MORTALITY FROM NONTUBERCULOUS RESPIRATORY DISEASES

On account of the importance of nontuberculous respiratory diseases, Table 70 is included, showing the proportionate mortality from asthma, bronchitis, pneumonia, and other respiratory diseases.

*On the nontuberculous respiratory diseases, see "Diseases of the Bronchi, Lungs and Pleura," by Frederick C. Lord, M. D., Philadelphia and New York, 1915, in "System of Medicine," edited by Sir Clifford Allbutt and Humphrey Davy Roberts-London, 1909.

OCCUPATIONS WITH EXPOSURE TO MINERAL DUST. 173

among workers in occupations with exposure to mineral dust, without reference to divisional periods of life:

It does not seem necessary, as observed in the discussion of occupations with exposure to metallic dust, to enlarge upon the facts disclosed by the preceding comparative statistics, which emphasize with a sufficient degree of scientific conclusiveness the obviously health-injurious consequences of considerable and continuous exposure to the inhalation of mineral dust. It is clearly recognized that the statistical data utilized for the present purpose are of rather limited intrinsic value, but they are in the main quite fully confirmed by the more extended consideration of occupations in detail where the exposure to mineral dust is sufficient to warrant their inclusion within the plan and scope of the present discussion.

ENGLISH OCCUPATIONAL MORTALITY DATA.

In conclusion, however, it has seemed advisable to add to the present observations a table obtained from English official sources which shows the combined mortality of glassworkers, potters, paper hangers, plasterers, and lithographers, and which may safely be considered sufficiently representative of the entire group of occupations with exposure to mineral dust, in the absence of more extensive information which unfortunately is not available.

GENERAL CONCLUSIONS.

Table 71 brings out clearly the fact that the mortality from pulmonary tuberculosis among men in occupations with exposure to mineral dust is decidedly excessive at ages 35 to 64, but that the mortality at the other ages is not appreciably lower than for occupied males generally. Death rates are, however, not as useful and conclusive for purposes of industrial hygiene as the proportionate mortality figure which precisely emphasizes the quantitative importance of a given disease or cause of death. The proportionate mortality from pulmonary tuberculosis and nontuberculous respiratory diseases is excessive at all ages among men with exposure to mineral dust, although the relative death rate per thousand exposed to risk is not, at least according to English experience, decidedly excessive at certain periods of life. The data are not of sufficient importance to invalidate the general conclusion, and in the main the death rates sustain the proportionate mortality figure, although this is not invariably the case. The death rate from nontuberculous respiratory diseases among men employed in occupations with exposure to mineral dust, according to the English experience, is at the older ages so decidedly excessive that obviously much more extended scientific consideration should be given to this group of diseases than has heretofore been given it. At ages 55 to 64, for illustration, in the English experience there is an actual excess in the mortality from all causes among men exposed to mineral dust 9.22 per 1,000, equivalent to 29.7 per cent, but in the mortality from pulmonary tuberculosis there is an excess of 1.73 per 1,000, equivalent to 82.1 per cent, against an excess of 0.32 per 1,000 in the mortality from other respiratory diseases.

mortality from nontuberculous respiratory diseases, equivalent to 96.6 per cent. The results of this analysis, therefore, reemphasize the scientific conclusiveness of the extended discussion on "Industrial pneumoconiosis with special reference to dust phthisis," by Edgar L. Collis, in the Milroy Lectures of 1915, and the corresponding observations on pneumoconiosis by Sir Thomas Oliver in Allbutt & Rolleston's System of Medicine, Volume V, Diseases of the Respiratory System.

