu per hour for the space.
2. Compute the quantity called the enthalpy-humidity difference ratio (also referred to as heat-moisture ratio) of the room load,  $\frac{h_1 - h_s}{W_1 - W_s}$ . Use the equation

$$\frac{h_1 - h_s}{W_1 - W_s} = \frac{(\text{Space sensible load} + \text{space latent load})}{\text{Space latent load}/1076} \quad (18)$$

where

$h_s$  = enthalpy of moist air supplied to the space, Btu per pound of dry air.

$h_1$  = enthalpy of moist air at room design conditions, Btu per pound of dry air.

$W_s$  = humidity ratio of moist air supplied to the space, pounds of vapor per pound of dry air.)

$W_1$  = humidity ratio of moist air at room design conditions, pounds of vapor per pound of dry air.

Note that the ratio (space latent load/1076) is the equivalent of the required rate of water vapor removal in pounds per hour. If the rate of water removed is known, it may be used directly in Equation 18.

3. Draw a line through the reference point on the A.S.H.V.E. psychrometric chart and the value of  $(h_i - h_e)/(W_i - W_e)$  determined above. Draw a second line through the state point of the room air (design wet-bulb and dry-bulb temperatures) parallel to this line. This is the *condition line* for the process.

4. Read the temperature where the condition line from step 3 intersects the saturation line. This is called the *apparatus dew point*.

See Fig. 5. Note that instead of using this graphical method the left hand side of Equation 18 may be solved by trial and error by substituting values of  $h_e$  and  $W_e$  corresponding to assumed apparatus dew-point temperatures.

5. Compute the *required air quantity* from the relation

$$Q_m = \frac{(\text{Space sensible load})}{1.08 \left[ \left( \frac{\text{Space}}{\text{dry-bulb}} \right) - \left( \frac{\text{Apparatus}}{\text{dew-point}} \right) \right]} \times \left( 1 - \frac{\text{Coil}}{\text{bypass factor}} \right) \quad (19)$$

The magnitude of  $Q_m$  is substantially the quantity, cfm, of cooled and dehumidified air for which the distribution system must be designed.

The numerical factor 1.08 is derived from the product  $1 \text{ cfm} \times 60 \text{ min} \times 0.244 \times 0.075 \left( 1 - \frac{0.00923}{0.62} \right) = 1.08$ , assuming an average supply air dew point of 55 F. Since standard air density (0.075) includes the weight of the water vapor, it is desirable to reduce it to the basis of dry air by the last factor where  $0.00923 =$  humidity ratio of air at 55 F dew point, and  $0.62 =$  ratio of density of water vapor to dry air at same temperature and pressure. Refer to Chapter 36 for coil selection.

Note that the product  $[(\text{space dry-bulb}) - (\text{apparatus dew point})] \times (1 - \text{coil bypass factor})$  is equal to the dry-bulb range through which the conditioned air is cooled. Hence, in rare instances when the *condition line* of the process may not intersect the saturation line, any other convenient reference temperature on the *condition line* may be used instead, provided that the coil bypass factor is specified accordingly on the proper basis.

### MINIMUM ENTERING AIR TEMPERATURE

Due consideration must be given to the temperature of the air entering the conditioned space in order to prevent objectionable drafts. With ceiling type diffusers or wall grilles with a high aspect ratio (see Chapter 31), many engineers consider 20 deg as the maximum difference for good design under average conditions. This difference can only be exceeded with extremely high ceiling outlets or wall grilles. Thus, if 80 F dry-bulb is to be maintained in a space with average ceiling height, the minimum delivered air temperature would be limited to about 60 F dry-bulb temperature. If the latent heat load is relatively high, it is often necessary to circulate more air with a higher delivered dry-bulb temperature in order to produce a thermodynamic balance. If the dry-bulb temperature of the air supplied to the space is known, the required air quantity can be calculated from the formula,

$$Q_m = \frac{q_s}{1.08 (t_i - t_e)} \quad (20)$$
