The full-shift sampling results were below the applicable exposure limits for both respirable dust and respirable silica. The respirable dust sample result of 1.95 mg/m³ noted in Table I was less than the WISHA (Washington Industrial Safety and Health Administration) standard of 5 mg/m³. The respirable silica result (<0.074 mg/m³) noted in Table II was less than the analytical limit of detection.

RECOMMENDATIONS

Given the results of this monitoring the following recommendations are submitted.

- (a) Personnel sampled during this survey are to be informed of their monitoring results following receipt of the data by the department representative.

For your convenience, employee notification forms are attached for completion and subsequent dissemination to the field.

- (b) Since there is a total dust threshold limit value for calcium silicate, it is recommended that total dust sampling be conducted during future work with calcium silicate insulation.

To quantify employee exposure to calcium silicate a total dust sample rather than a sample of respirable dust should be collected.

METHODS

Air samples for respirable silica and dust were collected for analysis by the use of calibrated sampling pumps drawing air through a pre-weighted polyvinyl chloride filter with a cyclone in train. The collection media was forwarded to NATLSCO, an accredited American Industrial Hygiene Association Laboratory and analyzed by gravimetric methods and NIOSH method 7500, an X-ray diffraction technique.