Of interest in this connection are the observations by Dr. J. S. Haldane contained in a contribution to the Proceedings of the Institution of Mining Engineers, abstracted in a letter from London to the Journal of the American Medical Association, August 19, 1916. In the paper referred to Dr. Haldane pointed out "that while up to the age of 50 the death rate from lung disease is much lower among miners than in the rest of the population, above 50 the opposite holds, and there is a marked excess of deaths from bronchitis." In continuation, however, he stated that "the deaths from this disease have greatly diminished since 1890, for which improved ventilation seems to be the cause. Fifty years ago miners often worked in air containing so much black damp that lamps and candles burned dimly. In such air there is usually 2 or 3 per cent of carbon dioxide, which enormously increases the breathing during muscular exertion. The breathing is exactly regulated so as to keep an average of about 5.6 per cent carbon dioxide in the alveolar air; and with 3 per cent of this gas in the air, a man breathes twice as much air, so as to keep the alveolar percentage right. A man doing moderate muscular work in pure air breathes about five or six times as much air as during rest. In air containing 3 per cent of carbon dioxide he would be breathing ten or twelve times as much air as during rest, and his breathing would be taxed to the utmost. He would thus be much more liable to contract emphysema. The better ventilation of coal mines is largely a consequence of the greater amount of fire damp and great heat encountered as mines have become deeper."

Dr. Haldane is inclined to think "that both the fire damp and the heat have indirectly caused great improvement to the health of miners. Where there is plenty of fire damp there is usually also plenty of fresh and dry air, and no harmful excess of carbon dioxide. The proportion of deaths from bronchitis among old miners was higher in Staffordshire in 1890-1892 and 1900-1902 than in any of the other coal fields; and Staffordshire mines are exceptionally subject to black damp. The excess in bronchitis among old coal miners has been attributed to the breathing of dust," and Dr. Haldane was previously inclined to agree with this theory. But it is difficult to see why, if dust is the cause, there has been so great a diminution in

176 MORTALITY FROM RESPIRATORY DISEASES IN DUSTY TRADES

the bronchitis mortality in recent years. Coal mines have, on whole, become drier and more dusty with increasing depth and better ventilation; and, if dust were the cause, one would have expected bronchitis to increase, whereas it has greatly diminished. Certainly an excess in mortality from bronchitis is associated with the breathing of harmful dust. But this excess is accompanied by a far greater excess in mortality from phthisis, and begins comparatively early in life, unlike the bronchitis mortality in colliers. Experiments on animals carried out by J. M. Beattie show that both coal dust and shale dust usually associated with it on mine roads are relatively harmless."

It is therefore quite clear that much remains to be ascertained concerning the true nature and extent of dust phthisis, and that in the solution of this important industrial problem a considerable advance is necessary in the practice of medicine, which to a much larger degree should be made to rest upon knowledge concerning disease causation ascertained by means of autopsies in industrial districts subject to an excessive mortality from pulmonary tuberculosis and nontuberculous respiratory diseases.

ASBESTOS.

The number of men employed in trades and industries involving exposure to asbestos dust in the United States is unknown. Asbestos is obtained from the mining of asbestos, in which exposure is rather limited. There are numerous processes involving the conversion or remanufacture of the materials which are distinctly more serious in their effects on health and longevity. Asbestos weaving and spinning are described by Netolitzki on the basis of observations in Bohemia, where the conditions were found to be decidedly unfavorable. In this country our information is very limited, although the quantity of asbestos used is very large. Its fire-resisting properties have led to its extensive employment for the covering of pipes, furnaces, etc., as well as its use in the form of wall plaster, roofing material, etc. On account of its nonconducting qualities it is extensively employed by electricians and also in the construction of storage rooms of refrigerating plants.

METHODS OF MINING.

"Geologically," according to the Technical World Magazine, "asbestos is a fibrous form of serpentine rock, occurring in strata of crystalline limestone. The veins run in an average thickness of one-fourth to one-half inch, but sometimes attain to as much as 6 inches."

"Mining Manual," by Aubrey Fullerton, in Technical World Magazine, 1900.

The asbestos fibers are, as nearly as possible, crystals of serpentine rock." According to the same magazine—

The ore is mined mostly in open quarries. Overlying soil, to a thickness of sometimes 20 or 30 feet, but quite often forming only a thin layer on top, has first to be removed; and as soon as the asbestos veins are thus laid bare, the actual quarrying operations may begin. The rock is cut in a series of terraces, reaching a total depth of sometimes 150 or 200 feet. Underground work has not proved successful, the open quarry having been found both more economical and more effective, despite the disadvantages of exposure to the weather. Drilling and blasting are employed much the same as in ordinary stone quarrying.

When the rock is thus broken up it is rough sorted at the quarry. Two or more grades are selected, according to the length of the fiber, and are then sent on to the "cobbing sheds," where the further process of dressing goes on. This process is merely the separation of the asbestos fibers from the dead rock, and is done in some cases by hand, but to an increasing extent by machine. Hand cobbing is the very simple method of breaking the stone by small sledge hammers, throwing the fiber into one box and the waste into another. This separation is ordinarily not difficult, since the fiber lies in layers more or less loosely clinging to the rock, and can frequently be picked off with the fingers. The crude fiber, thus separated as cleanly as possible from the waste rock and looking very much like mineralized wool, is packed in 100-pound bags, in which form it goes to the market and the manufacturer.

Hand dressing is not, however, an absolutely thorough method. The waste material from the cobbing tables and the fine pickings from the quarries have still some fiber in them, and the utilization of this frequently represents the largest profits of the mine. All these fine pickings are mechanically dressed. In case the asbestos contains a large percentage of water, the moisture is first dried out, by exposure to the air, by steam pipes, or by rotary driers, and the rock is then passed on to the crushers, where it is broken by successively finer-set rolls. Cylindrical fiberizers and the cyclone machine reduce it still further. The latter is the most effective apparatus yet devised for asbestos separation. It consists of two beaters, one of the screw-propeller type, driven within a cast-iron chamber at a violent speed, reducing the particles of stone almost to a powder. This is then passed over a shaking screen to remove the sand, and in some mills strong electric magnets are used to take up the particles of iron.

In all of these operations there must necessarily be a considerable degree of dust exposure, which, however, becomes exaggerated in the spinning and weaving processes in connection with the manufacture of asbestos yarn and cloth. These processes are briefly referred to in an article in the Engineering Magazine,¹ in part, as follows:

The spinning and weaving of asbestos have offered many difficulties, as the asbestos fibers have no rough surface like wool or cotton, but

¹ "Asbestos, its mining, preparation, markets, and use," by E. Schenck Reigelman, Engineering Magazine, Oct. 1907.

are very smooth, and thus have a tendency to slip by one another when twisted and subject to tension. An admixture of vegetable or animal fiber was therefore often necessary, but, while this facilitated the manufacturing operations, they impaired the fire resistance of the fabric, and special machinery and ingenious devices had to be invented to enable the successful spinning of a pure asbestos. It is, however, now possible to make a single asbestos thread, though weighing no more than 1 ounce per hundred yards, of great strength, and braided material can be made much more resistant to torsion and tension. While asbestos ropes, chiefly used by the fire department, can be strengthened either by interwoven wire or by having a wire-rope core.

HEALTH-INJURIOUS OCCUPATIONAL CONDITIONS.

On account of the rather limited extent of the asbestos industry in the United States, at least in the large centers of population, industrial insurance mortality experience data are insufficient to draw definite conclusions. During the period 1907 to 1914 in the Pennsylvania experience there were only 13 deaths, of which 3, or 23.1 per cent, were from pulmonary tuberculosis. At ages 25 to 44, there were 13 deaths, of which 3, or 50 per cent, were from this disease. Asbestos dust is not described in the extensive consideration of Dust Diseases by Hayhurst, nor by W. Gilman Thompson in his treatise on Occupational Diseases. In 1914 the production of asbestos in the United States was only 1247 tons, or much less than in earlier years, indicating a very limited available source of supply. Most of the asbestos used in the United States is mined in Canada, and a recent report on "Asbestos, its occurrence, exploitation, and uses" has been published by the mines branch of the Department of the Interior of the Dominion of Canada (Ottawa, 1905), which contains a descriptive account of mining methods and of the dressing of asbestos by hand or by mechanical treatment, including the final crushing means of rollers, fiberizers, beaters, cyclones, and pulverizers. These processes unquestionably involve a considerable dust hazard. The hygienic aspects of the industry have not been reported upon. It may be said, in conclusion, that in the practice of American and Canadian life insurance companies asbestos workers are generally declined on account of the assumed health-injurious conditions of the industry.¹

It is regrettable that there should be no further information available regarding the asbestos industry in its various branches, including the utilization of by-products of manufacture, on account of the self-evident injuriousness of asbestos dust as a predisposing cause of pulmonary tuberculosis. The subject is not referred to by

¹ For a descriptive account of the Canadian asbestos district, see *Engineering and Mining Journal*, New York, Apr. 29, 1910.

and Hanson in their recently published treatise on Diseases of Occupation and Vocational Hygiene, nor by Sir Thomas Oliver in his recent work on Diseases of Occupation. The rapidly increasing development of industries using asbestos, as ascertained from domestic or foreign sources, suggests the urgency of more qualified medical consideration than has heretofore been given the subject. There are no references to asbestos in the Index Catalogue of the Surgeon General's Library, which, however, brings the literature of the subject down only to 1896. The discussion of asbestos in the annual reports of the United States Geological Survey on Mineral Resources is limited entirely to the technical aspects of the mining industry, which during recent years has experienced a rather retrograde movement in that the production has diminished from a maximum of 7,600 tons in 1911 to 1,247 tons in 1914. In contrast, however, there has been a gradual increase in the quantity of the unmanufactured asbestos imported, chiefly from Canada. The American production is practically limited to the States of Arizona, California, Georgia, and Vermont. Georgia has for years been one of the chief producers of asbestos in the United States, but no medical observations are on record as regards the possibly injurious results experienced in the mining and manufacturing of asbestos materials in that State. The industry itself has been described, however, in a report on the asbestos, talc, and soapstone deposits of Georgia in Bulletin No. 29 of the Georgia Geological Survey, 1914.

EVIDENCE OF DUST EXPOSURE.

The relation of asbestos dust to pulmonary tuberculosis is reported upon at some length in the Annual Report of the Chief Inspector of Factories and Workshops for England and Wales for 1910. The investigation was made by Dr. Collis, who states, in part, that—

Following up information received from the registrar-general, it was found that five deaths of persons suffering from phthisis had occurred in five years among a staff of under 40 workers employed at a factory where asbestos is woven. The process which appeared most dangerous is the production of asbestos mattresses. These mattresses, which are composed of bags of woven asbestos filled with short asbestos fiber, are placed on a table and beaten out flat by a man with a wooden flail, from which process much dust arises. Women who sew the mattresses into sections with asbestos threads worked close to the man who beat the mattresses and of necessity inhaled the dust. The reorganization of this process with the application of localized exhaust draft was called for, and an annual medical examination of the workers by the certifying surgeon has been instituted in the hope of detecting and removing from exposure to dust those showing early signs of respiratory disease. Weaving asbestos has only become an important industry during the last 15 years. Two other large asbestos factories were visited, each of which was found to have its own specialty in the production of which best prevention is required.

180 MORTALITY FROM RESPIRATORY DISEASES IN DUSTY TRA

There is evidently an urgent need for a more qualified and live investigation of the health aspects of asbestos manufacture especially so, in view of the fact, as observed in the Scientific can (August 1, 1916), that, on account of the restrictions placed on shipments of asbestos from Canada, the possibilities of utilizing asbestos deposits of this country are increased, as well as because of the much larger demand for asbestos products on account of the recognized value of asbestos for protective purposes in the finance of the industrial safety movement. Of value in this connection is the evidence of Dr. H. M. Murray before the Departmental Committee on Industrial Diseases, limited, in relation to the single case of an asbestos worker, verified as a diagnosis by a post mortem examination. In reply to a question by the chairman of the committee as to whether, in view of the fact "that there is something characteristic in the earlier stages of dust phthisis in the predominance of shortness of breath, and physical signs become very obvious," such a condition had been observed in the case of the asbestos worker under treatment by Dr. Murray, and under observation for fourteen months, the doctor stated that it had been noticed in the case in question, and in other words, there was a definite relation between the dust phthisis and the physical incapacity resulting from the inhalation of asbestos dust. It is therefore to be anticipated that the case of asbestos workers will attract more qualified attention in this country in the future than it has in the past.

MICA.

No special investigation has been made to ascertain the less health-injurious effects of mica dust. According to W. J. Thompson the dust is slightly irritating to the respiratory tract like dust containing any sharp solid particles, but as a general conclusion he states that the dust does not appear to be particularly injurious. Mica is extensively used in the manufacture of electrical machinery, as well as in the glazing trade, as a substitute for glass and in the decorative trades, including the manufacture of paper. There are two principal varieties of mica, known as muscovite and phlogopite, but whether there is any essential difference between the physical and mechanical properties of the dust has not been determined. There are mica deposits in some 20 States in the United States, but the annual production has fluctuated considerably, reaching the lowest point in the last decade during 1914. As there are any special hazards in mica mining in consequence of dust has not been ascertained. The occurrence, exploitation, and uses of mica have been admirably described in a report published by the mines branch of the Department of the Interior of Canada.

port, however, includes no observations on the sanitary aspects of the various employments. It is pointed out, with special reference to the manufacture of ground mica, that the difficulties of grinding are great, owing to the tough and scaly nature of the mineral, which may be assumed to indicate that even when reduced to a fine powder the dust is apparently not of very serious importance to the employees.

Mica dust is briefly referred to by Kober and Hanson in their *Diseases of Occupation and Vocational Hygiene*, in which it is said that mica is "a mineral of widely varying chemical composition, but is essentially composed of silicates of aluminum and an alkali, such as potassium, sodium, or lithium." It is stated that the mineral splits easily into thin, flexible, colorless, transparent plates or scales, known as isinglass, and that in the powdered form it is employed in the manufacture of giant powder, and that it is also used for decorative purposes, chiefly in the manufacture of wall paper, illuminated designs, etc. The only medical conclusion arrived at by the authors is that "mica dust is doubtless a frequent cause of inflammatory conditions of the eyes and air passages." It is therefore suggested by inference that the dust in finely comminuted form may also have an irritating effect upon lung tissue, and to that extent predispose mica workers to pulmonary tuberculosis, although much more extended observations are required before definite conclusions can be arrived at.¹

THE STONE INDUSTRY.

The stone industry in the United States is of vast areal extent and commercial importance. The product for 1914 was valued at nearly \$5,000,000. Stone is quarried or produced in every State and Territory, and the number of persons employed in the stone industry exceeds 100,000. The principal varieties are granite, trap rock, marble, limestone, and sandstone. The industry may broadly be divided into the manufacture of crushed stone for road making and other purposes, paving stone, building stone, and monumental stone. The two latter are subdivided into rough and dressed products. The labor conditions in an industry of such vast extent and fundamental differences in the nature of the product must neces-

¹For a valuable descriptive account of mica, see the National Museum Report, 1899, p. 303.

²For a discussion of mica mining in the United States with special reference to underground conditions, see an article in the *Engineering and Mining Journal*, May 4, 1909. With reference to mining methods in Canada, see an article in the same publication in the issue of April 19, 1908.

³See also an extended discussion by Mr. C. Hanford Henderson on "Mica and the mica industry" in the *Popular Science Monthly* for Sept., 1902.

⁴According to a statement by the manager of the Crown Mica Co., of Crown City, O., "Mica mining is considered very healthy, as most of it is done in open cuts."
